The iliocapsularis muscle is a lesser-known structure that originates from the anterior medial hip capsule and inserts just distal to the lesser trochanter so that it overlies the anterior hip capsule. Its function is to help stabilize and tighten the anterior hip capsule.[55] The iliocapsularis muscle has been found to be significantly hypertrophied in dysplastic hips versus normal hips.[56]

Tensor Fascia latae

The TFL arises from the anterior aspect of the outer lip of the iliac crest and the lateral surface of the ASIS, and part of the lateral border of the notch below it (Fig. 19-5). As it passes inferiorly, the TFL envelops the muscles of the thigh. The trochanteric bursa is found deep to this muscle, as it passes over the greater trochanter (see later).[57] The TFL, which flexes, abducts, and externally rotates the hip, also serves to counteract the backward pull of the gluteus maximus on the iliotibial band (ITB). The attachment of the TFL via the ITB to the anterolateral tibia provides a flexion moment in knee flexion and an extension moment in knee extension. The anteromedial fibers of the TFL have been shown to be increasingly active during jogging, running, and sprinting.[9] This is theorized to be because of its role in assisting decelerating hip extension and accelerating hip flexion.[58]

CLINICAL PEARL

The TFL and conjoined ITB must be closely monitored during therapeutic exercise as uncontrolled hip forces cause compressive bursa/tendinopathies at the greater trochanter and proximal lateral tibia when these two structures become overactive secondary to improper exercise selection and dosage.[59]

Gluteus Maximus

The gluteus maximus (Fig. 19-5) is the largest and most powerful hip extensor. It is also an important external rotator of the hip when the hip is in an anatomic neutral position.[50] The larger, superficial portion of this muscle inserts into the proximal part of the ITB, while the deep portion inserts into the gluteal tuberosity of the femur. The inferior gluteal nerve, which innervates the muscle, is located on the deep portion.

The gluteus maximus[50] is normally active only when the hip is in flexion, as during walking up an incline, stair climbing or cycling, or when extension of the hip is resisted.[60] The superior portion of the gluteus maximus acts as a hip abductor during gait.[61] Fibrous attachments over the sacroiliac joint from the gluteus maximus assist in trunk extension, control of lateral sway,

TABLE 19-3 Origin, Insertion, and Innervation of Muscles Acting Across the Hip Joint

Muscle	Origin	Insertion	Innervation
Adductor brevis	External aspect of the body and inferior ramus of the pubis	The line from the greater trochanter of the linea aspera of the femur	Obturator nerve
Adductor longus	In angle between pubic crest and symphysis	The middle third of the linea aspera of the femur	Obturator nerve
Adductor magnus	Inferior ramus of pubis, ramus of ischium, and the inferolateral aspect of the ischial tuberosity	To the linea aspera and adductor tubercle of the femur	Obturator nerve and tibial portion of the sciatic nerve
Biceps femoris	Long head arises from the sacrotuberous ligament and posterior aspect of the ischial tuberosity. Short head does not act across the hip	On the lateral aspect of the head of the fibula, the lateral condyle of the tibial tuberosity, the lateral collateral ligament, and the deep fascia of the leg	Tibial portion of the sciatic nerve, S1
Gemelli (superior and inferior)	Superior-posterior (dorsal) surface of the spine of the ischium and inferior-upper part of the tuberosity of the ischium	Superior- and inferior-medial surface of the greater trochanter	Sacral plexus
Gluteus maximus	Posterior gluteal line of the ilium, iliac crest, aponeurosis of the erector spinae, posterior (dorsal) surface of the lower part of the sacrum, side of the coccyx, sacrotuberous ligament, and intermuscular fascia	Iliotibial tract of the fascia latae and gluteal tuberosity of the femur	Inferior gluteal nerve
Gluteus medius	Outer surface of the ilium between the iliac crest and the posterior gluteal line, anterior gluteal line, and fascia	Lateral surface of the greater trochanter	Superior gluteal nerve
Gluteus minimus	Outer surface of the ilium between the anterior and inferior gluteal lines, and the margin of the greater sciatic notch	On the anterior surface of the greater trochanter	Superior gluteal nerve
Gracilis	The body and inferior ramus of the pubis	The superior medial surface of the proximal tibia, just proximal to the tendon of the semitendinosus	Obturator nerve
Iliacus	Superior two-thirds of the iliac fossa and upper surface of the lateral part of the sacrum	Fibers converge with tendon of the psoas major to lesser trochanter	Femoral nerve
Obturator externus	Rami of the pubis, ramus of the ischium, and medial two-thirds of the outer surface of the obturator membrane	Trochanteric fossa of the femur	Obturator nerve
Obturator internus	Internal surface of the anterolateral wall of the pelvis and obturator membrane	Medial surface of the greater trochanter	Sacral plexus
Pectineus	Pectineal line	Along a line extending from the lesser trochanter to the linea aspera	Femoral or obturator or accessory obturator nerves
Piriformis	Pelvic surface of the sacrum, gluteal surface of the ilium, capsule of the sacroiliac joint, and sacrotuberous ligament	Upper border of the greater trochanter of femur	Sacral plexus
Psoas major	Transverse processes of all the lumbar vertebrae bodies and intervertebral disks of the lumbar vertebrae	Lesser trochanter of the femur	Lumbar plexus
Quadratus femoris	Ischial body next to the ischial tuberosity	Quadrate tubercle on femur	Nerve to quadratus femoris
Rectus femoris	By two heads, from the anterior-inferior iliac spine, and a reflected head from the groove above the acetabulum	Upper border of the patella	Femoral nerve
Sartorius	Anterior-superior iliac spine and notch below it	Upper part of the medial surface of the tibia in front of the gracilis	Femoral nerve
Semimembranosus	Ischial tuberosity	The posterior-medial aspect of the medial condyle of the tibia	Tibial nerve
Semitendinosus	Ischial tuberosity	Upper part of the medial surface of the tibia behind the attachment of the sartonus and below that of the gracilis	Tibial nerve
Tensor fascia latae	Anterior part of outer lip of the iliac crest and the lateral surface of the anterior-superior iliac spine	Iliotibial tract	Superior gluteal nerve

TABLE 19-4 Hip Actions and Muscles If in Anatomic Position

Hip Action	Prime Movers	Assistant Movers
Flexors	Iliopsoas Sartorius Tensor fascia latae Rectus femoris Pectineus Adductor longus	Adductor brevis Gracilis Gluteus minimus (anterior fibers)
Extensors	Gluteus maximus Semitendinosus Semimembranosus Biceps femoris (long head) Adductor Magnus (posterior head)	Gluteus medius (middle and posterior fibers) Adductor magnus (anterior head)
Abductors	Gluteus medius (all fibers) Gluteus minimus (all fibers) Tensor fascia latae	Sartorius Rectus femoris Piriformis
Adductors	Adductor magnus (anterior and posterior heads) Adductor longus Adductor brevis Gracilis Pectineus	Biceps femoris (long head) Gluteus maximus (posterior fibers) Quadratus lumborum Obturator externus
External rotators	Gluteus maximus Gemellus inferior Gemellus superior Obturator internus Quadratus femoris Piriformis (at less than 60 degrees hip flexion)	Gluteus medius (posterior fibers) Gluteus minimus (posterior fibers Biceps femoris (long head) Sartorius Obturator externus
Internal rotators	No specific muscle	Semitendinosus Semimembranosus Gracilis Piriformis (at 90 degrees hip flexion) Gluteus medius (anterior fibers) Adductor longus Adductor brevis Pectineus Adductor Magnus (posterior head) Gluteus minimus (anterior fibers) Tensor fascia latae

Data from Anderson LC. The anatomy and biomechanics of the hip joint. J Back Musculoskeletal Rehabil. 1994;4:145–153; Neumann DA. Kinesiology of the hip: a focus on muscular actions. J Orthop Sports Phys Ther. 2010;40:82–94.

and contributes to bipedal locomotion.[59] The hip extensors as a group create the greatest amount of torque across the hip joint.[9]

Gluteus Medius

Because of its shape and functional similarities, the gluteus medius is known as the deltoid of the hip and, like the deltoid muscle at the shoulder, the gluteus medius can be divided into three functional parts: an anterior portion, a middle portion, and a posterior portion, each of which are innervated by separate branches of the superior gluteal nerve.[9] The anterior portion, the fibers of which are oriented the most vertical, works to flex, and internally rotate the hip. The middle portion, the fibers of which are slightly obliquely oriented, abducts the hip. The posterior portion, the fibers of which are oriented almost parallel to the femoral neck, extends and externally rotates the hip while also stabilizing the femoral head in the acetabulum.[9] On the deep surface of this muscle is located the superior gluteal nerve and the superior and inferior gluteal vessels.

The gluteus medius (Fig. 19-5) is the primary source of dynamic stabilization of the hip joint in the frontal plane, making it critical for balancing the pelvis during single-limb stance, which accounts for approximately 60% of the gait cycle

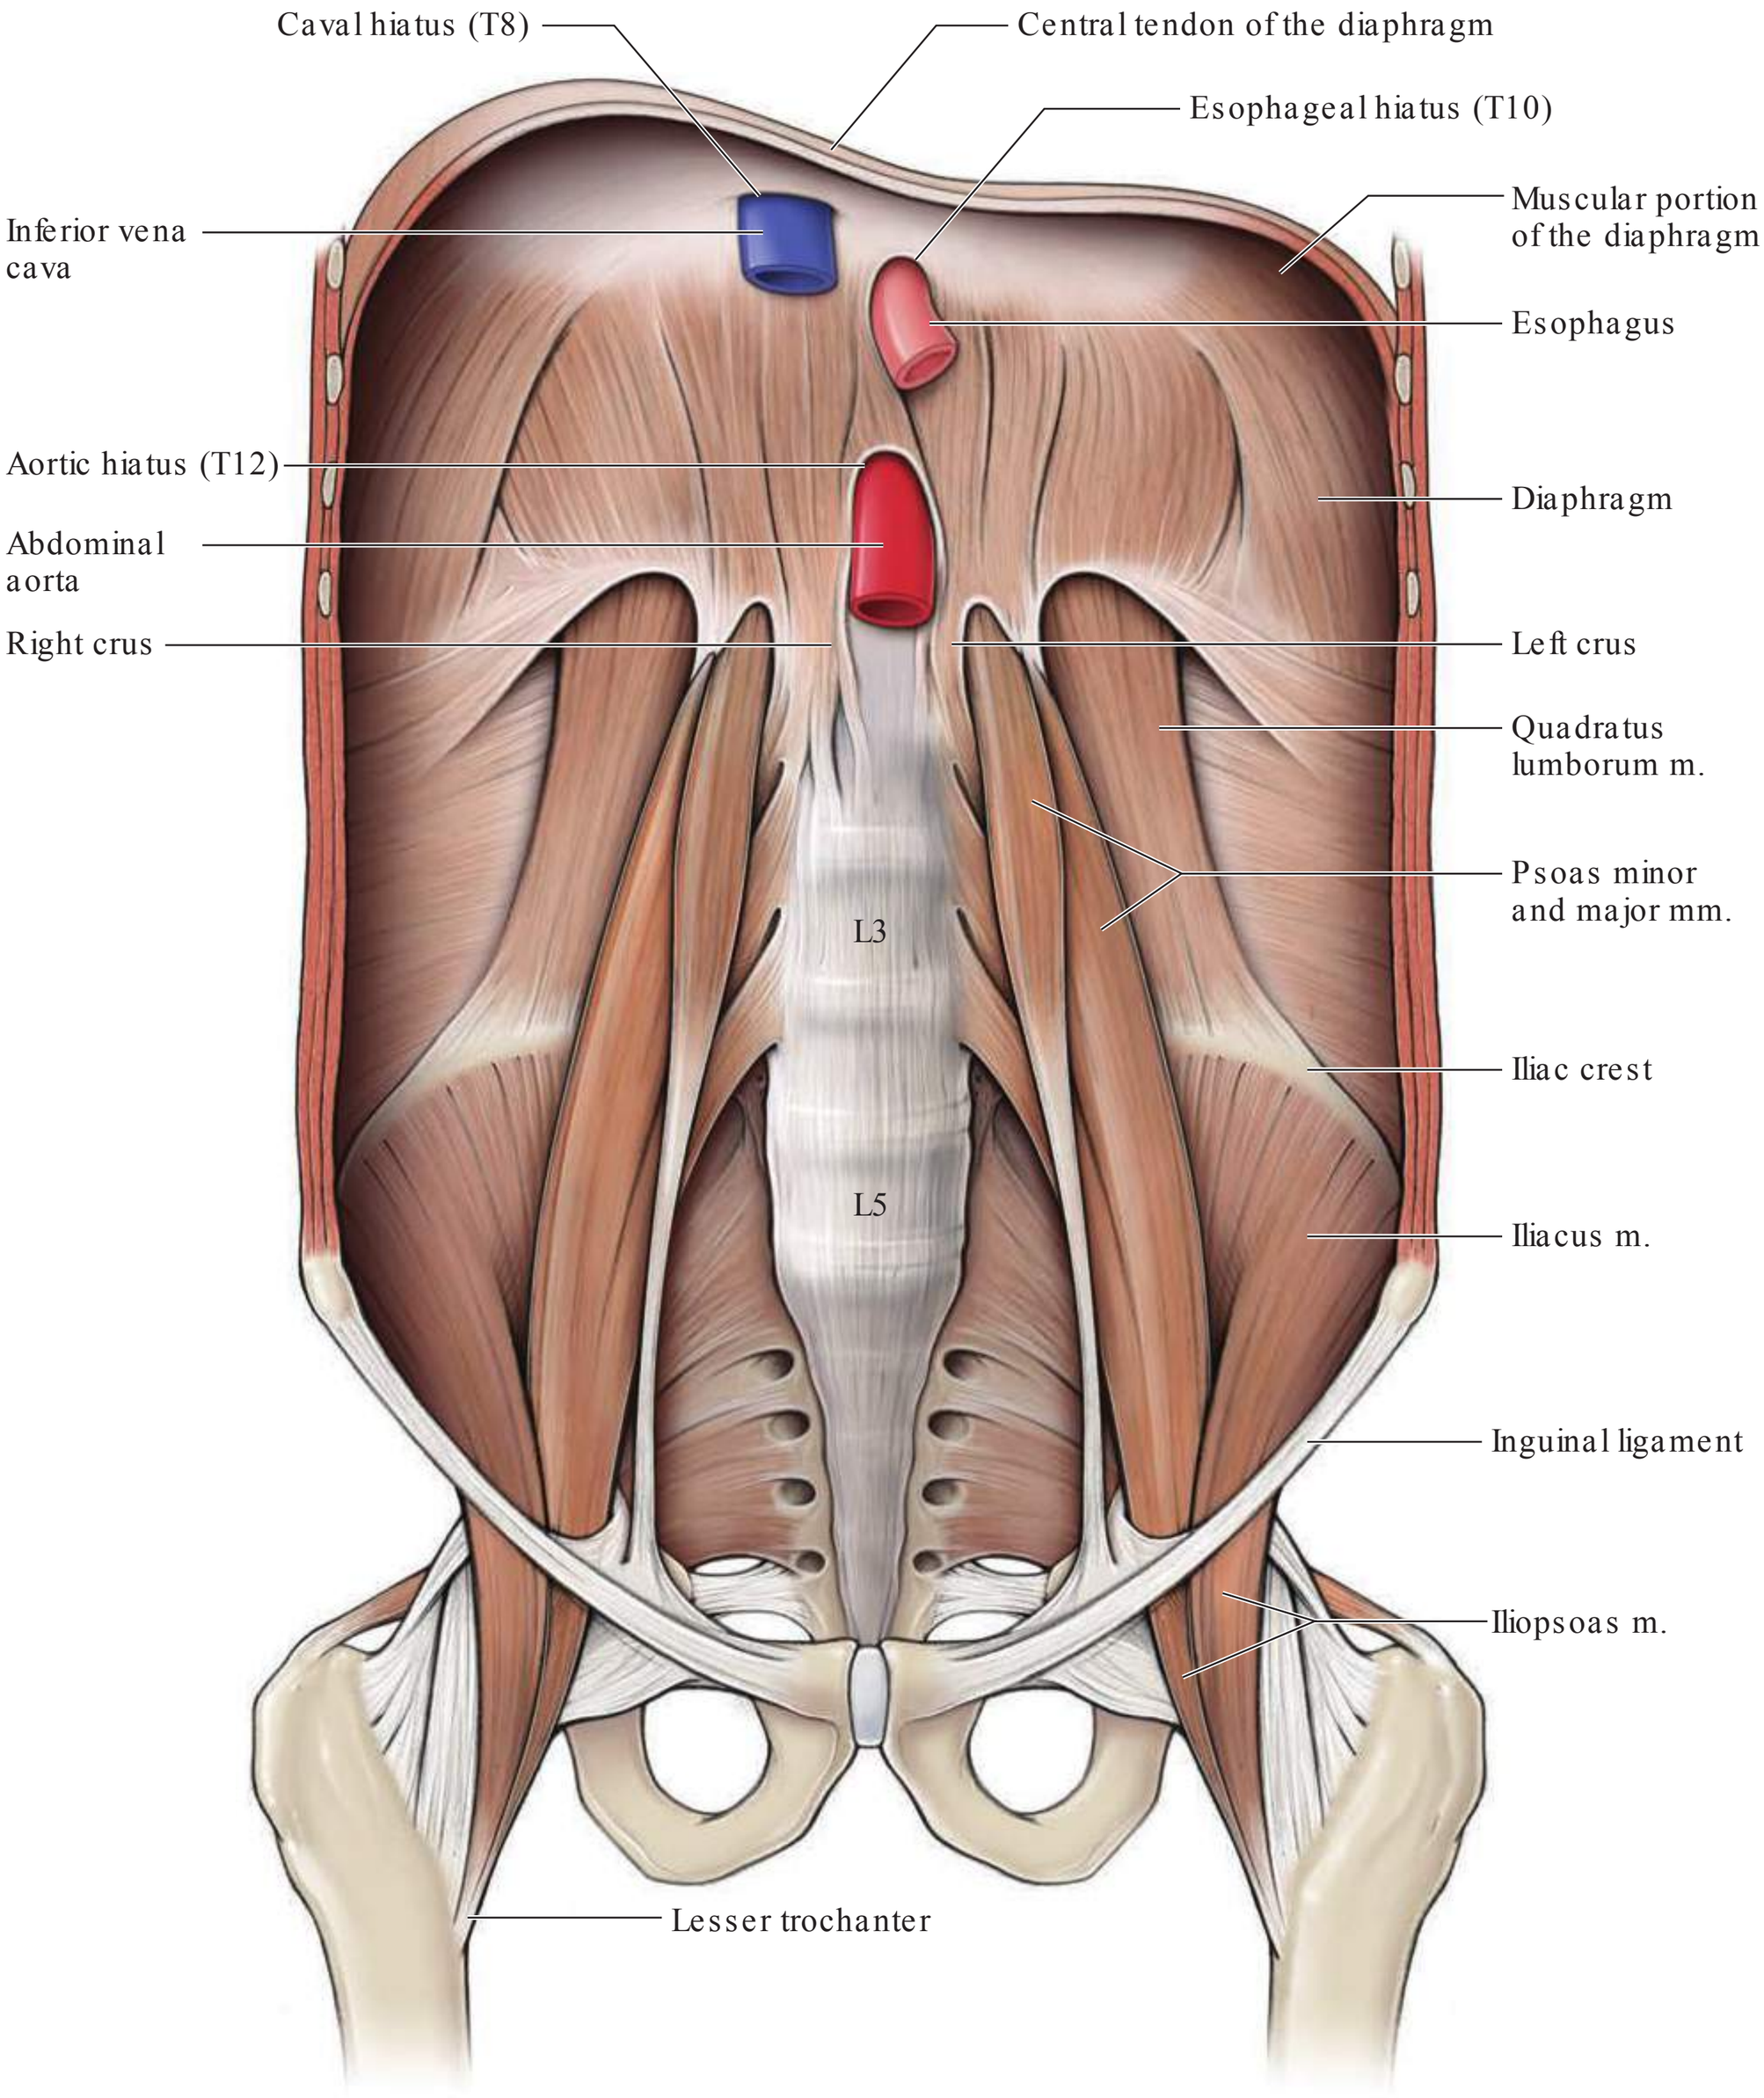

FIGURE 19-4 Muscles of the anterior hip. (Reproduced, with permission, from Chapter 11. Posterior Abdominal Wall. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

(see Chapter 6).[62] During single-limb stance, approximately three times the body weight is transmitted to the hip joint with two-thirds of that being generated by the hip abductor mechanism.[62] In addition to its role as a stabilizer, the gluteus medius also functions as a decelerator of hip adduction.

Gluteus Minimus

The gluteus minimus (Fig. 19-6), the most major internal rotator of the femur, is a relatively thin muscle situated between the gluteus medius muscle and the external surface of the ilium. The gluteus minimus also abducts the thigh, as well as having a primary function as a joint stabilizer, creating compression through its attachment to the capsule.[63] The ability to maintain joint centering to facilitate efficient joint mobility and decrease joint injury is an important function of this muscle in relation to pathological conditions related to joint instability, acetabular undercoverage, and congenital anomalies.[59] It receives support from the TFL, semitendinosus, semimembranosus, and gluteus medius.[60]

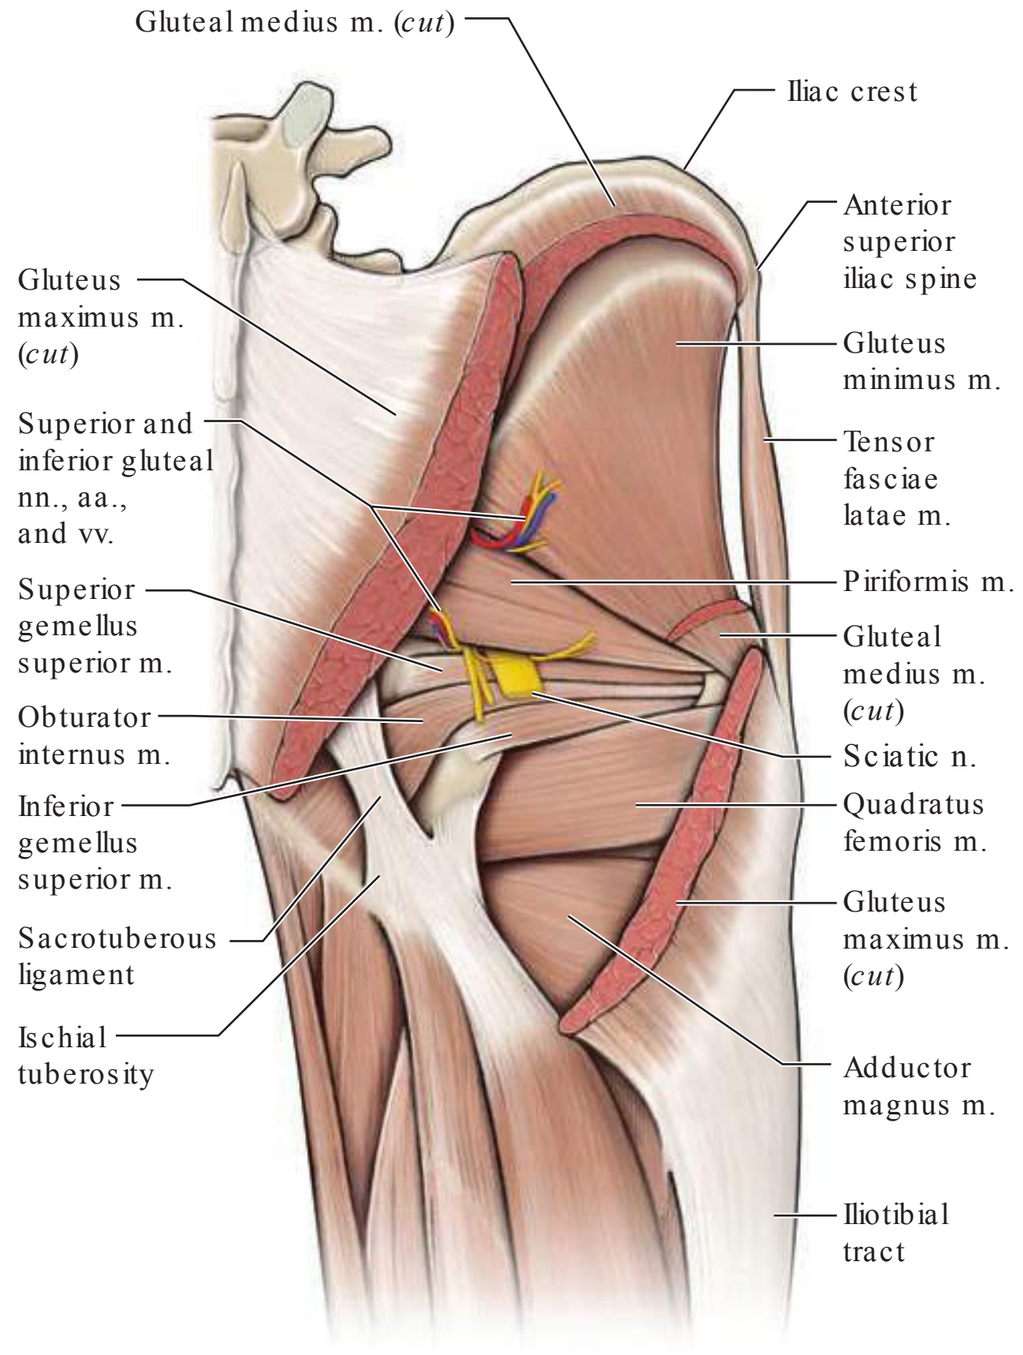

FIGURE 19-6 Deeper muscles of the posterior hip. (Reproduced, with permission, from Chapter 35. Gluteal Region and Hip. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Piriformis

The piriformis (Fig. 19-6) is an external rotator of the hip at less than 60 degrees of hip flexion. At 90 degrees of hip flexion, the piriformis reverses its muscle action, becoming an internal rotator and abductor of the hip.[64] Because of its close association with the sciatic nerve, the piriformis can be a common source of buttock and leg pain (see Chapter 5).[65–68]

Rectus Femoris

The rectus femoris muscle (Fig. 19-7), one of the four quadriceps muscles (see Chapter 20), is a two-joint muscle that arises from two tendons: one, the anterior or direct, from the AIIS; the other, the posterior or indirect, from a groove above the brim of the acetabulum. The rectus femoris, which is a powerful hip flexor, also contributes to extension of the knee. It functions more effectively as a hip flexor when the knee is flexed, as when a person kicks a ball.[60] During athletic function, the rectus femoris prevents excessive hip extension during gait.[69]

CLINICAL PEARL

No muscle has the primary function of internally rotating the hip, but a number of muscles, including the anterior fibers of the gluteus medius, gluteus minimus, TFL, adductor longus, adductor brevis, pectineus, and the posterior head of the adductor magnus, have a secondary function of internal rotation.[9]

Obturator Internus

The obturator internus (Fig. 19-6) is normally an external rotator of the hip and an internal rotator of the ilium but becomes an abductor of the hip at 90 degrees of hip flexion.[70]

CLINICAL PEARL

Controversy exists regarding the structure and insertion of the obturator internus, obturator externus, and the gemelli muscles, and it has been suggested that this group actually represents a single muscle with multiple points of insertion.[71]

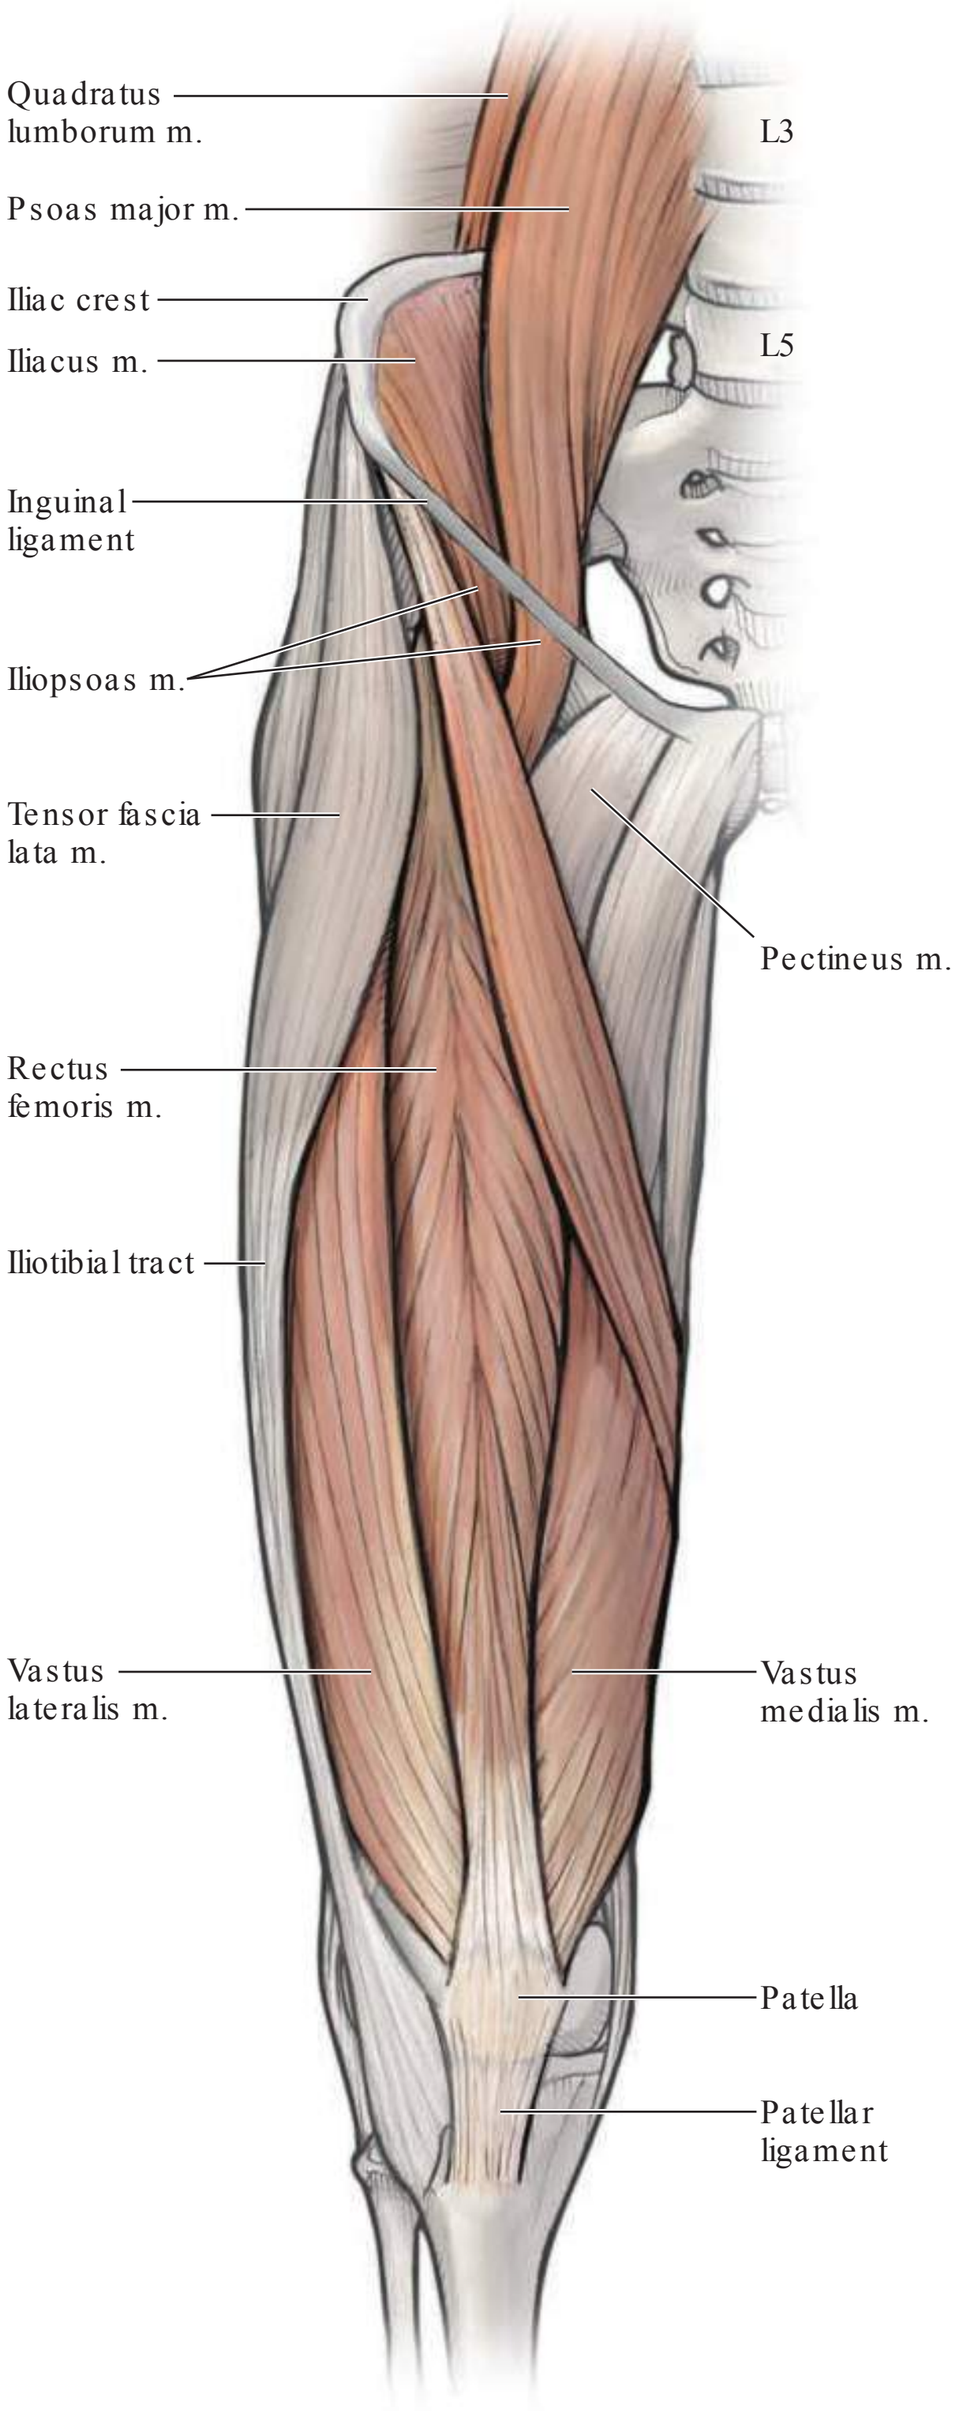

FIGURE 19-7 Muscles of the anterior hip and thigh. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Obturator Externus

The obturator externus (Fig. 19-6), named for its location external to the pelvis, is an adductor and external rotator of the hip.[17]

Gemelli

The superior and inferior gemelli muscles (Fig. 19-6) are considered extensions of the obturator internus tendon. The superior gemellus is the smaller of the two. Both the gemelli function as minor external rotators of the hip.[17]

Quadratus Femoris

The quadratus femoris muscle (Fig. 19-6), another external rotator of the hip, is a flat, quadrilateral muscle, located between the inferior gemellus and the superior aspect of the adductor magnus. The quadratus femoris and the inferior gemellus share the same innervation (L4–L5).[17] The obturator internus and superior gemellus also share the same innervation (L5–S1).[17]

CLINICAL PEARL

In a manner generally similar to the infraspinatus and teres minor at the glenohumeral joint, the short external rotators of the hip also like to provide an important element of mechanical stability to the hip articulation by producing compression of the hip joint.[62] Interestingly, the popular posterior surgical approach to a total hip arthroplasty used by some surgeons necessarily cuts through at least part of the hips posterior capsule, potentially disrupting several of the short external rotator tendons.[50] Studies have reported a significant reduction in the incidence of posterior hip dislocation when the surgeon carefully repairs the posterior capsule and external rotator tendons.[50,72,73]

Pectineus

The pectineus (Fig. 19-7) is an adductor, flexor, and internal rotator of the hip. Like the iliopsoas, the pectineus attaches to and supports the joint capsule of the hip.

CLINICAL PEARL

The hip external and internal rotators' role in stabilization may become more crucial when the acetabular labrum is torn secondary to the subsequent loss of passive rotational stability.[74]

Sartorius

The sartorius muscle (Fig. 19-7) is the longest muscle in the body. The sartorius is responsible for flexion, abduction, and external rotation of the hip, and some degree of knee flexion.[75]

Hamstrings

The hamstrings muscle group consists of the biceps femoris, the semimembranosus, and the semitendinosus.

Biceps Femoris. The biceps femoris (Fig. 19-8), which arises by way of a long and short head, extends the hip, flexes the knee, and externally rotates the tibia. Only the long head, which originates from the ischial tuberosity and lower part of the sacrotuberous ligament, acts on the hip. The short head arises from the lateral linea aspera, lateral supracondylar line, and intermuscular septum. The tibial portion of the sciatic nerve innervates the long head and the fibularis (peroneal) division innervates the short head. The long head

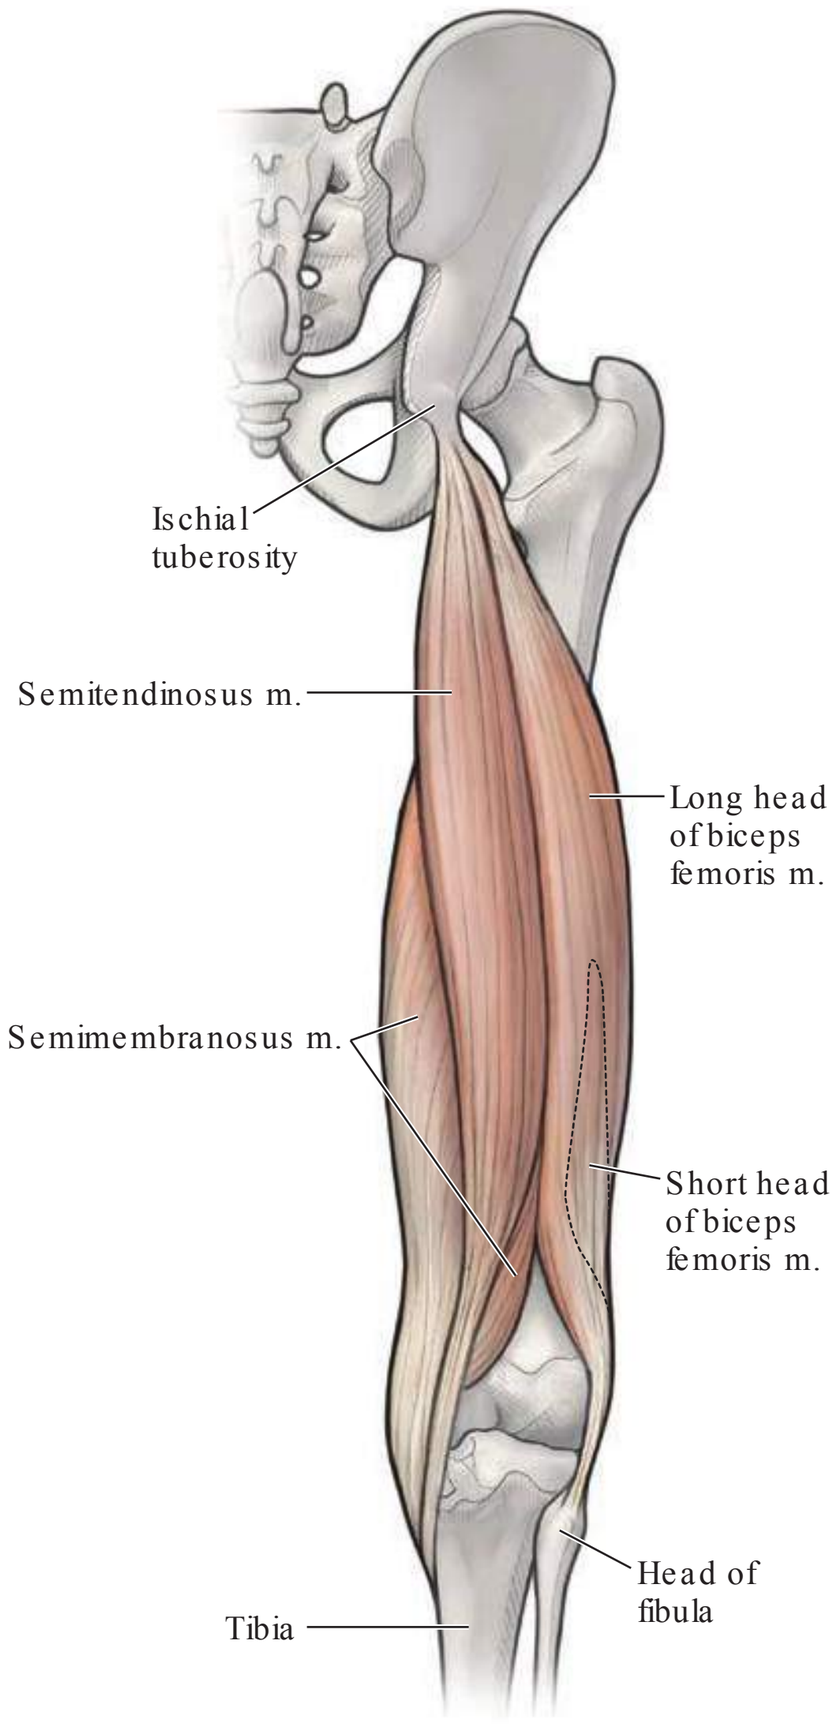

FIGURE 19-8 The hamstrings. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

is active during conditions that require lower amounts of force, such as decelerating the limb at the end of the swing phase and during forceful hip extension.[76] The biceps femoris is the most commonly strained muscle of the hamstring complex (53%).[77] The anatomy of the biceps femoris may help to explain its higher rate of injury. First, both the long and the short head have separate nerve supplies. This dual innervation may lead to asynchronous stimulation of the two heads—a mistimed contraction of the different parts of the muscle group may mean a reduced capacity to generate effective tension to control the imposed loads of the muscle.[78] There may also be anatomical variations in the attachments of biceps femoris, which may predispose certain people to injury. Due to the origin of the long head of the biceps femoris, it could be argued that the biceps femoris has a triarticular function and is, therefore, more predisposed to injury than the other hamstring muscles.[78] The insertion of the biceps femoris into the head of the fibula may also be a predisposing factor to injury—previous knee or ankle injury resulting in alteration in the movement of the superior tibiofibular joint may affect the biomechanics of the biceps femoris although this notion is speculative.[78] However, incomplete knee excursion caused by meniscal damage may lead to excessive loading of the biceps femoris.[79] In addition to the anatomical reasons, the biceps femoris is susceptible to high rates of injury as it is subjected to the greatest amount of eccentric load during high-speed activities such as sprinting.[80] Given the rotational demands of many sports, this function may also predispose the biceps femoris to injury.

Semimembranosus

The semimembranosus (Fig. 19-8) gains its name from its membranous origin at the ischial tuberosity beneath the semitendinosus and inserts onto the medial tibial condyle, posterior oblique ligament, arcuate ligament, and posterior joint capsule. The semimembranosus is innervated by the tibial division of the sciatic nerve.

Semitendinosus. The semitendinosus (Fig. 19-8) arises from the ischial tuberosity by a conjoint tendon with the biceps femoris and inserts as part of the pes anserinus on the superior and medial aspect of the tibia, and deep fascia of the leg at Gerdy's tubercle. The semitendinosus is innervated by the tibial division of the sciatic nerve.

CLINICAL PEARL

Increased anterior pelvic tilt has been linked to hamstring strains in runners, which is likely due to the increased tension on the muscle group, because of the lengthened position.[81,82] A common cause for an increased anterior pelvic tilt is decreased mobility of the anterior capsule or decreased extensibility of the hip flexors.[83]

All three muscles of the hamstring complex (except for the short head of the biceps) work with the posterior adductor magnus and the gluteus maximus to extend the hip.[84] The hamstrings also flex the knee and weakly adduct the hip. The long head of the biceps femoris helps with external rotation of the thigh and leg; the more medial semimembranosus and semitendinosus muscles assist with internal rotation of the thigh and leg.[84] When the hamstrings contract, their forces are exerted on both the hip and knee joints simultaneously; functionally, however, they can actively mobilize only one of the two joints at any one time.[84] During gait, prior to heel contact, the hamstrings decelerate knee extension and hip flexion to prepare for foot contact with the ground (see Chapter 6) and are active for the initial 10% of the stance phase to provide hip extension and stability to the knee through coactivation for dynamic stabilization.[84] Compared to walking and jogging, running is a stressful activity for the hamstrings and increases the high demands on their tendon attachments, especially during eccentric contractions. While running, the hamstrings have three main functions[84]:

1. They decelerate knee extension at the end of the forward swing phase. Consequently, hamstring injuries are most likely to occur during the terminal swing phase of running, while contracting eccentrically and while the muscle is in the more lengthened position.[85] Through an eccentric contraction, the hamstrings decelerate the forward momentum (i.e., leg swing) at approximately 30 degrees short of

full knee extension. The length–tension relationship and changing moment arm of the hamstrings decreases torque production near full knee extension when the hip joint is in 90-degree flexion as in the seated position.[86]

2. At foot strike, the hamstrings elongate to facilitate hip extension through an eccentric contraction, thus further stabilizing the leg for weight bearing.
3. The hamstrings assist the gastrocnemius in paradoxically extending the knee during the takeoff phase of the running cycle.

Hip Adductors

The adductors of the hip (Fig. 19-9) are found on the medial aspect of the joint.

Adductor Magnus. The adductor magnus is the most powerful adductor, and it is active to varying degrees in all hip motions except abduction. In addition, the adductor magnus has the greatest moment arm for hip extension. The posterior portion of the adductor magnus is sometimes considered functionally as a hamstring because of its anatomic alignment. Because of its size, the adductor magnus is less likely to be injured than the other hip adductors.[87]

Adductor Longus. The pectineus and adductor longus muscles serve as primary adductors of the hip while contributing to hip flexion. The adductor longus is the most prominent muscle of the adductors during resisted adduction and forms the medial border of the femoral triangle. The adductor longus also assists with external rotation, in extension, and internal rotation in other positions. The adductor longus is the most commonly strained adductor muscle due to its limited mechanical advantage.[88,89] This mechanical disadvantage is due to the large distance from the axis of rotation to the center of mass of the lower extremity, resulting in the requirement of a greater force production to achieve the intended movement.[59]

Gracilis. The gracilis (Fig. 19-9), the longest of the hip adductors, is also the most superficial and medial of the hip adductor muscles. The gracilis functions to adduct and flex the thigh and flex and internally rotate the leg.

The other adductors of the hip include the adductor brevis, obturator externus, and the pectineus muscles. The main

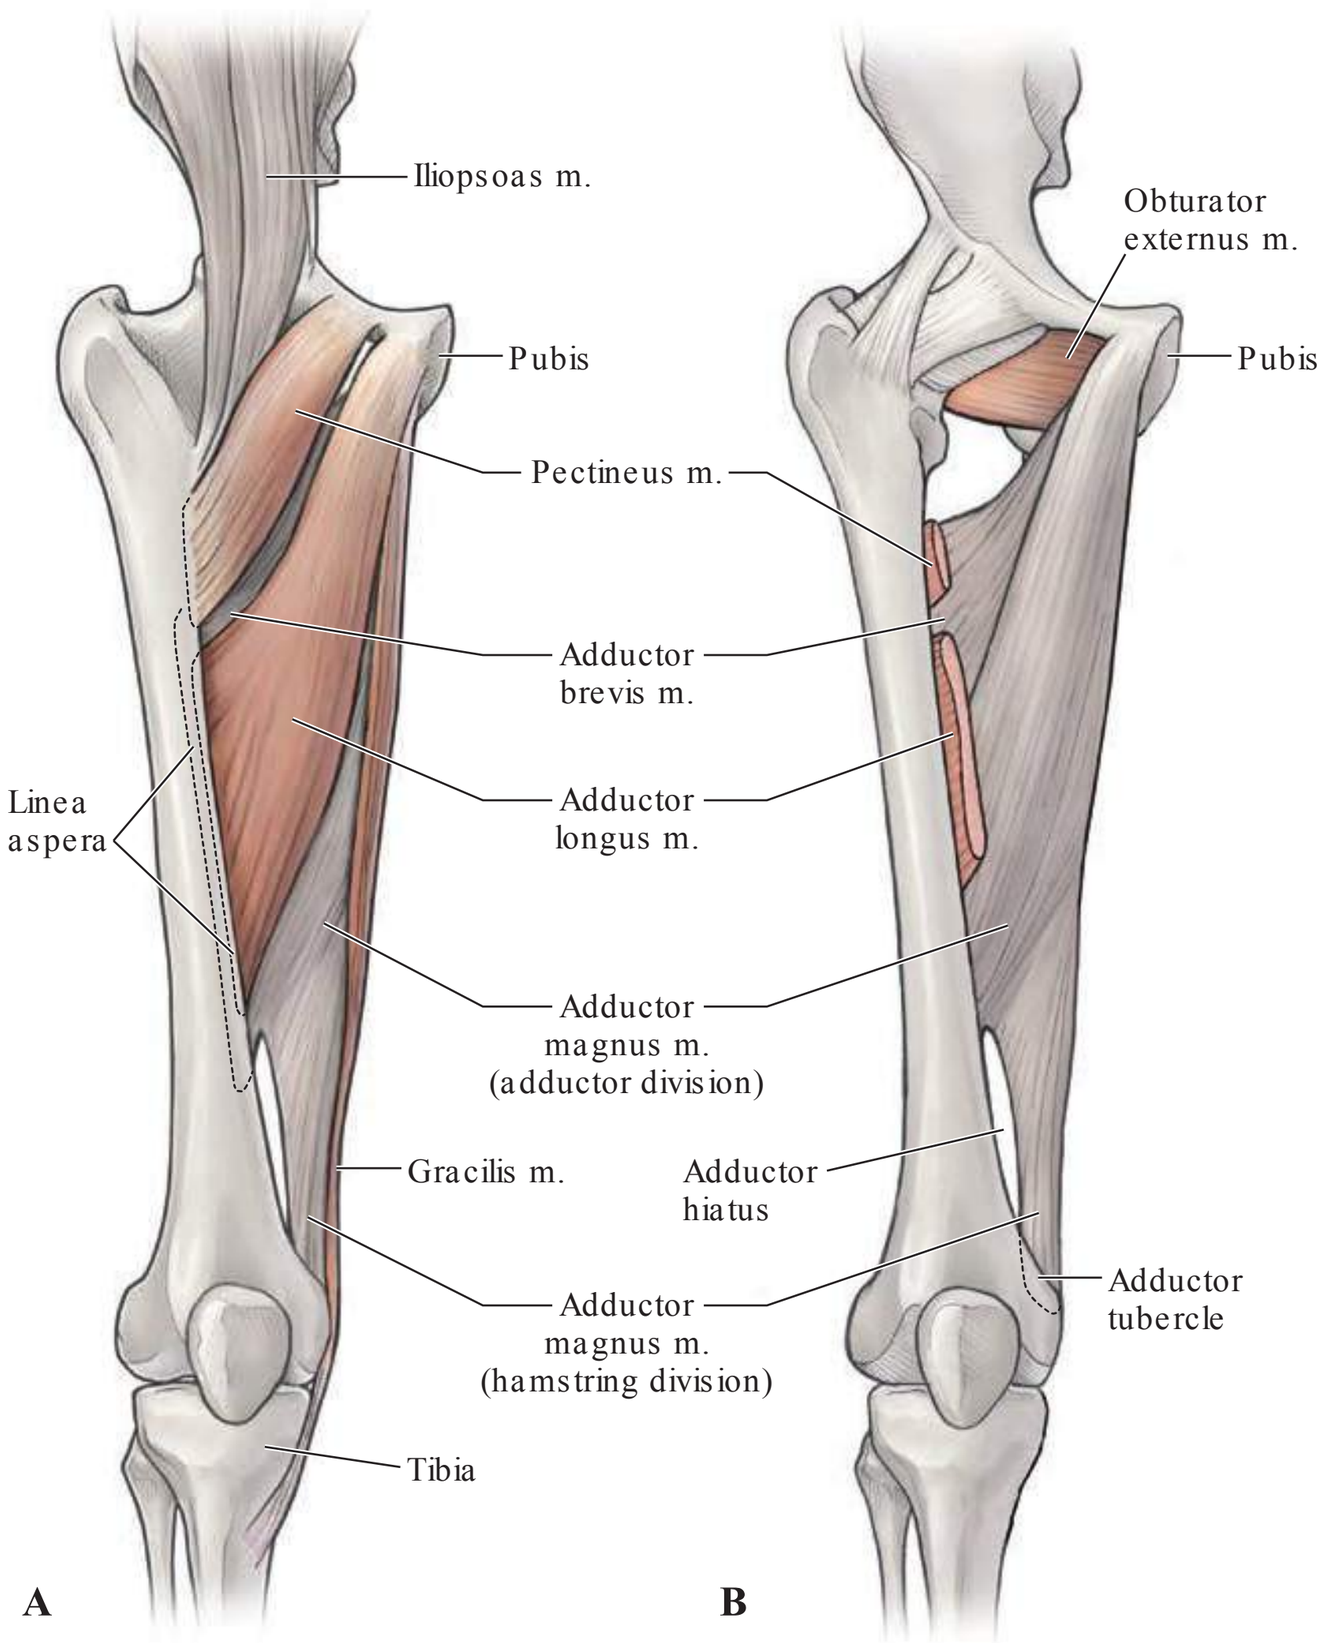

FIGURE 19-9 The hip adductors. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

action of this muscle group is to adduct the thigh in the open kinetic chain and stabilize the lower extremity to perturbation in the closed kinetic chain. Each individual muscle can also provide assistance in femoral flexion and rotation.[90]

Bursa

There are more than a dozen bursae in this region.[91] The more clinically significant ones are described below.

Iliopsoas Bursa

Many names have been used to describe the iliopsoas bursa (IPB), including the iliopsoas, iliopectineal, iliac, iliofemoral, and subpsoas bursa.[92] The IPB is the largest and most constant bursa about the hip, present in 98% of normal adult individuals, usually bilaterally.[93] The IPB is situated deep to the iliopsoas tendon and serves to cushion the tendon from the structures on the anterior aspect of the hip joint capsule. Its dimensions may be up to 7 cm in length and 4 cm in width.[93] Anatomic boundaries of the bursa include the iliopsoas muscle anteriorly, the pectineal eminence and the hip joint capsule posteriorly, the iliofemoral ligament laterally, and the acetabular labrum medially.[94]

In 15% of patients, the IPB communicates with the hip joint via a 1-mm–3-cm point of relative capsular thinning between the iliofemoral and pubofemoral ligaments.[21,92] While this connection may occur on a congenital basis,[92] this number rises to 30–40% of patients with hip joint pathology.[95]

As with other bursae, the IPB can become inflamed and distended. Inflammation and distension of this bursa are most commonly associated with rheumatoid arthritis, but it is also seen in association with athletic activity, overuse and impingement syndromes, osteoarthrosis, pigmented villonodular synovitis, synovial chondromatosis, infection, pseudogout, metastatic bone disease, and, in rare cases, after Total Hip Arthroplasty (THA) (see "Intervention Strategies").[96]

Trochanteric Bursa

There are three bursae consistently present at the greater trochanter, two major bursae, and one minor bursa. The two clinically significant trochanteric bursae are the subgluteus medius bursa, and the more superficial subgluteus maximus bursa.

- Subgluteus medius bursa: located at the superoposterior tip of the greater trochanter and functions to prevent friction between the gluteus medius muscle and the greater trochanter and also between the gluteus medius and gluteus minimus muscles.
- Subgluteus maximus bursa: located between the greater trochanter and the fibers of the gluteus maximus and TFL muscles as they blend into the ITB.

Ischiogluteal Bursa

The ischiogluteal bursa is located between the ischium and the gluteus maximus muscle. It can be painfully squeezed between the ischial tuberosity and the hard surface of a chair while sitting, producing ischial bursitis. This condition is often referred to as weaver's bottom.

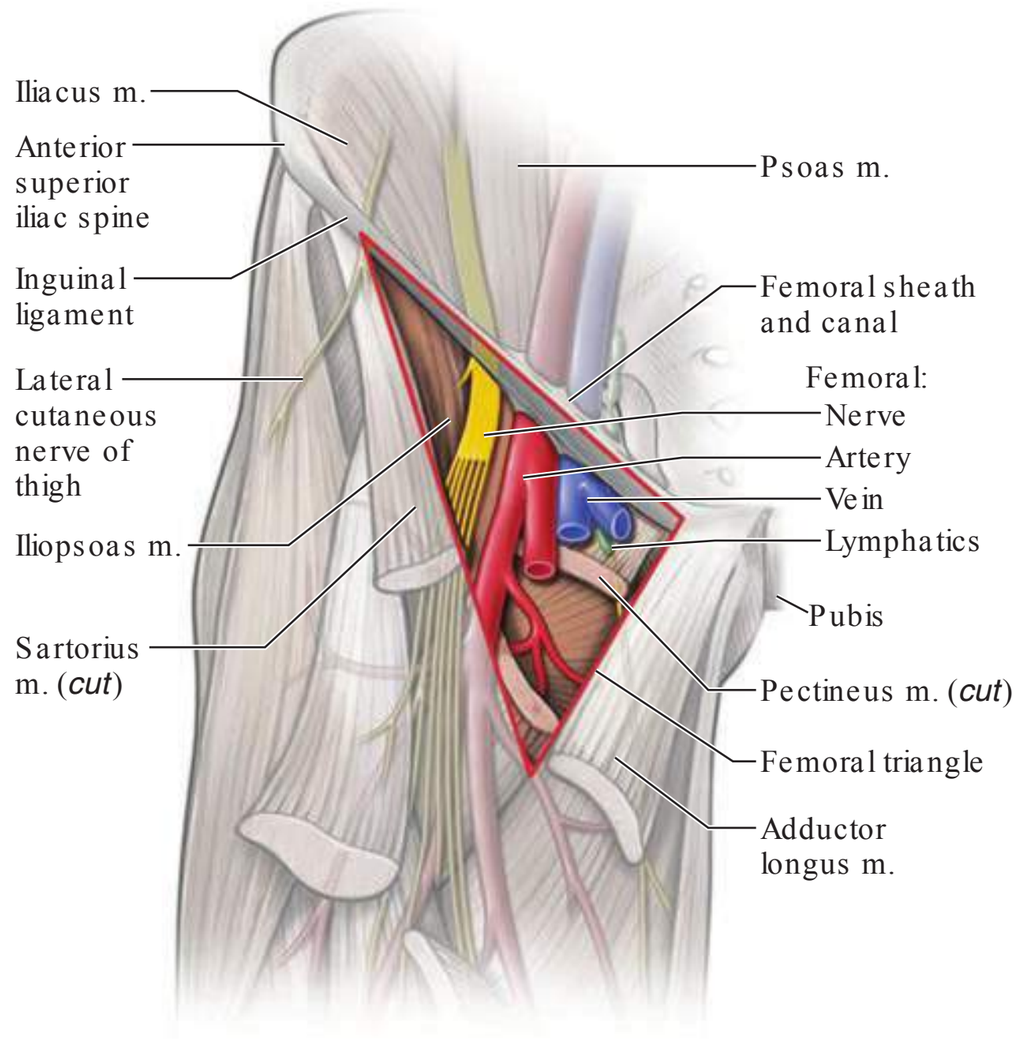

FIGURE 19-10 The femoral triangle. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Femoral Triangle

For topographic reasons, it is important to have an understanding of the anatomy of the femoral triangle. The femoral triangle is defined superiorly by the inguinal ligament, medially by the adductor longus, and laterally by the sartorius (Fig. 19-10). The floor of the triangle is formed by portions of the iliopsoas on the lateral side and by the pectineus on the medial side (Fig. 19-10). A number of neurovascular structures pass through this triangle. These include (from medial to lateral) the femoral vein, artery, and nerve (Fig. 19-10). Thus, the clinician should use caution when palpating in this area or applying soft tissue techniques.

Neurology

The hip joint is innervated primarily by L3 but also has contributions from L1–S1.[9] In addition, many nerves have contributions to the hip, including the iliohypogastric, ilioinguinal, genitofemoral, lateral cutaneous nerve of the thigh, obturator, and femoral nerves.[9] The posterior gluteal region receives cutaneous innervation by way of the subcostal nerve; the iliohypogastric nerve; the posterior (dorsal) rami of L1, L2, and L3; and the posterior (dorsal) primary rami (cluneal nerves) of S1, S2, and S3 (Figs. 19-11 and 19-12A).[97]

The anterior region of the hip has its cutaneous supply divided by the inguinal ligament. The area superior to the ligament is supplied by the iliohypogastric nerve. The area inferior to the ligament is supplied by the subcostal nerve, the femoral branch of the genitofemoral nerve, and the ilioinguinal nerve (see Chapter 3).[97]

The nerves of the muscles that cross the hip joint (femoral, obturator, superior gluteal, and the nerve to the quadratus femoris) also supply the joint capsule and the joint. Therefore,

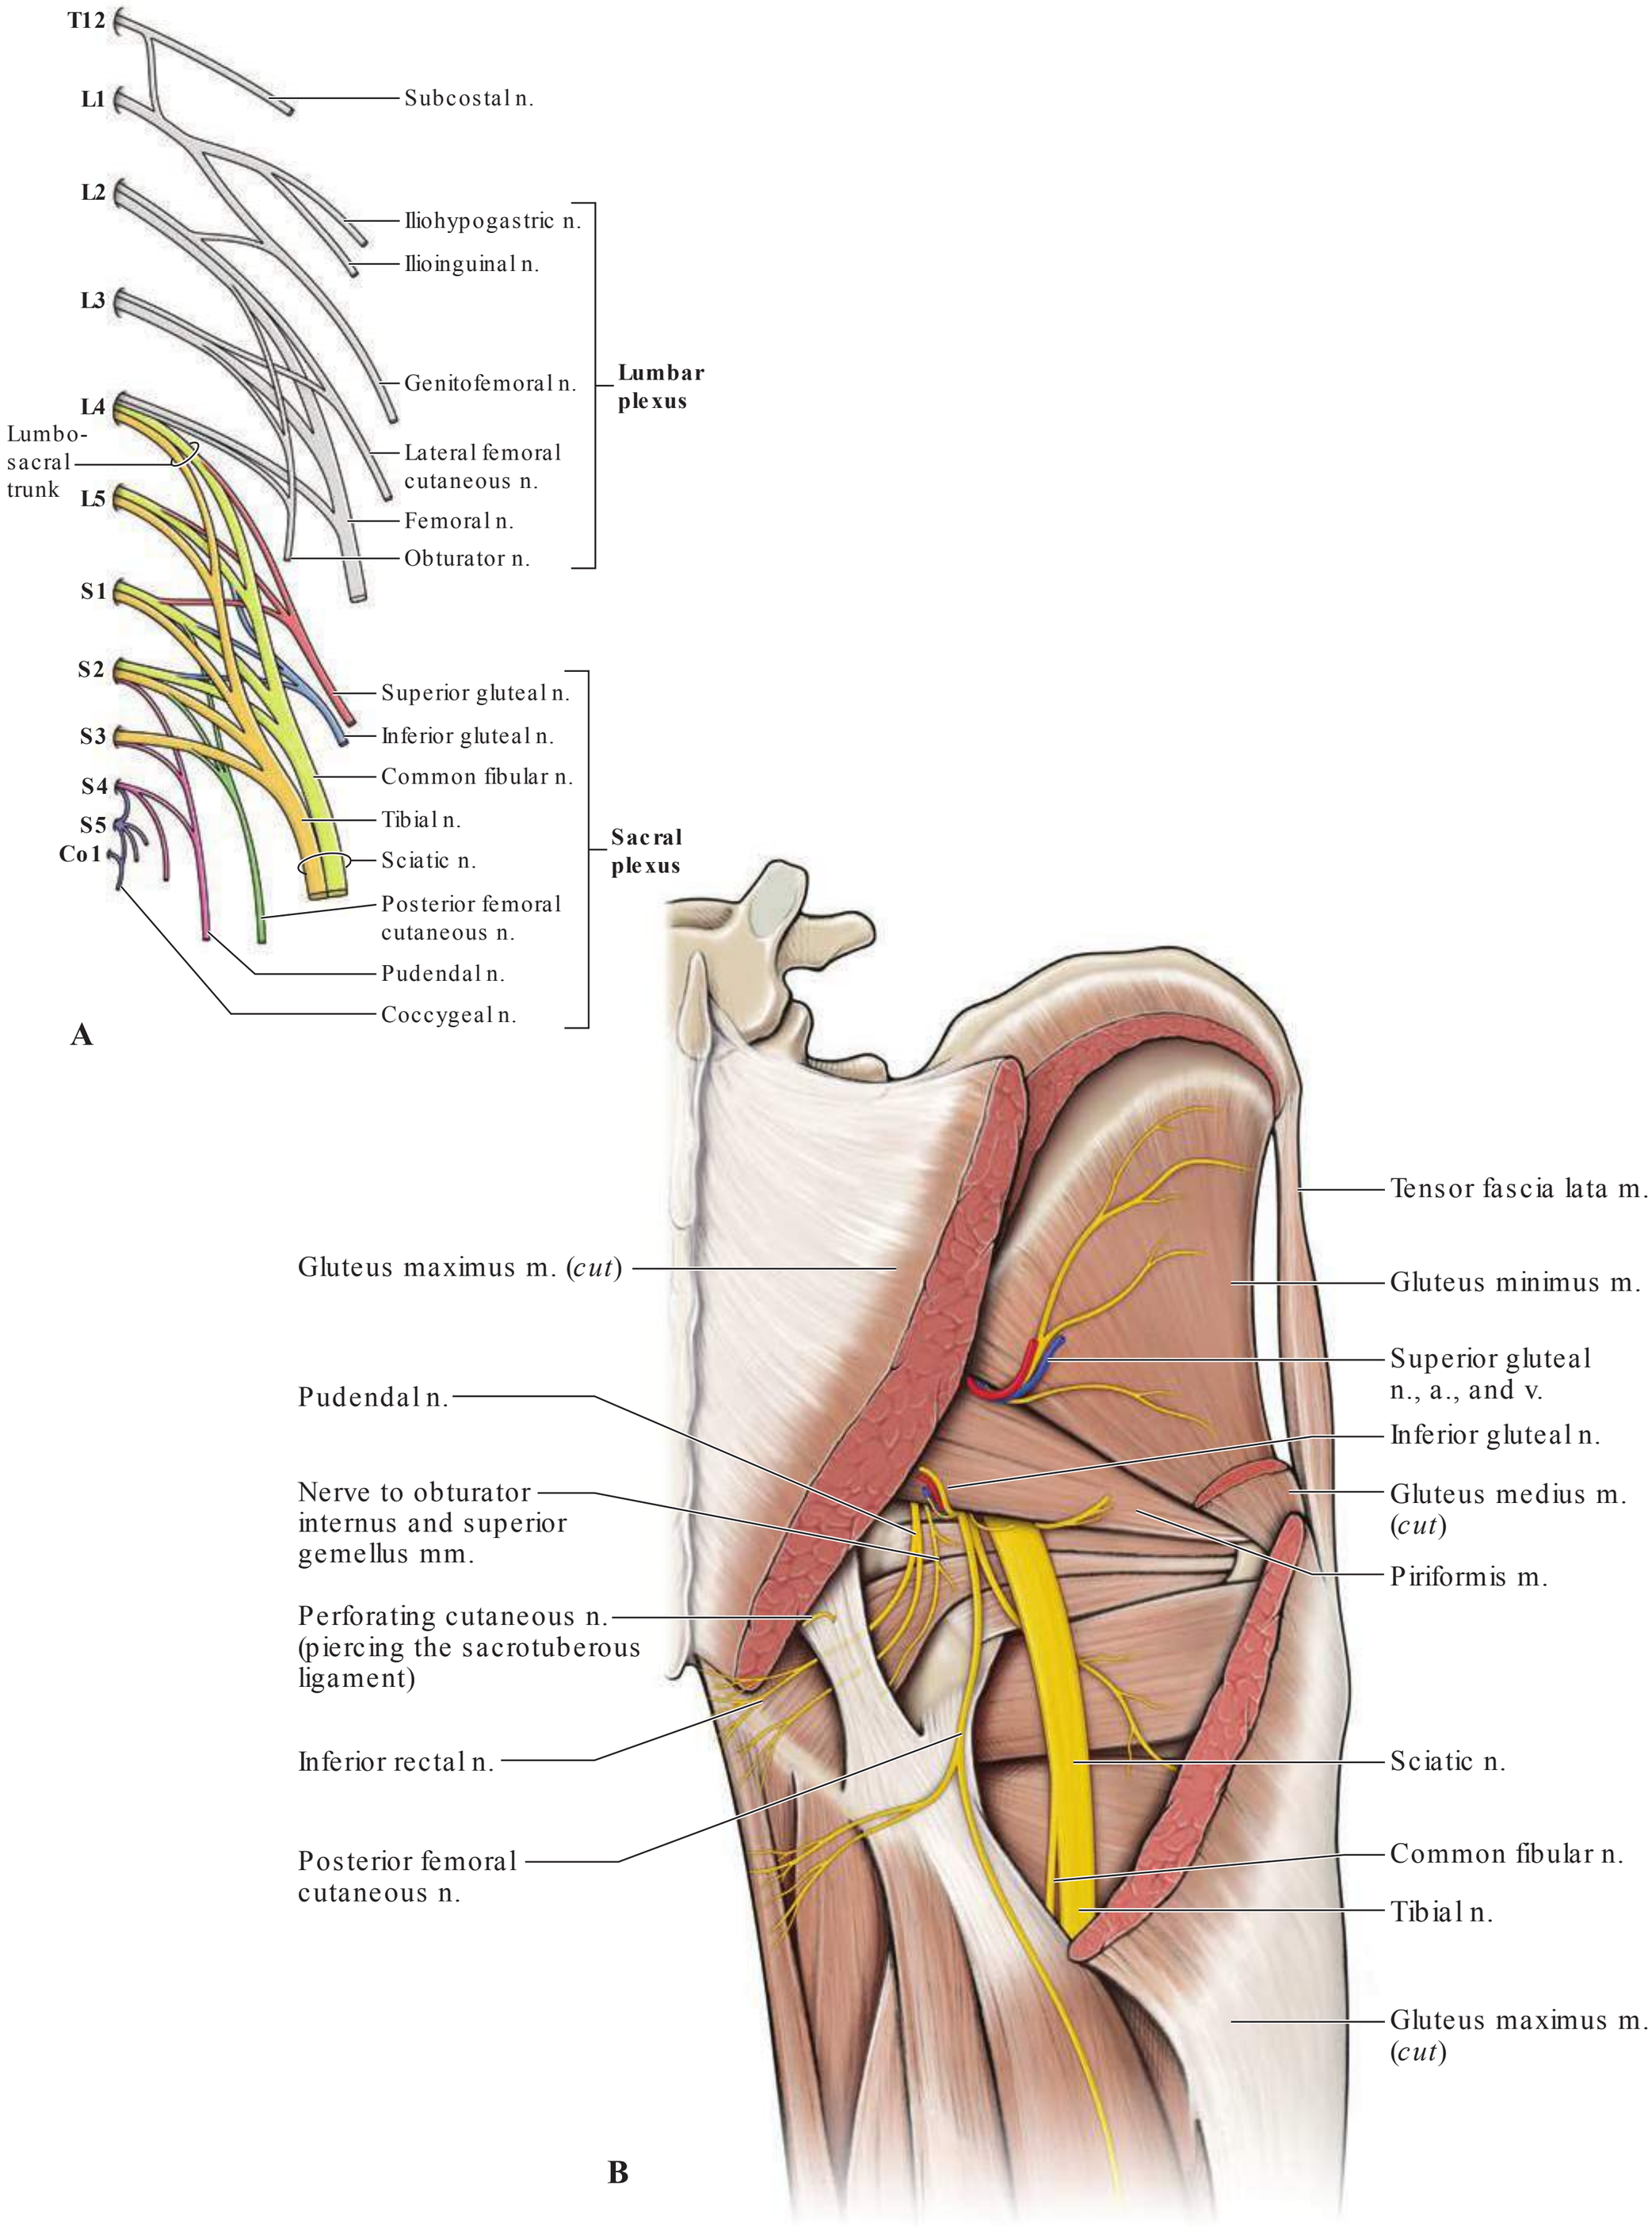

FIGURE 19-11 Neurology and vasculature of the posterior hip. (Reproduced, with permission, from Chapter 35. Gluteal Region and Hip. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

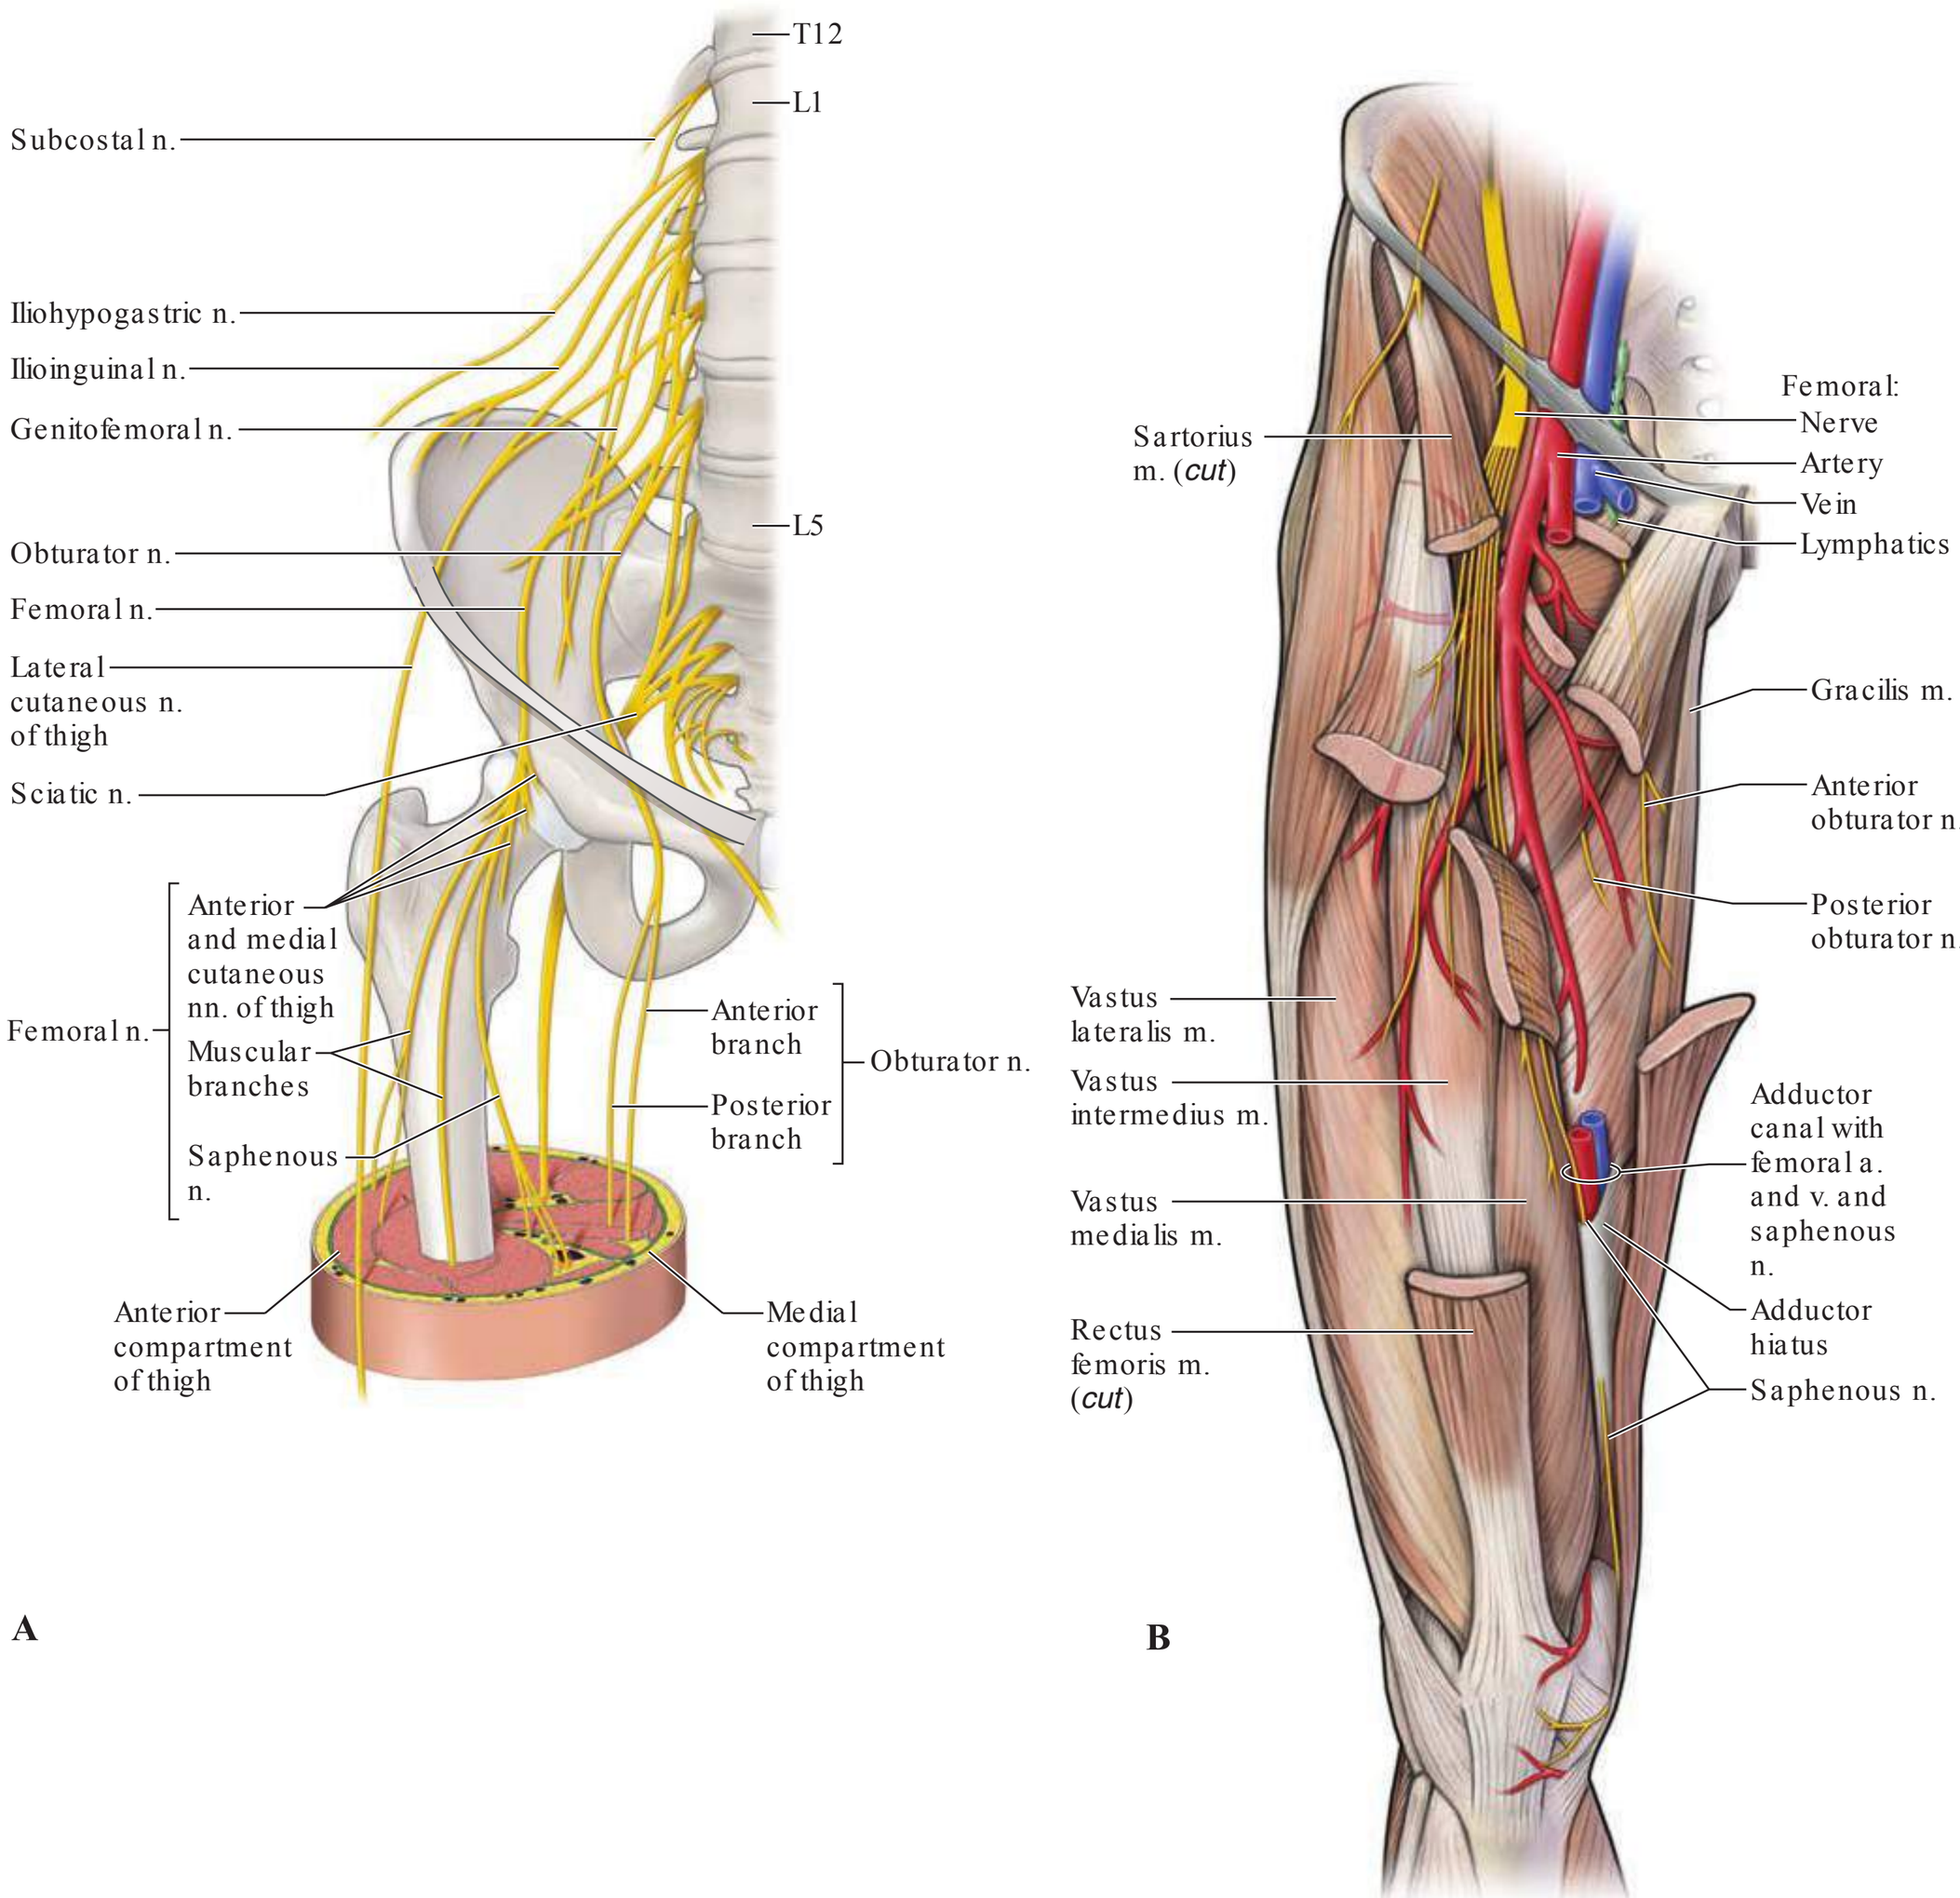

FIGURE 19-12 Neurology and vasculature of the anterior hip. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

pain referred from the hip joint may be felt anywhere in the thigh, leg, or foot.

Arthrogenic inhibition, defined as the reflex inhibition of the musculature surrounding the joint following effusion or injury, and which also occurs at the knee joint, is evident in the hip joint.[98]

Vascular Supply

The internal iliac artery becomes the femoral artery (Figs. 19-12B and 19-13), as it passes underneath the inguinal ligament. The femoral artery forms two branches. The anterior portion of the femoral neck and the anterior portion of the capsule of the hip joint are supplied by the lateral femoral circumflex artery. The medial femoral circumflex artery (MFCA) perforates and supplies the posterior hip joint capsule and the synovium.[97] The deep branch of the MFCA gives rise to two to four superior retinacular vessels and, occasionally, inferior retinacular vessels.[99,100]

Most of the femoral head, comprising its upper one-half or upper two-thirds, is supplied by the obturator artery and a terminal branch of the MFCA (Fig. 19-3).[32] The inferior epiphyseal artery, a branch of the lateral circumflex artery, contributes to the vascularization of the lower area of the femoral head. The supply to the femoral head from the ligamentum teres artery is extremely variable.[101] The blood supply to the weight-bearing portion of the head of the femur is derived from the MFCA.[102]

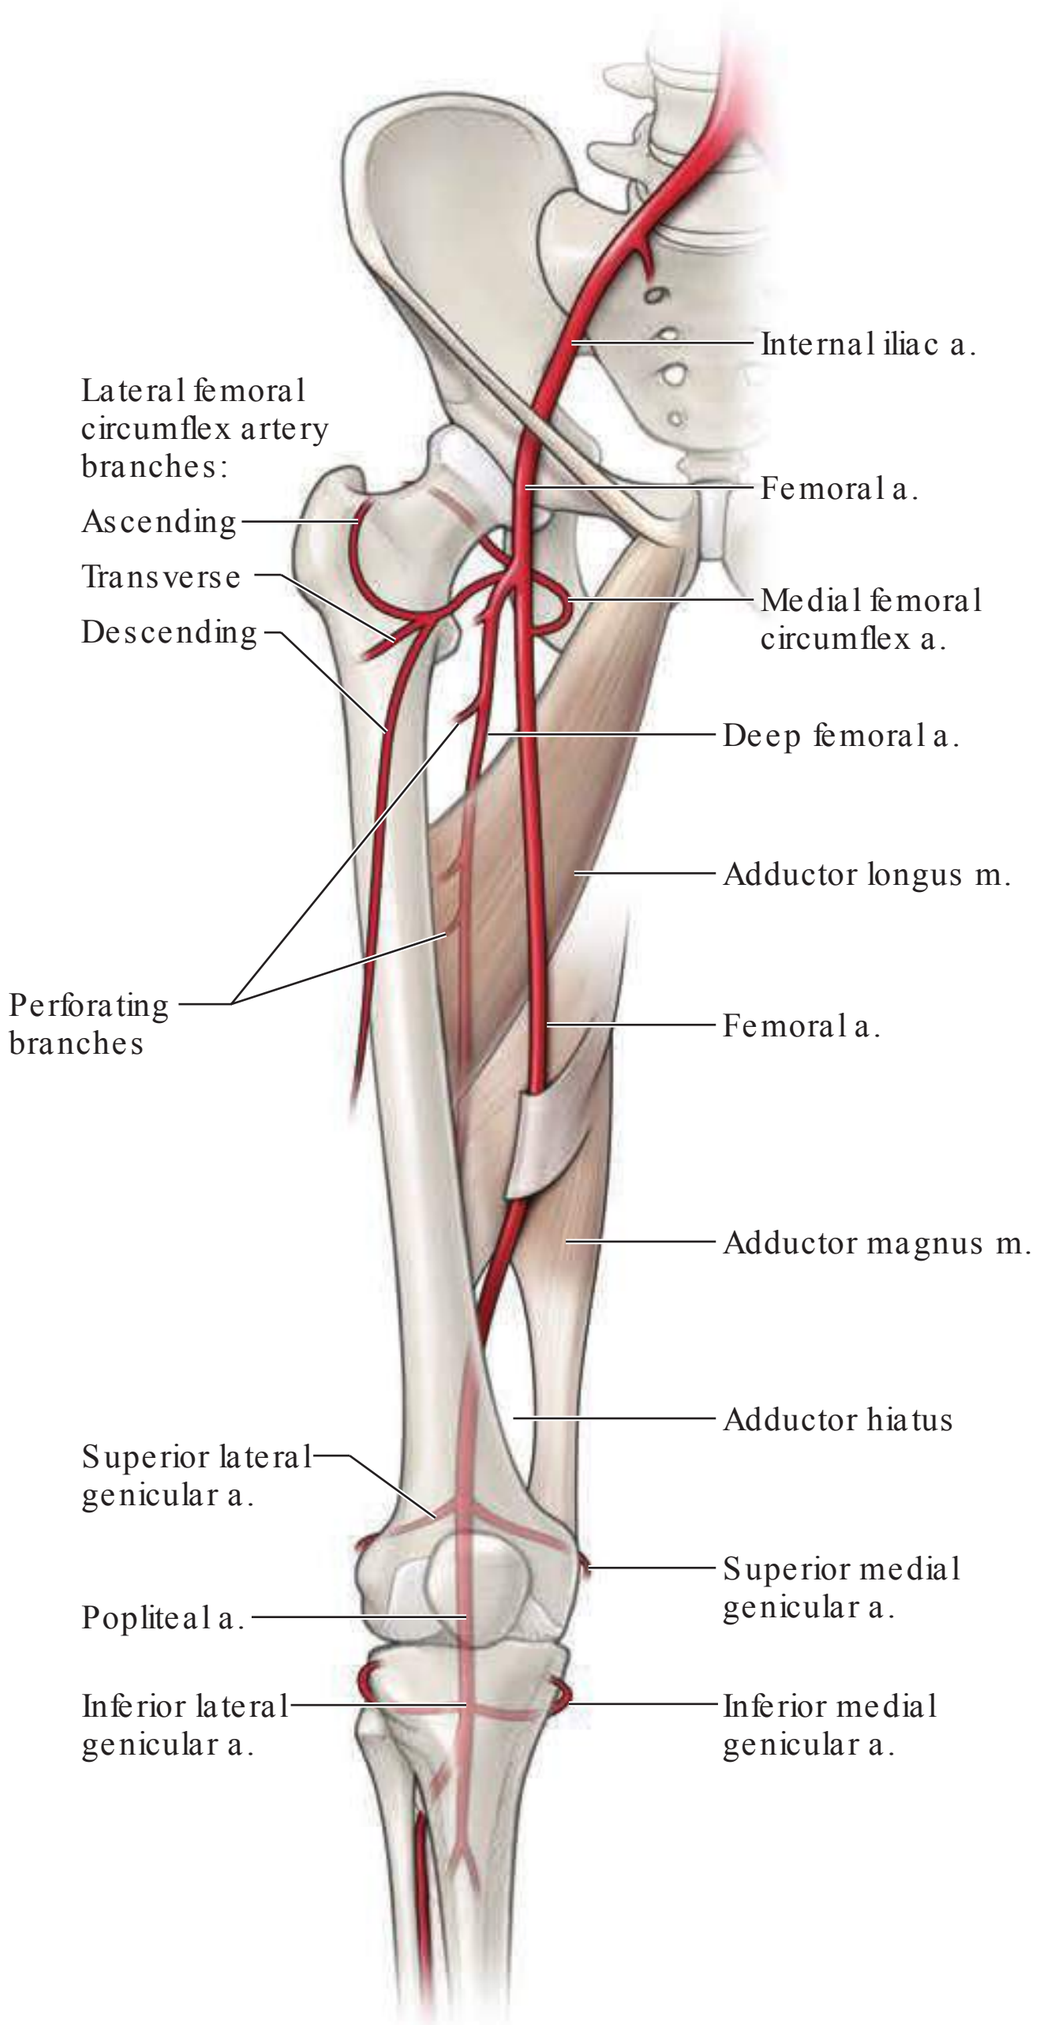

FIGURE 19-13 Vasculature of the hip and thigh. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Two other branches are formed from the internal iliac artery: the inferior and superior gluteal arteries. These arteries supply the superior portion of the capsule and the gluteus maximus muscle.

BIOMECHANICS

The hip joint has three degrees of freedom, which permits motion in three planes: sagittal (flexion and extension around a transverse axis), frontal (abduction and adduction around an anteroposterior axis), and transverse (internal and external rotation around a vertical axis) (Fig. 19-14). All three of these axes pass through the center of the femoral head. The normal motion of the hip joint is primarily rotational, and there is very little translation.[103] Control of the hip during movement involves complex interactions between the nervous, muscular, and skeletal systems. Motion at the hip joint can occur through movement of the femur on the pelvis or from the motion of the pelvis on the femur (i.e., anterior or posterior pelvic tilt).

The 27 muscles that cross the hip joint act as primary movers and dynamic stabilizers of the hip and lower extremity.[104] These muscles provide a myriad of possibilities for compensation and pathology.[9] For example, abnormal hip mechanics can result in gluteus medius tendinosis, hip flexor tendinitis, TFL strain, hamstring tendinosis, and ITB syndrome. Musculoskeletal disorders of the lower limbs are often associated with poor hip muscle performance and altered kinematics during dynamic weight-bearing tasks, such as running. For example, patellofemoral pain and Achilles pathology have both been linked to hip dysfunction.[105]

Active range of motion (AROM) of the hip is variable. Hip flexion averages 110–120 degrees, extension 10–15 degrees, abduction 30–50 degrees, and adduction 25–30 degrees. Hip external rotation averages 40–60 degrees and internal rotation averages 30–40 degrees (Table 19-5). Motions about the hip joint can occur independently; however, the extremes of motion require motion at the pelvis.[106]

CLINICAL PEARL

End-range hip flexion is associated with a posterior rotation of the innominate bone. The end-range of hip extension is associated with an anterior rotation of the innominate. Hip abduction/adduction are associated with an upward/downward tilting of the pelvis (Table 19-6).

The hip joint is a marvel of physics, transmitting truly impressive loads, both tensile and compressive making it the fulcrum for all of the forces. Quantitative and qualitative analyses of the generation of compressive forces at the hip and the muscular mechanisms during weight bearing have been thoroughly documented.[107–114] Depending on the length of the moment arm created by the abductor muscles, the added force of the hip abductors acting on the hip joint can increase the pressures translated across the joint. During ambulation, these compressive joint forces are further multiplied by ground reaction forces and inertial forces related to acceleration and deceleration of the lower limb. Because of muscle tension, compression on the hip is approximately the same as body weight during the swing phase.[115] However, during the support phase, peak joint forces can range from 300% to 400% of body weight at normal walking speed, to 550% of body weight during fast walking and jogging, and as high as 870% of body weight during stumbling.[60,116] Stair climbing and descending increase the loads on the hip by approximately 10% and 20%, respectively.[60,117]

When body weight is evenly distributed across both legs during upright standing, the forces acting on the hip joint are equivalent to half the partial weight made up of the trunk, head, and upper extremities.[118] Were this partial body weight to represent 60% of total body mass, then each hip would be

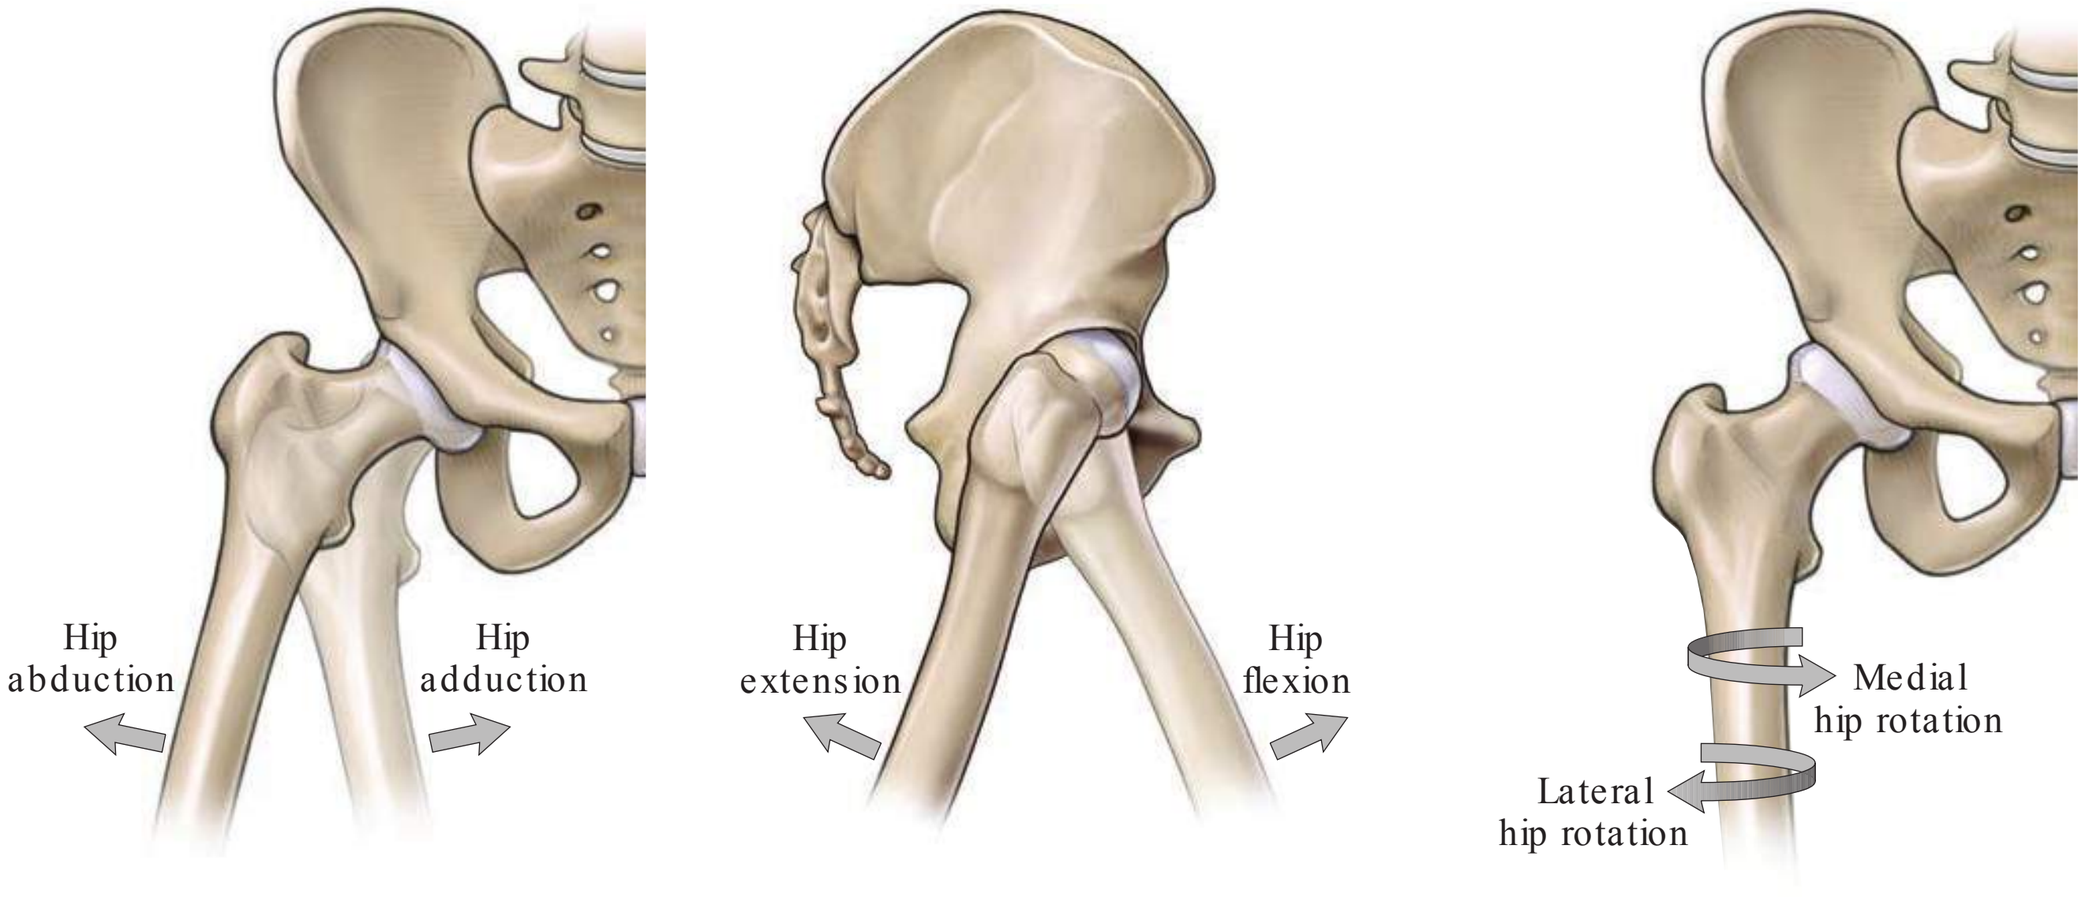

FIGURE 19-14 Movements of the hip. (Reproduced, with permission, from Chapter 35. Gluteal Region and Hip. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

compressed by a force equal to 30% of the total body weight. In a single-limb support, however, shifts in the center of gravity away from the supporting limb dramatically change the equilibrium forces necessary to maintain balance and create a state of disequilibrium. T is state of disequilibrium requires the generation of compensatory forces by the hip musculature, in order to maintain balance.

When pain accompanies degeneration of the hip joint articulation, the body compensates by attempting to reduce the forces generated on the articular surfaces. Since the contribution of body mass cannot be changed, the patient attempts to reduce joint pressures by shifting the upper trunk over the supporting limb during the stance phase. While this maneuver decreases the joint compression forces, the energy expended by laterally bending the trunk during stance significantly increases the energy cost of gait. For a patient with a painful hip, the use of a cane or crutch in the hand contralateral to the involved hip can be used to substantially reduce the excessive trunk motion and to decrease pressure on the hip joint.

T e relationship between the proximal femur, the greater trochanter, and the overall femoral neck width is affected by muscle pull and the forces transmitted across the hip joint. In addition, normal joint nutrition, circulation, and muscle tone during development play an important role.[3,119–121]

In the anatomic position, the orientation of the femoral head causes the contact force between the femur and the acetabulum to be high in the anterosuperior region of the joint.[122] Since the anterior aspect of the femoral head is somewhat exposed in this position; the joint has more flexibility in flexion than extension.[123]

T e femoral neck is subjected to shearing and torsional strains because of its oblique orientation to the shaft of the femur.[8] Downward forces act to displace the femoral head inferiorly and to bend the femoral neck downward. To counter these forces, the femoral neck has developed a unique system of obliquely oriented trabeculae that traverse the head and the neck.[8] T e angle between the femoral shaft and the neck is called the angle of inclination (Fig. 19-15) and is normally approximately 125 degrees (Fig. 19-15)[64] although it can vary with body types. In a tall person, the angle of inclination is larger. T e opposite is true with a shorter individual. T e angle of inclination has an important influence on the hips. An increase in this angle causes the femoral head to be directed more superiorly in the acetabulum and is often referred to as coxa valga (Fig. 19-15). Coxa valga has the following effects at the hip joint:

- It alters the orientation of the joint reaction force (JRF) from the normal vertical direction to one that is almost

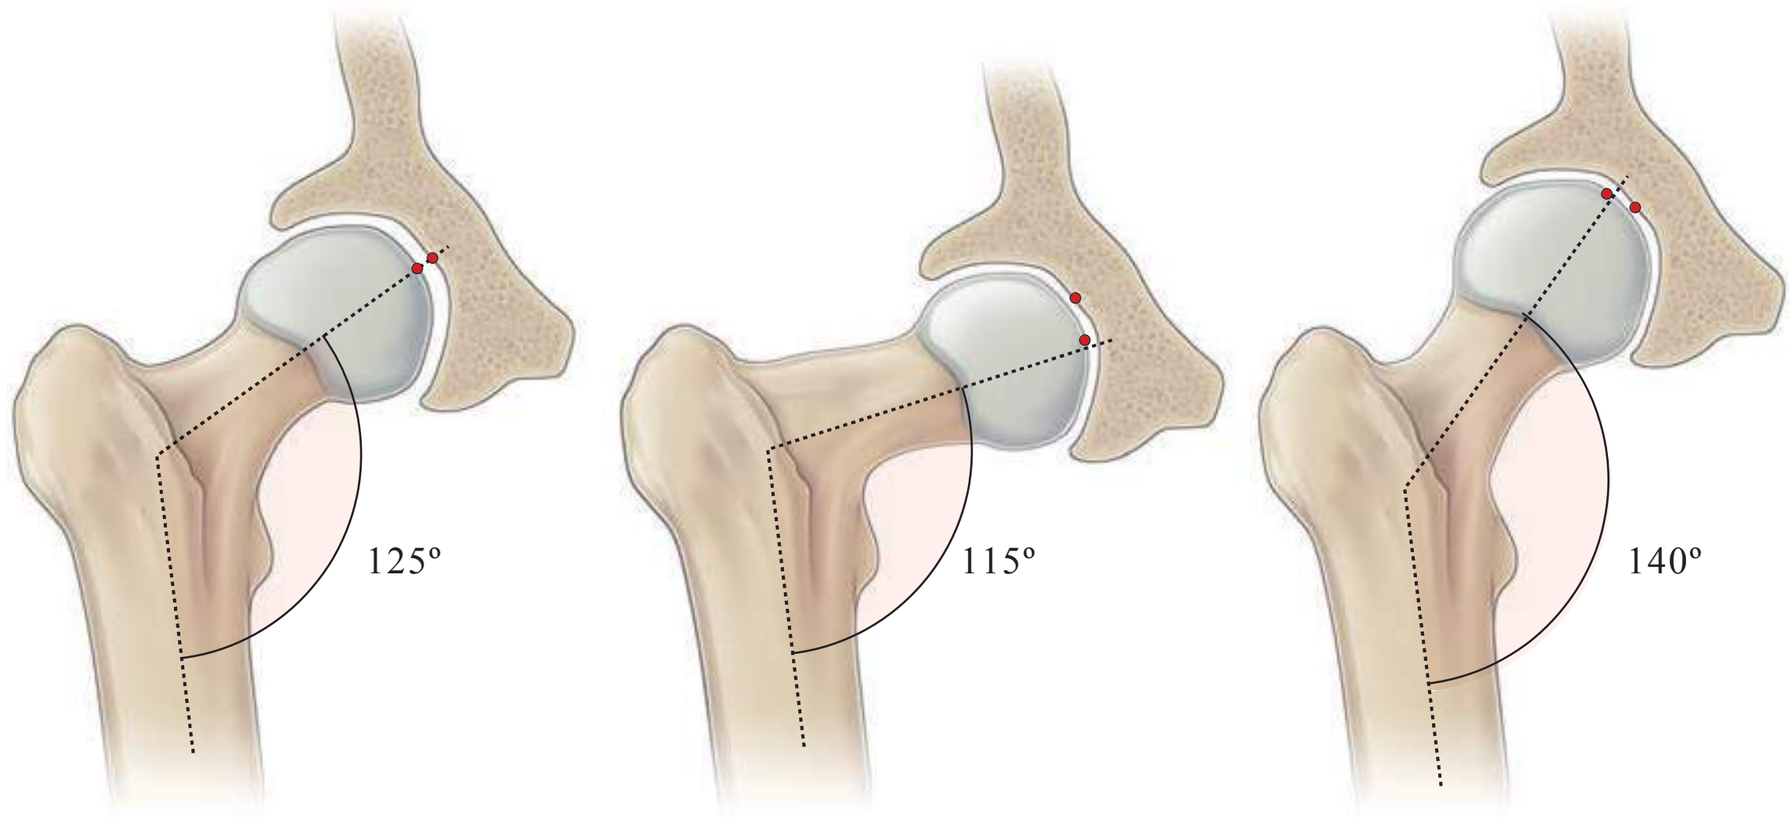

TABLE 19-5 Normal Ranges and End-Feels at the Hip

Motion	Range of Motion (Degrees)	End-Feel
Flexion	110–120	Tissue approximation or tissue stretch
Extension	10–15	Tissue stretch
Abduction	30–50	Tissue stretch
Adduction	25–30	Tissue approximation or tissue stretch
External rotation	40–60	Tissue stretch
Internal rotation	30–40	Tissue stretch

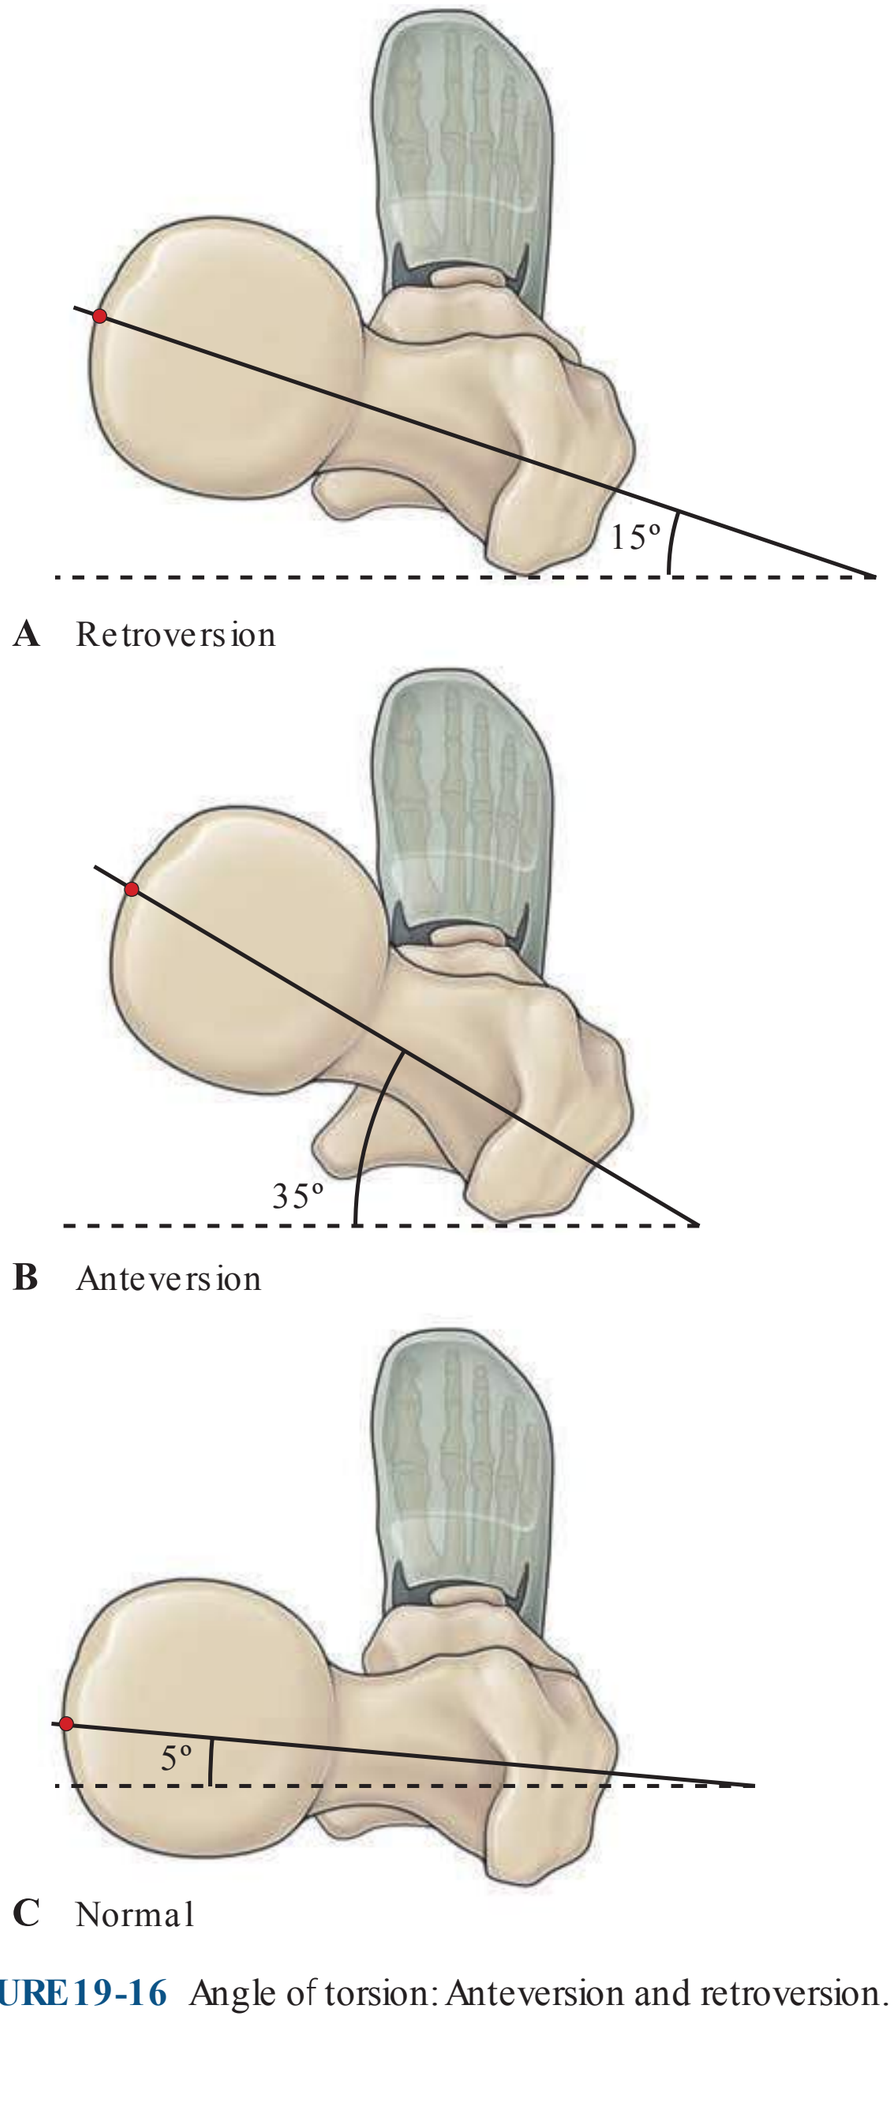

FIGURE 19-15 Angle of inclination and coxa vara/valga.

parallel to the femoral shaft.[124,125] T is lateral shift of the JRF reduces the available weight-bearing surface, resulting in an increase in stress applied across joint surfaces not specialized to sustain such loads.

- T e moment arm of the hip abductors is shortened, placing these muscles in a position of mechanical disadvantage.[125] T is causes the abductors to contract more vigorously to stabilize the pelvis, producing an increase in the JRF.[123]
- It increases the overall length of the lower extremity, impacting other components in the kinetic chain. For example, coxa valga decreases the normal physiologic angle at the knee, which places an increased mechanical stress on the medial aspect of the knee joint and more tensile stress on the lateral aspect of the joint.

If the angle of inclination is reduced, resulting in a more horizontal orientation of the femoral neck, it is referred to as coxa vara (Fig. 19-15). T is position increases the downward shear forces on the femoral head and the tensile stretching forces through the superior trabecular bone along the lateral portion of the neck.[8] In coxa vara, the joint compression forces are significantly reduced as the greater trochanter is displaced lateral and superior, which increases the effective angle of pull and the lever arm of the hip abductors.[126] While the reduced compressive forces generated across the joint surfaces serve to decrease the incidence of articular cartilage damage, the increase in shearing and torsional forces at the femoral head/neck junction significantly increases the incidence of damage to the epiphyseal plate.[8]

Femoral alignment in the transverse plane also influences the mechanics of the hip joint. T e torsion angle of the femur describes the relative rotation that exists between the shaft and the neck of the femur. An anterior orientation of the femoral neck to the transverse axis of the femoral condyles, is known as anteversion (Fig. 19-16), or a reverse orientation known as retroversion.[25,123,127] Excessive anteversion directs the femoral head toward the anterior aspect of

A Retroversion

B Anteversion

C Normal

FIGURE 19-16 Angle of torsion: Anteversion and retroversion.

the acetabulum when the femoral condyles are aligned in their normal orientation. Subjects with excessive anteversion usually have more hip internal rotation ROM than external rotation, resulting in an in-toeing gait pattern, and a gravitation toward the typical "frog-sitting" posture as a position of comfort. Some studies have supported the hypothesis that a persistent increase in femoral anteversion predisposes to osteoarthritis (OA) of the hip,[126,128–131] and knee,[132–134] although other studies have refuted this.[135–137] Nyland et al.[138] demonstrated that those with increased femoral anteversion had significantly decreased peak electromyographic (EMG) amplitude of the vastus medialis and gluteus medius which they postulated might lead to an increased risk of knee injury due to a decrease in frontal and transverse plane stability.[138] A cadaveric study by Sobczak et al.[139] found that anteversion decreased the moment arm of the medial musculature including the gracilis and the semitendinosus, whereas retroversion increases the moment arm of the same muscles. Excessive retroversion of the femur will result in the opposite limitation: increased femoral external rotation ROM and decreased femoral internal rotation ROM.[39] Retroversion is associated with an out-toeing gait pattern.

In contrast with most other joints in the body, the close-packed position for the hip is not the position of maximal articular congruency. The position of maximum articular congruence corresponds to a quadruped position: 90 degrees flexed, slightly abducted, and externally rotated. The most stable functional position of the hip is the normal standing position: hip extension, slight abduction, and slight internal rotation, which closely resembles the close-packed position of full extension, internal rotation, and abduction.[17,114,140] The commonly cited open-packed (resting) positions of the hip are between 10 and 30 degrees of flexion, 10–30 degrees of abduction, and 0–5 degrees of external rotation.

CLINICAL PEARL

Rapid flexion of the hip is generally associated with abdominal muscle activation that slightly precedes the activation of the hip flexor muscles.[50,141] This anticipatory activation may reflect a feedforward mechanism intended to stabilize the lumbopelvic region by increasing intra-abdominal pressure and increasing the tension in the thoracolumbar fascia.[50,142,143] Without sufficient stabilization of the pelvis by the abdominal muscles, a strong contraction of the hip flexor muscles may inadvertently tilt the pelvis anteriorly, thereby accentuated lumbar lordosis which may contribute to low back pain in some individuals.[50]

Bending forward at the waist requires a coordinated sequence of movements between the lumbar spine, pelvis, and hips referred to as the lumbopelvic rhythm. As the head and the upper trunk initiate flexion, the pelvis shifts posteriorly to maintain the center of gravity over the base of support. The trunk continues to forward bend, being eccentrically controlled by the extensor muscles of the spine, until approximately 45 degrees at which point the posterior ligaments of the spine become taut, and the facets of the zygapophyseal joints approximate. Once all of the vertebral segments are at the end of the range and stabilized by the posterior ligaments and facets, the pelvis begins to rotate forward (anterior pelvic tilt), being controlled eccentrically by the gluteus maximus and hamstring muscles. The pelvis continues to rotate forward until the full length of the muscles is reached. The return to the upright position begins with the hip extensor muscles rotating the pelvis posteriorly through reverse muscle action, then the back extensor muscles extending the spine from the lumbar region upward.

Functional Relationships of the Lower Kinetic Chain

Motions and positions at the hip during weight bearing can affect the alignment and function of the distal joints.

- Hip *flexion.* Hip flexion results in knee flexion and ankle dorsiflexion.
- Hip extension. Hip extension causes knee extension and ankle dorsiflexion.
- Hip rotation. Internal rotation of the hip results in the femur rotating medially on a fixed tibia at the knee, pronation of the foot and eversion of the calcaneus. The reverse occurs with external rotation of the hip.

Altered pelvic-femoral biomechanics resulting from deficits in hip muscle performance has been linked to numerous lower extremity conditions.[144–146] The hip extensor muscles, as a group, produce the greatest torque across the hip of any of the muscle groups.[147] This extensor torque is often used to rapidly accelerate the body upward and forward from a position of hip flexion, such as when pushing off into a sprint, arising from a deep squat, or climbing a very steep hill.[50] Furthermore, with the hip markedly flexed, many of the adductor muscles produce an extensor torque, thereby assisting the primary hip extensors.[148] In a standing position, weakness of the hip extensors causes the pelvis to fall forward.[149] With the trunk held relatively stationary, contraction of the hip extensors and abdominal muscles (with the exception of the transversus abdominis) functions as a force couple to posteriorly tilt the pelvis (Fig. 19-17).[50] Assuming the trunk remains upright during this action, the lumbar spine must flex slightly, thereby reducing its natural lordotic posture.[50] During the stance phase of activities, such as walking, running, or hopping, the hip extensors and abductors play a complex role in the control of the lower extremities, pelvis, and trunk.[150] This includes deceleration of hip internal rotation and adduction[151] and maintenance of the equilibrium of the pelvis and trunk over the stance limb.[150] As body weight is dropped onto the forward limb, the extensor muscles contract sharply to preserve upright stance by resisting the forward fall of the pelvis and the trunk.[149] The hip's flexed position, before attaining the passive stability provided by full extension in midstance, creates the demand (see Chapter 6). The most frequent demands placed on the hip abductors occur while walking during the single-limb support phase of walking.[50] The external (gravitational) abduction torque about the hip dramatically increases within the frontal plane as soon as the contralateral limb leaves the ground.[152] The hip abductors respond by generating an abduction torque about the stance hip that stabilizes the pelvis relative to the femur.[152] In addition, the hip abductors

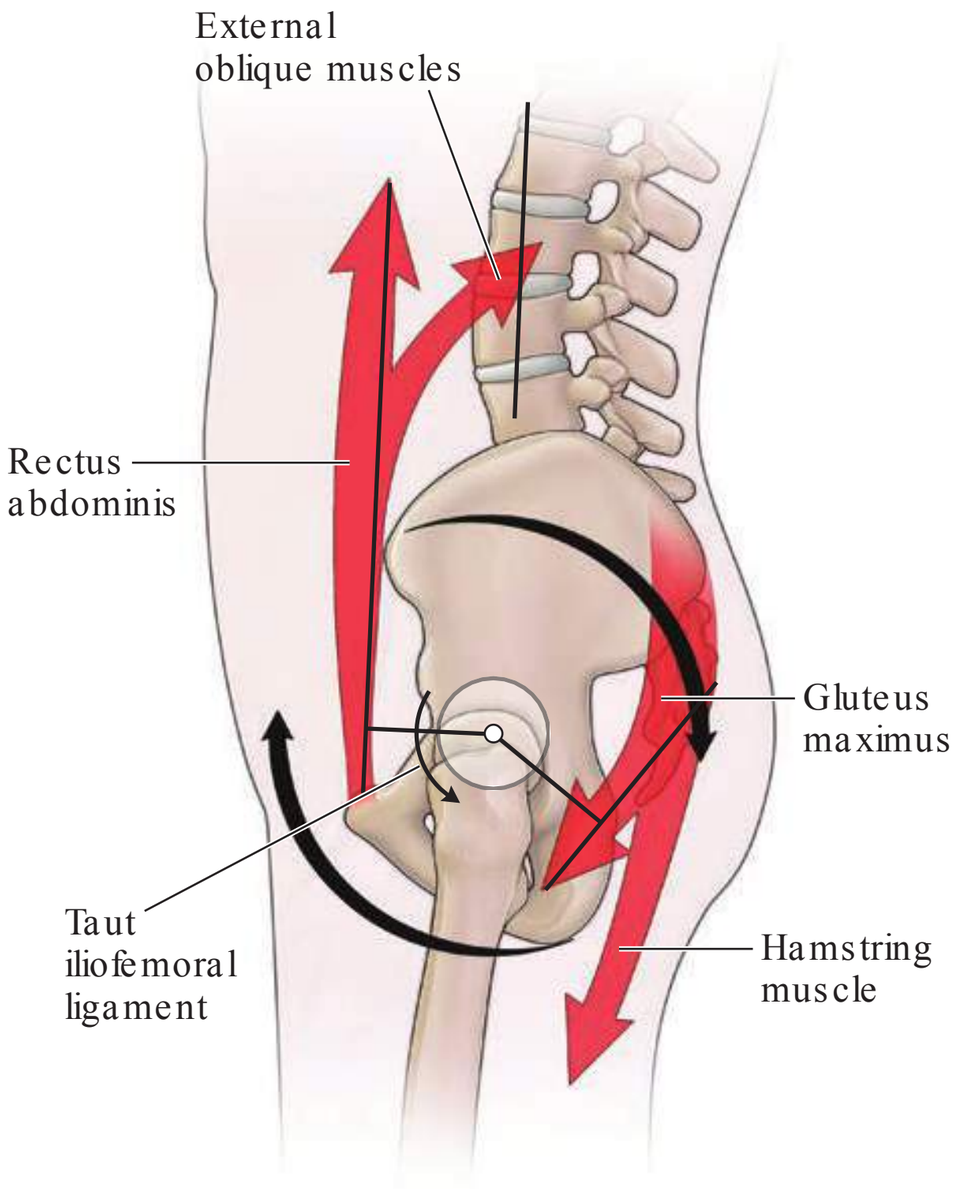

FIGURE 19-17 Force couples at the hip.

can hike the hip when working concentrically, and can lower the pelvis when working eccentrically.

CLINICAL PEARL

Increasing running step rate for a given running speed, which conversely reduces step length, has been advocated as a rehabilitation strategy to reduce hip joint loads for those with running-related injuries,[153] thereby promoting recovery and reducing reinjury risk[154]:

- Increasing the running step rate heightens hamstring and gluteus maximus muscle loading in late swing.
- After foot strike, increased step rate results in a more erect limb posture,[153] which lessens the hip muscle forces and powers needed in the load response phase of stance. This decrease loading is particularly evident in the gluteal muscles and piriformis which are muscles often implicated in running injuries.[155,156]

The biomechanical demands of the hip muscles during running have been principally inferred from analysis of the relative timing and coordination of motion between joints and segments, joint moments and powers.[154] Adaptations in patterns of joint or segmental coordination have the potential to alter joint loading during the stance phase of dynamic activities, and, therefore, may also be associated with the development of lower limb pathologies.[150]

Determining muscle function during running is fraught with problems as many hip muscles have moment arms about more than one axis,[50] and the length of the moment arm typically changes as a function of joint position. For example, the ability of the gluteus maximus to externally rotate the hip decreases with increased hip flexion.[51]

CLINICAL PEARL

Bartlett et al.[157] analyzed the activity and functions of the human gluteal muscle during walking, running, sprinting, and climbing. The study demonstrated that gluteus maximus activity was greatest during sprinting. Running and climbing produced similar levels of intensity to each other, both of which were greater than that of walking. Intriguingly, only the inferior portion of the gluteus maximus muscle had a significant change in the altered trunk pitch angles associated with walking and running, which might suggest that the hip extensors play a limited role in controlling the trunk pitch demands while running. The conclusions from this study would tend to implicate that the large size of the gluteus maximus reflects its multifaceted role during explosive movements as opposed to specifically adapting for submaximal tasks such as endurance running.

The functional potential of the entire external rotator muscle group at the hip is most fully recognized while performing pelvic and trunk rotation activities while bearing weight on one limb. For example, with the right femur held relatively fixed, contraction of the external rotators would rotate the pelvis and the attached trunk to the left. This action of planting the limb and cutting to the opposite side is a natural way to abruptly change direction while running.[50] The gluteus maximus appears uniquely designed to perform this action as, with the right limb securely planted, a strong contraction of the gluteus maximus would, in theory, generate a very effective extension and external rotation torque about the right hip, helping to provide the necessary thrust to the combined-cutting and propulsion action.[50]

Thus, the abductors and external rotators not only provide stability to the hip joint but are also important in maintaining proper segmental alignment of the extremity during weight-bearing tasks.[158,159] An inability of the hip abductors and external rotators to produce adequate torque during weight-bearing activities can lead to pelvic drop, excessive hip adduction, excessive hip internal rotation, and an increase in the knee valgus angle.[159]

In sharp contrast to the external rotators, no muscle with any potential to internally rotate the hip lies even close to the horizontal plane in the anatomic position, making it difficult to assign any muscle as a primary internal rotator of the hip.[50,160] Since the overall orientation of the internal rotator muscles is positioned closer to the vertical and horizontal position, these muscles possess a far greater biomechanical potential to generate torque in the sagittal and frontal planes than in the horizontal plane.[50]

The adductors of the hip are found on the medial aspect of the joint. The primary function of this muscle group is to create an adduction torque bringing the lower extremity toward the midline.[161] This adduction torque can also bring the pubis symphysis region of the pelvis closer to the femur.[161] From the anatomic position, the adductors are also considered hip flexor muscles.

A number of studies have examined the relationship between diminished hip muscle performance and kinematics in individuals with musculoskeletal dysfunction.[150] For example, females with patellofemoral pain syndrome have a lower maximum hip abductor and extensor torque and greater peak knee external rotation and hip adduction during the stance phase of running compared to healthy controls.[105,162] Similarly, hip OA is associated with lower hip abductor strength, as well as greater pelvic drop and hip internal rotation, during the stance phase of walking.[163,164] In addition, in the frontal plane, individuals with weak hip abductors often demonstrate greater trunk motion toward the stance limb, resulting in altered moments at the hip and knee.[150]

Cl INICAl PEARl

According to Cyriax,[165,166] the capsular pattern of the hip is a marked limitation of flexion, abduction, and internal rotation. Kaltenborn[140] considers the capsular pattern of the hip to be extension more limited than flexion, internal rotation more limited than external rotation, and abduction more limited than adduction. Klassbo et al.[167] performed a theory-testing, observational, cross-sectional, and descriptive study involving 168 patients (mean age 61.7 years, range 36–90 years), of whom 50 had no hip OA, 77 had unilateral hip OA, and 41 had bilateral OA, based on radiological reports. The purpose of the study was to arrange and describe passive range of motion (PROM) patterns and to count the number of hips presenting with Cyriax's or Kaltenborn's capsular patterns. One examiner tested PROM bilaterally, using a goniometer and a standardized protocol. PROM limitations were calculated by comparing norms from the symptom-free hips (n = 100) in the study, from Kaltenborn, and, in patients with unilateral hip OA (n = 77), from the non-OA hip. The limitations were arranged by size in PROM patterns. The patterns and the numbers of hips with patterns corresponding to Cyriax's and Kaltenborn's capsular patterns were counted. Between 68 and 138 PROM patterns were identified by the use of different PROM norms for defining limitations. The results of this study showed that few OA hips showed Cyriax's capsular pattern and none demonstrated Kaltenborn's capsular pattern. In addition, it was concluded that it is impossible to anticipate radiological evidence of hip OA from the multitude of PROM patterns. A more useful determination can be made by assessing hip ROM in all planes and, if three planes of motion or more are restricted, OA is likely present.[168]

EXAMINATION

Although injuries of the hip are not as common as injuries to the knee or shoulder, they can create diagnostic and therapeutic challenges, and diseases of the hip can be very disabling. A hip joint injury is often associated with the complex interaction between structural and biomechanical factors. T e diagnosis of a hip injury can be challenging due to the similar clinical presentation of intra-articular and extra-articular pathology. T e common pathologies and the interventions for the hip joint are detailed after the examination. Table 19-7 outlines the clinical findings, differential diagnosis, and intervention strategies for some hip conditions, and Table 19-8 describes some of the physical findings for some of the more common causes of hip and thigh pain. An understanding of the pathology and the clinical findings is obviously necessary. T e goal of the clinical examination is to identify the primary source of hip pain and symptoms. Identifying the primary source of the pain/symptoms is essential if one hopes to provide long-lasting relief. Acute presentations usually have a clear and identifiable cause, whereas in chronic conditions the true etiology may not be as obvious. For example, a protracted hip joint disorder can result in compensations that can develop secondary dysfunctions, which in turn may lead to symptoms such as trochanteric bursitis or chronic gluteal discomfort. As mention of the various pathologies occurs with reference to the examination and vice versa, the reader is encouraged to switch between the two.

Cl INICAl PEARl

One study demonstrated that the clinical assessment of the hip can be 98% reliable at detecting the presence of the hip joint problem; although the examination may be poor at defining the exact nature of the intra-articular disorder.[169] However, as many structures can refer pain to the hip and groin region, the symptoms are often both confusing to the patient and challenging to the clinician. For example, a hip joint disease may coexist with lumbar spine disease.

History

T e importance of history taking cannot be overemphasized as the potential causes of hip pain are numerous (Table 19-9). T e history should determine the onset of the symptoms, the mechanism of injury if any, and the patient's chief complaint. A medical screening questionnaire for the pelvis, hip, and thigh is provided in Table 19-10. It is important for the clinician to determine the following:

Patient Age

T e patient's age may help in the diagnosis. OA of the hip is diagnosed most often in patients over 60 years of age, although it can occur earlier.

Pain l ocation

T e location of the pain can provide the clinician with some useful information. Groin pain is a common orthopaedic problem, and the differential diagnosis of groin pain can be extremely challenging given the multitude of structures and conditions that can be potential sources of groin pain. T ese include referred symptoms due to nerve compression (e.g., obturator or lateral femoral cutaneous nerve of the thigh), or referred symptoms from a sports hernia, the abdominal viscera, and the lumbar spine. For example, lateral and posterior hip (buttock) and thigh pain may be referred from the lumbar spine. In addition, hip joint pathologies (e.g., OA,

TABLE 19-7 History, Clinical Findings, Differential Diagnosis, and Intervention Strategies of Some Hip Conditions

Diagnosis	Medical Findings	Intervention	Whether to Refer
Legg–Calvé–Perthes disease	Insidious onset (1–3 months) of limp with hip or knee pain	Limited hip abduction, flexion, and internal rotation	Juvenile arthritis and other inflammatory conditions of the hip
Slipped capital femoral epiphysis	Acute (<1 month) or chronic (up to 6 months) presentation; pain may be referred to knee or anterior thigh	Pain and limited internal rotation, leg more comfortable in external rotation; chronic presentation may have leg-length discrepancy	Muscle strain and avulsion fracture
Avulsion fracture	Sudden, violent muscle contraction; may hear or feel a "pop"	Pain on passive stretch and active contraction of involved muscle; pain on palpation of involved apophysis	Muscle strain and slipped capital femoral epiphysis
Hip pointer	Direct trauma to iliac crest	Tenderness over iliac crest; may have pain on ambulation and active abduction of hip	Contusion and fracture
Contusion	Direct trauma to soft tissue	Pain on palpation and motion and ecchymosis	Hip pointer, fracture, and myositis ossificans
Myositis ossificans	Contusion with hematoma approximately 2–4 weeks earlier	Pain on palpation; firm mass may be palpable	Contusion, soft tissue tumors, and callus formation from prior fracture
Femoral neck stress fracture	Persistent groin discomfort increasing with activity, history of endurance exercise, and female athlete triad (eating disorder, amenorrhea, and osteoporosis)	ROM may be painful, pain on palpation of greater trochanter	Trochanteric bursitis, osteoid osteoma, and muscle strain
Osteoid osteoma	Vague hip pain present at night and increased with activities	Restricted motion and quadriceps atrophy	Femoral neck stress fracture and trochanteric bursitis
Iliotibial band syndrome	Lateral hip, thigh, or knee pain; snapping as iliotibial band passes over the greater trochanter	Positive Ober test	Trochanteric bursitis
Trochanteric bursitis	Pain over greater trochanter on palpation; pain during transitions from standing to lying down to standing	Pain on palpation of greater trochanter	Iliotibial band syndrome and femoral neck stress fracture
Aseptic necrosis of the femoral head	Dull ache or throbbing pain in groin, lateral hip, or buttock; history of prolonged steroid use; prior fracture; and slipped femoral capital epiphysis	Pain on ambulation, abduction, and internal and external rotation	Early degenerative joint disease
Piriformis syndrome	Dull posterior pain, may radiate down the leg mimicking radicular symptoms, and history of track competition or prolonged sitting	Pain on active external rotation, passive internal rotation of hip, and palpation of sciatic notch	Nerve root compression and stress fractures
Iliopsoas bursitis	Pain and snapping in medial groin or thigh	Reproduce symptoms with active and passive flexion/extension of hip	Avulsion fracture
Meralgia paresthetica	Pain or paresthesia of anterior or lateral groin and thigh	Abnormal distribution of lateral cutaneous nerve of the thigh on sensory examination	Other causes of peripheral neuropathy
Degenerative arthritis	Progressive pain and stiffness	Reduction in internal rotation early, in all motion later, and pain on ambulation	Inflammatory arthritis

TABLE 19-7 History, Clinical Findings, Differential Diagnosis, and Intervention Strategies of Some Hip Conditions (Continued)

Diagnosis	Medical Findings	Intervention	Whether to Refer
Legg–Calvé–Perthes disease	Normal CBC and ESR; plain films positive (early with changes in the epiphysis, later with flattening of the femoral head)	Maintain ROM, and follow position of femoral head in relation to acetabulum radiographically	Orthopaedic surgery if unresolved
Slipped capital femoral epiphysis	Plain films show widening of epiphysis early, later slippage of femur under epiphysis	Non–weight-bearing, and surgical pinning	Urgent orthopaedic surgery with acute, large slips
Avulsion fracture	Plain films; if these are negative, CT or MRI	Rehabilitation program of progressive increase in ROM and strengthening	Orthopaedic surgery of >2-cm displacement
Hip pointer	Plain films if suspect fracture	Rest, ice, NSAIDs, local steroid, and anesthetic injection for severe pain; gradual return to activities with protection of site	PT appropriate
Contusion	Plain films negative	Rest, ice, compression, static stretch, and NSAIDs	PT appropriate
Myositis ossificans	Radiograph or ultrasound examination reveals typical calcified, intramuscular hematoma	Ice, stretching of involved structure, NSAIDs; surgical resection after 1 year if conservative treatment fails	PT appropriate; orthopaedic surgery if resection needed
Femoral neck stress fracture	Plain films may show cortical defects in femoral neck (superior or inferior surface); bone scan, MRI, and CT may also be used if plain films are negative and diagnosis is suspected	Inferior surface fracture; no weight bearing until evidence of healing (usually 2–4 weeks) with gradual return to activities; superior surface fracture: ORIF	Orthopaedic surgery for ORIF
Osteoid osteoma	Plain films; if these are negative and symptoms persist, MRI or CT	Surgical removal if unresponsive to medical therapy with aspirin or NSAIDs	Orthopaedic surgery
Iliotibial band syndrome		Modification of activity, footwear; stretching program, ice massage, and NSAIDs	PT appropriate
Trochanteric bursitis	Plain films, bone scan, and MRI negative for bony involvement	Ice, NSAIDs, stretching of iliotibial band, protection from direct trauma, and steroid injection	PT appropriate
Avascular necrosis of the femoral head	Plain films and MRI	Protected weight bearing, exercises to maximize soft tissue function (strength and support), and total hip replacement	PT trial appropriate; orthopaedic surgery
Piriformis syndrome	EMG studies may be helpful; MRI of lumbar spine, if nerve root compression is suspected	Stretching, NSAIDs, relative rest, and correction of offending activity	PT appropriate
Iliopsoas bursitis	Plain films are negative	Iliopsoas stretching and steroid injection	PT appropriate
Meralgia paresthetica	Nerve conduction velocity testing may be helpful	Avoid external compression of nerve (clothing, equipment, and pannus)	—
Degenerative arthritis	Plain films help with diagnosis and prognosis	Maximizing support and strength of soft tissues, ice, NSAIDs, modification of activities, cane, and total hip replacement	PT trial appropriate; orthopaedic surgery

CBC, complete blood count; CT, computed tomography; EMG, electromyelography; ESR, erythrocyte sedimentation rate; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs; ORIF, open reduction with internal fixation; PT, physical therapy; ROM, range of motion.

TABLE 19-8 Physical Findings in Some of the More Common Causes of Hip and Thigh Pain

Condition	Description of Findings
Osteoarthritis of the hip	Tenderness over the anterior hip capsule Pain reproduced by passive rotation of the hip Restricted range of motion (rotation is usually first affected) Pain reproduced by Stinchfield's test (see "Special Tests") Abductor limp (more severe cases) Functional leg-length discrepancy (if abduction contracture has developed)
Meralgia paresthetica	Altered sensation over the anterolateral thigh Symptoms reproduced by pressure or percussion just medial to the anterior–superior iliac spine
Piriformis tendinitis	Tenderness to deep palpation near the hook of the greater trochanter. Pain reproduced by piriformis stretch
Gluteus medius tendinitis	Tenderness just proximal to the greater trochanter Pain reproduced by resisted abduction of the hip
Trochanteric bursitis	Tenderness over the lateral aspect of the greater trochanter Popping or crepitation felt with flexion–extension of the hip (occasionally) Tight iliotibial tract revealed by Ober test (variable)—see "Special Tests"
Quadriceps strain or contusion	Tenderness and swelling of the involved area of the quadriceps Weakness of quadriceps contraction Restriction of knee flexion, especially when the hip is extended Palpable divot in the quadriceps (more severe strains) Warmth and firmness in quadriceps (impending myositis ossificans)
Hamstring strain	Localized tenderness and swelling at the site of injury Ecchymosis (frequently) Restricted knee extension and straight-leg raising Palpable divot in the injured hamstring (more severe injuries) Abnormal tripod sign

labral tear, impingement, osteonecrosis), osteitis pubis, hip flexor and adductor strain, rectus abdominis strain, greater trochanter bursitis, and fractures of the femoral neck and pubic ramus are all capable of producing groin pain. One of the more common causes of groin pain in the older patient is OA of the hip. However, OA of the hip may also cause pain behind the greater trochanter, anterior thigh, and knee because

TABLE 19-10 Medical Screening Questionnaire for the Pelvis, Hip, and Thigh Region

	Yes	No
Have you recently had a trauma, such as a fall?		
Have you ever had a medical practitioner tell you that you have osteoporosis?		
Have you ever had a medical practitioner tell you that you have a problem with the blood circulation in your hips?		
Are you currently taking steroids or have you been on prolonged steroid therapy?		
Do you have a history of cancer or has a member of your immediate family (i.e., parents or siblings) ever been diagnosed with cancer?		
Have you recently lost weight even though you have not been attempting to eat less or exercise more?		
Have you had a recent change in your bowel functioning such as black stools or blood in your rectum?		
Have you had diarrhea or constipation that has lasted for more than a few days?		
Do you have groin, hip, or thigh aching pain that increases with physical activity, such as walking or running?		

Data from DuVall RE, Godges J. Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1. La Crosse, WI: Orthopaedic Section, APTA, Inc; 2003:1–44.

of the various nerves that cross the hip.[170] Additional questioning can provide some guidance. For example, complaints of hip or groin pain, morning stiffness, stiffness after sitting, and hip pain with weight bearing are suggestive of joint involvement, such as OA. However, it is important to identify patients with symptomatic OA correctly and to exclude conditions that may be mistaken for or coexist with OA.[171,172] Periarticular pain that is not reproduced by passive motion and direct joint palpation suggests an alternate etiology such as bursitis, tendinopathy, or periostitis.

Distribution of Symptoms

The distribution of painful joints is helpful to distinguish OA from other types of arthritis because metacarpophalangeal (MCP), wrist, elbow, ankle, and shoulder arthritis are unlikely locations for OA except after trauma.

Symptom Fluctuations

The time of day that appears to change the pain for better or worse can provide some clues. Hip joint pathology is usually associated with stiffness of the hip in the morning on arising. Such pathologies include

- OA of the hip joint;
- rheumatoid arthritis of the hip joint; prolonged morning stiffness (greater than 1 hour) should raise suspicion for this type of inflammatory arthritis;
- osteonecrosis of the femoral head.

Motion Restrictions

The first two motions that are diminished in hip OA are usually hip internal rotation and hip flexion, although as previously discussed, this can vary significantly.[173] A significant decrease or loss of motor function will always necessitate imaging studies to rule out an avulsion fracture, and/or nerve injury (see Chapter 7).

Mechanism of Injury

Patients who present with acute macrotrauma (e.g., falls and motor vehicle accidents) and who report having difficulty moving the hip or bearing weight require radiographs to rule out a fracture and/or dislocation. Falls on the outside of the hip are a common cause of trochanteric bursitis or contusion of the iliac crest (hip pointer). Such an injury may also involve the abdominal and/or gluteal muscles at their attachment sites. When the abdominal muscles are involved, patients may complain of pain with deep inspiration or have difficulty with trunk rotation.[174] Macrotraumatic forces applied along the femur, such as those that occur with dashboard injuries and falls on the knee, can result in damage to the articular cartilage, an acetabular labrum tear, a pelvic fracture, or a hip subluxation. An immediate loss of movement following direct trauma to this area usually indicates the presence of a hip or pelvic fracture or a dislocation. Posterior contusions to the gluteus maximus and sciatic nerve can occur from a direct blow to the buttock.[174] In such cases, the patient may complain of pain in the buttocks and of pain, numbness, and/or tingling radiating down the course of the sciatic nerve. Both the athlete and nutritionally compromised individual are at risk of pelvic rami or femoral neck stress fractures. Anterior blows to the thigh can produce quadriceps contusions. These contusions can also result in myositis ossificans. The femoral nerve is fairly well protected and not usually injured. Acute muscle strains in the hip and thigh regions, especially of the hamstrings, are usually seen in the athletic individual, most often occurring following a short sprint, jump kick, fall, or collision.[174] Quadriceps strains, usually involving the rectus femoris, occur in sprinters and kickers. The most frequently strained adductors are the longus and magnus while hamstring injuries usually involve the biceps femoris.[175–177]

CLINICAL PEARL

Ironically, in general, a history of a significant traumatic event is a good prognostic indicator of a potentially correctable problem,[178] whereas arthritis is an indicator of poor long-term outcomes.[179]

If the patient is unable to recall a specific mechanism, the clinician should suspect a systemic (see "Systems Review" and Chapter 5) or biomechanical cause. The hip is a region that is prone to overuse injuries. Walking or running can aggravate trochanteric bursitis, ITB friction syndrome (ITBFS), hamstring

TABLE 19-11 Subjective Reports and Possible Diagnoses

Subjective Report	Possible Diagnosis
Pain that is usually worse with sitting on hard surfaces, cycling, and prolonged standing	Ischiogluteal bursitis
Pain with squatting, lying on the involved side, climbing stairs, and walking	Subtrochanteric bursitis
A clicking or popping sound that occurs during running and dancing activities	Snapping hip syndrome
Pain with prolonged sitting, trunk flexion, and coughing/sneezing	Lumbar disk herniation
Pain with activities that involve lumbar extension	Spinal stenosis, spondylolisthesis, or facet syndrome
Pain at night unrelated to movement	Malignancy
Pain with walking, which is relieved with cessation of the activity	Vascular claudication
Pain that appears to be affected by the weather	Arthritic condition or fibromyalgia syndrome
Progressive loss of or change in motor, bowel, bladder, or sexual function	Myelopathy, conus medullaris syndrome, or cauda equinus syndrome

Data from Feinberg JH. Hip pain: Differential diagnosis. J Back Musculoskeletal Rehabil 1994; 4:154–173.

and adductor strains, or a femoral neck stress fracture. Pain with bursitis is frequently referred along the course of the muscle it underlies and nearby neurologic structures.[174] Obturator internus bursitis can refer pain to the back and buttock or along the course of the sciatic nerve. Subtrochanteric bursitis commonly refers pain to the LB, lateral thigh, knee, and hip.[174] Iliopectineal bursitis can refer pain along the course of the femoral nerve and anterior thigh. Ischiogluteal bursitis can refer pain along the posterior femoral cutaneous or sciatic nerve.[174]

The Behavior of the Symptoms

Reports of twinges of pain with weight-bearing activities may indicate the presence of a loose body within the joint. Noises in and around the joint can result from many causes so are not particularly diagnostic. One of the more common causes for clicking is a "snapping" hip, especially if the snapping consistently occurs at approximately 45 degrees of hip flexion. This is type of snapping hip is thought to be because of the iliopsoas tendon riding over the greater trochanter or anterior acetabulum. The other types of snapping hip are described in the "Intervention Strategies". If the pain is associated with the clicking, it requires further investigation.

CLINICAL PEARL

Mechanical symptoms such as locking, catching, popping, or ones that are sharp stabbing in nature are better prognostic indicators of a correctable problem.[180]

Aggravating or Relieving Factors

Information must be gathered with regard to the activities or positions that appear to aggravate or lessen the symptoms. For example, prolonged sitting on a hard surface may aggravate the ischial bursa, whereas buttock pain with prolonged sitting on a soft surface is more likely to be the result of a lumbar disk lesion. Rising from a seated position can be especially painful, and the patient may experience an accompanying catching or sharp stabbing sensation. Entering and exiting an automobile is often difficult because the hip is in a flexed position along with twisting maneuvers. As the hip is a weight-bearing joint and weight bearing tends to aggravate articular pathologies, it is very important to gather information concerning the role of weight bearing in painful activities, particularly whether the patient has pain at rest as well as during weight bearing, or whether specific weight-bearing activities (e.g., stair climbing and walking) are the cause of increased pain.

Questions about the work environment, athletic participation, and other daily and recreational activities help the clinician identify risk factors for the cumulative trauma that might not be apparent to the patient.[174] Activities and positions that aggravate and alleviate symptoms should be identified (Table 19-11).

The hip and pelvic areas are also common sites for pain referral (Table 19-12). The differential diagnosis of hip pain is described in Chapter 5. To help determine the symptom distribution, a pain diagram should be completed by the patient (see Chapter 4). Following its completion, the patient should be encouraged to describe the type of symptoms experienced for each of the areas highlighted on the diagram, as well as the motions or positions that increase or decrease the symptoms. Since the lumbar spine can refer symptoms to the hip region, the clinician should always rule out the involvement of the lumbar spine before a hip problem is suspected. The most common source of referred pain from the LB includes both neurogenic (nerve root compression) and spondylogenic (facet or sacroiliac joint) causes. Brown et al.[181] identified a limp, groin pain, and limited hip internal rotation as signs that significantly predicted a hip problem rather than a lumbar problem.

Finally, the clinician should determine the impact that the patients' condition has on their activities of daily living (ADL).

Systems Review

Referred pain to the hip is common and should be considered in the absence of acute trauma or when symptoms do not clearly originate from the hip. Pain may be referred to the

TABLE 19-12 Differential Diagnosis for Pain in the Hip or Buttock Area

Pain Distribution	Potential Cause
Groin area	Stress fractures of the pelvis and femur
	Crystal-induced synovitis (gout)
	An inguinal/femoral hernia
	Muscle calcification
	Hip adductor strain
	Iliopectineal bursitis
	Iliopsoas strain or avulsion fracture of the lesser Trochanter
	Arthritis of the hip
	Hip arthrosis
	Femoral neck fracture
	Osteonecrosis of the femoral head
	Pubic symphysis dysfunction: ▯ Osteitis pubis ▯ Osteomyelitis pubis ▯ Pyogenic arthritis ▯ Pubic fracture ▯ Pubic osteolysis ▯ Postpartum symphyseal pain
	Sacroiliac joint lesion
	Tumor
	Ureteral stone
	Hernia
	Inflammatory synovitis (e.g., rheumatoid arthritis, ankylosing spondylitis, and systemic lupus erythematosus)
	Subluxation
	Dislocation
Groin and inner thigh region	Transient synovitis
	Infection
	Loosened prosthesis
	Inflamed lymph nodes
	Lower abdominal muscle strain
	Referred pain from viscera or spinal nerve
	Sprain of pubic symphysis
Pubic area	Osteitis pubis
Lateral buttock area	Abdominal muscle strain
Anterior and lateral thigh	Bladder infection
Medial thigh	Trochanteric bursitis
Anterior-superior iliac spine	Tendinitis of abductors or external rotators
Iliac crest	Apophysitis of greater trochanter
	Referred pain from mid or lower lumbar spine
	Thrombosis of gluteal arteries
	Strain of quadriceps
	Meralgia paresthetica
	Entrapment of femoral nerve
	Thrombosis of femoral artery or great saphenous vein
	Stress fracture of femur
	Referred pain from hip or mid-lumbar spine
	Strain of adductor muscles
	Entrapment of obturator nerve
	Referred pain from hip or knee
	Apophysitis or sartorius or rectus femoris
	Strain of gluteal, oblique abdominals, tensor fascia latae, and quadratus lumborum
	Entrapment of iliohypogastric nerve
	Referred pain from upper lumbar spine

Data from Beattie P. The hip. In: Malone TR, McPoil T, Nitz A, eds. Orthopaedic and Sports Physical Therapy, 3rd ed. St. Louis, MO: CV Mosby; 1996:506.

hip region from a number of neuromusculoskeletal sources (see Chapter 5). In addition to those already mentioned, these can include

- pubic symphysis dysfunction;
- sacroiliac joint dysfunction;
- lumbar and low thoracic disk-degenerative disease;
- lumbar stenosis with neurogenic claudication;
- peripheral nerve entrapments (the lateral cutaneous nerve of the thigh);
- myofascial pain syndrome;
- spondyloarthropathy.

Complaints associated with referred pain include

- thigh pain, knee pain, and leg pain with or without hip pain, which may be indicative of lumbar radiculopathy;
- pain that is decreased with walking upstairs, which may indicate the presence of lumbar spine stenosis.

Referred pain is often related to posture and positioning. Other conditions that can refer symptoms to the pelvis, hip, and thigh region in an adult include cancer, pathological fractures of the femoral neck, and osteonecrosis of the femoral head (avascular necrosis) (Table 19-13). In the child, pain and loss of range at the hip joint should always alert the clinician to the possibility of transient synovitis, Legg–Calvé–Perthes disease, or a slipped femoral capital epiphysis.

T e Cyriax lower quarter scanning examination can be used to screen for the presence of upper or lower motor neuron lesions or the referral of symptoms from the spine (see Chapter 4). Key muscle testing is used to test for neurologic weakness (see also "Active, Passive, and Resistive Tests").

Trigger points in patients with myofascial pain syndrome can cause both localized and referred symptoms that often closely resemble the referral patterns of a radiculopathy.[174]

Evidence of intense inflammation on examination suggests infectious or microcrystalline processes such as gout or pseudogout. Weight loss, fatigue, fever, and loss of appetite should

TABLE 19-13 Red Flags for the Pelvis, Hip, and Thigh Region

Condition	Red Flags
Colon cancer	Age over 50 years Bowel disturbances (e.g., rectal bleeding or black stools) Unexplained weight loss History of colon cancer in immediate family Pain unchanged by positions or movement
Pathological fractures of the femoral neck	Older women (>70 years) with hip, groin, or thigh pain History of a fall from a standing position Severe, constant pain that is worse with movement A shortened and externally rotated lower extremity
Osteonecrosis of the femoral head (avascular necrosis)	History of long-term corticosteroid use (e.g., in patients with rheumatoid arthritis, systemic lupus erythematosus, or asthma) History of avascular necrosis of the contralateral hip Trauma

Data from DuVall RE, Godges J. Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1. La Crosse, WI: Orthopaedic Section, APTA, Inc.; 2003:1–44.

be sought out because these are clues to systemic illness such as polymyalgia rheumatica, rheumatoid arthritis, lupus, or sepsis.

Examples of viscerogenic referred pain (see Chapter 5) include renal calculi (pain radiates into the groin), ovarian cysts or an ectopic pregnancy (pain radiating into the back or hip, or along the course of the sciatic nerve when there is direct compression), and diverticulitis or inguinal hernias (pain radiating across the abdomen or back or into the groin).[174]

Referred pain to the buttock can be a form of vasculogenic pain (see Chapter 5) and occurs in patients who have vascular claudication from stenosis of the distal aorta or common iliac vessels.[174]

If, following the history and systems review, the clinician is concerned with any signs or symptoms of a visceral, vascular, or systemic disorder, the patient should be referred to the appropriate healthcare professional.

Tests and Measures

The hip can be one of the most challenging joints to examine. Unlike the knee or ankle, the joint is not readily palpable, and one must rely on a number of provocative tests and maneuvers to identify intra-articular or bony abnormalities.[174] Even many of the soft tissue structures are difficult to manually identify but can usually be isolated with proper clinical skills.

Observation

The most important aspect of inspection is stance (standing and sitting) and gait. The patient is observed from the front, back, and sides for general alignment of the hip, pelvis, spine, and lower extremities (see Chapter 6). While standing, a slightly flexed position of the involved hip and the ipsilateral knee is a common finding associated with hip pathology. In the seated position, slouching or listing to the uninvolved side avoids extremes of flexion. An antalgic gait may or may not be present depending on the severity of the symptoms.

The clinician observes the hip region, noting any scars, anatomical abnormalities, muscle atrophy, bruising, swelling, etc.

- A localized soft tissue mass or swelling may indicate bursitis, an acute muscle contusion or tear with a hematoma, an avulsion fracture, myositis ossificans, a tumor, infection, or deep vein thrombosis (DVT).[174]
- Asymmetric muscle atrophy is usually an indication of a radiculopathy or peripheral neuropathy, but can also be seen with a tendon rupture.
- An ecchymosis may be seen with contusions, muscle tear, fracture, and patients with a bleeding diathesis.[174]
- Vesicular skin lesions that have a dermatomal distribution may be found in cases of herpes zoster. Café au lait spots greater than 3 cm and greater than six in number are characteristic of neurofibromatosis.
- Skin rashes may be because of secondary psoariatic arthritis, drug reactions, or one of the collagen vascular diseases.
- Obvious joint or bony deformity should raise suspicion of a fracture or dislocation.

Both pain and musculotendinous dysfunction can produce movement and postural dysfunctions at the hip joint.[182] According to Kendall,[183] the ideal alignment of the pelvis is indicated when the ASIS is on the same vertical plane as the symphysis pubis. The degree of pelvic tilt, which is measured as the angle between the horizontal plane and a line connecting the ASIS with the PSIS, varies from 5–12 degrees in normal individuals.[184] Both a low ASIS in women and a structurally flat back in men can cause structural variations in pelvic alignment, which can be misinterpreted as acquired postural impairments.[182] According to Sahrmann, all of the following are necessary to indicate the presence of a postural impairment of the hip[182]:

- An increase or decrease in the depth of the normal lumbar curve.

- A marked deviation from the horizontal line between the ASIS and PSIS.
- An increase or decrease in the hip joint angle in the anterior–posterior plane, with neutral knee joint alignment.

The following should be examined[182]:

- The glutei should be symmetrical and well rounded, not hanging loosely. The pelvic crossed syndrome (see Chapter 6) demonstrates weakness and inhibition of the glutei muscles.[185] This syndrome can be easily identified by having the patient perform a partial bridge with single-leg support. This maneuver results in cramping of the hamstrings within a few seconds if the pelvic crossed syndrome is present. Atrophy of one buttock cheek compared with the other side may also indicate a superior or inferior gluteal nerve palsy. A balling-up of the gluteal muscle typically indicates a grade III tear of the gluteal muscles. Buttock swelling occurs with the "sign of the buttock."[165]

CLINICAL PEARL

The pelvic crossed syndrome is exhibited by adaptively shortened hip flexors and hamstrings and inhibited glutei muscles and lumbar erector spinae.

- Swelling over the greater trochanter could indicate trochanteric bursitis.
- Adaptive shortening of the short hip adductors is indicated by a distinct bulk in the muscles of the upper third of the thigh.[185]
- The bulk of the TFL should not be distinct. A visible groove passing down the lateral aspect of the thigh may indicate that the TFL is overused, and both it and the ITB are adaptively shortened.[185]

The architecture and position of the hip joint and lower extremity is observed.

- In acute arthritis and gross osteoarthrosis, the hip joint is usually held in flexion and external rotation. This may be compensated for by an anterior tilt of the pelvis, together with an increased lordosis of the lumbar spine.
- Excessive external rotation of the leg, accompanied with toeing-out, occurs in extreme femoral neck retroversion, or a slipped femoral epiphysis.
- Increased hip flexion in standing can result from weakness or excessive lengthening of the external oblique or rectus abdominis muscles. Increased hip flexion may also be because of a hip flexion contracture.
- Increased hip extension in relaxed standing is indicative of a swayback posture. This is characterized by a posterior pelvic tilt and hyperextension of the knees and results in a stretch on the anterior joint capsule of the hip and stress on the iliopsoas muscle and tendon.
- Lateral asymmetry in relaxed standing is characterized by a high iliac crest on one side. The difference in height between the two crests must be greater than one-half inch to have clinical significance. Lateral asymmetry may indicate a positive Trendelenburg sign (see "Special Tests"), which indicates hip abductor weakness.

Observation of the lower components of the kinetic chain includes

- the degree of genu varum/valgus (see Chapter 20);
- the degree of tibial torsion (see Chapter 20);
- the amount of calcaneal inversion/eversion (see Chapter 21).

Gait. Analysis of both the stance and swing phases of gait is essential (see Chapter 6). Determinants of the stance phase of gait involve interaction between the pelvis and hip and distal limb joints (knee and ankle).[186,187] The clinician should note whether[114]

- the patient is using an assistive device. If they are, is it fitted at the correct height and do they use it correctly?
- there is a lack of hip motion, particularly extension. A lack of hip extension can have an impact on gait (see Chapter 6).
- there is a lateral horizontal shift of the pelvis and trunk over the stance leg during the swing phase. This may indicate a positive Trendelenburg sign (see "Special Tests"). Activation of the abductor mechanism on weight bearing is necessary to stabilize the hip and pelvis and prevent excessive lateral tilting of the pelvis to the contralateral side during the swing phase.
- the ankle alignment is neutral. Increased ankle pronation increases the degree of hip internal rotation which can place greater stress on hip rotators. This can be especially traumatic to those hip rotators that cross bony prominences, increasing the risk of bursitis; conversely, supination causes greater external rotation.

Strong activation of the hip extensors (with the abductors) is necessary at initial contact into the early stance, from 30 degrees initial flexion to approximately 10 degrees of extension at terminal stance.[186] If the hip flexors are short or stiff in relation to the abdominal muscles, there may be an exaggeration in the anterior pelvic tilt and increased lumbar extension during this phase.[182]

Joint Loading Tests. Pain on weight bearing is a common complaint in some patients with hip joint pathology, including rheumatoid arthritis and OA.[114] Depending on the capability of the patient, the following weight-bearing tests may produce pain:

- High step. The patient places one foot on a chair and then leans on it (Fig. 19-18). This maneuver flexes the raised hip and extends the other. The test is repeated on the other side. This test gives the clinician an indication as to the range of flexion and extension at the hip.
- Unilateral standing. The patient stands on one leg (Fig. 19-19). An inability to maintain the pelvis in a horizontal position during unilateral standing is called a positive Trendelenburg (see "Special Tests").

Palpation

The palpatory examination is done to identify both anatomic abnormalities and potential sources of symptoms other than from the hip joint itself. Given the location of the hip joint,

FIGURE 19-18 High step.

palpation is usually unrevealing as far as any specific areas of discomfort related to an intra-articular source of hip symptoms. A palpable mass following acute trauma that is not well defined usually indicates a muscle tear, a muscle spasm, or hematoma.[174] A mass that developed 2–3 weeks after the initial injury and is warm and erythematous may be the first indication of myositis ossificans. Bursitis usually presents with some localized swelling, warmth, and erythema, and no history of acute trauma. Trigger points are usually identified as discrete nodules or bands within muscle tissue. There is no associated swelling and no warmth or erythema. Postural or bony malalignment can increase the risk of both acute traumatic and overuse injuries. The anatomic relationships of the joints of the lower extremity should be compared, looking for valgus and varus deformities, pes cavus or planus, spine mobility, hip anteversion, pelvic asymmetry, and leg-length discrepancies (see Chapter 29).[174]

FIGURE 19-19 Trendelenburg sign indicating weakness of the left hip abductors.

CLINICAL PEARL

The following are useful landmarks to use when locating the hip joint center of rotation[21]:

- The midpoint between the ASIS and pubic symphysis, over the femoral pulse.
- The superior tip of the greater trochanter in line with the center of rotation.

Anterior Aspect of Hip and Groin

Anterior-Superior Iliac Spine. The anterior iliac spine serves as the origin for the sartorius muscle and the TFL. Both can be located by flexing and abducting the patient's hip, which produces a groove that resembles an inverted **V** close to the ASIS. The lateral side of the inverted **V** is formed by the TFL, while the medial side is formed by the tendon of the sartorius.

Anterior-Inferior Iliac Spine. The AIIS can be palpated in the space formed by the sartorius and the TFL, during passive flexion of the hip in the space known as the lateral *f*emoral triangle. The lateral cutaneous nerve of the thigh passes through this triangle. Compression of this nerve produces a condition called meralgia paresthetica (see Chapter 5). The AIIS serves as the origin for the rectus femoris tendon.

Pubic Tubercle. The pubic tubercle is located by finding the groin crease and then traveling in an inferomedial direction, or by following the tendon of the adductor longus proximally. In males, the spermatic cord runs directly over the tubercle and can be tender to palpation in normal individuals. Inguinal hernias are usually found superior and medial to the tubercle, while femoral hernias are located lateral to the tubercle.

Adductor Magnus. The adductor magnus is palpable in a small triangle in the distal thigh, posterior to the gracilis muscle and anterior to the semimembranosus.

Rectus Femoris. The rectus femoris has its origin at the AIIS, which is located just distal to the ASIS, between the TFL and sartorius.

Iliopsoas Bursa. At the iliopectineal eminence, the iliopsoas muscle makes an angle of about 30 degrees in a posterolateral direction. To palpate this bursa, the patient is positioned in supine, with the hip being positioned in approximately 40 degrees of flexion and external rotation, and resting on a pillow. At the proximal end of the femur, the clinician palpates the adductor tubercle and then moves to the ASIS.

From there, the clinician proceeds to the inguinal ligament, under the fold of the external oblique, and into the femoral triangle. T e psoas bursa is located under the floor of the triangle, close to the pubic ramus.

Femoral Triangle. T e femoral artery lies superficial and medial to the iliopsoas muscle and is easily located by palpation of the pulse. T e femoral nerve is the most lateral structure in the femoral triangle. To examine the femoral triangle, the patient is positioned in supine and, if it is possible for the patient to do this, the heel of the leg is placed on the opposite knee. T is places the patient in a position of flexion–abduction and external rotation.

Inguinal Ligament. T e inguinal ligament is located in the fold of the groin, running from the ASIS to the pubic tubercle. It can be located by using transverse palpation.

Adductor Longus. Together with the gracilis, the adductor longus forms the medial border of the femoral triangle. T e gracilis is located medial and posterior to the adductor longus. T e adductor longus is best viewed during resisted adduction, when it forms a cord-like structure just distal to the pubic tubercle, before crossing under the sartorius. It is often tender in dancers, cheerleaders, and others who perform strenuous activities requiring abduction at the hip.

l ateral Aspect of the Hip

T e patient is positioned in side lying.

Iliac Crest. T e iliac crest is easy to locate. T e cluneal nerves are superficial structures and can be located just superior to the crest.

Greater Trochanter. T e superior border of the greater trochanter represents the transverse axis of hip, and when the leg is abducted, an obvious depression appears above the greater trochanter. T e gluteus medius inserts into the upper portion of the trochanter and can be palpated on the lateral aspect.[188]

Palpation of the greater trochanter is also used to assess the angle of anteversion and retroversion using the Craig test (see "Special Tests").

Lesser Trochanter. T e lesser trochanter, covered as it is with the iliopsoas and adductor magnus, is very difficult to palpate directly, but it can be located on the posterior aspect if the hip is placed in extension, and internal rotation, and the palpation is performed deeply lateral to the ischial tuberosity.

Piriformis Attachment. T e origin of the piriformis can be found on the medial aspect of the superior point of the greater trochanter. Moving inferiorly from this point, the quadratus femoris is located on the quadrate tubercle, and following tendon insertions can be palpated: superior gemellus, obturator internus, and inferior gemellus.

Psoas. T e insertion for the psoas is located on the inferior aspect of the greater trochanter and can be found by placing the patient's hip in a position of maximal internal rotation. Once the superior aspect of the greater trochanter is located, the clinician moves in a posterior/medial/inferior direction to locate the inferior aspect of the greater trochanter.

Subtrochanteric Bursa. T e subtrochanteric bursa cannot be palpated directly. However, it can be tested by positioning the patient's leg in hyperadduction. At this point, the patient is asked to abduct the hip isometrically against the clinician's resistance. T e contraction of the hip abductors compresses the bursa and may cause pain if the bursa is inflamed.

Posterior Aspect of the Hip

T e patient is positioned in side lying or prone.

Quadratus Lumborum. Palpation of the quadratus lumborum is best accomplished with the patient in side lying, with the arm abducted overhead to open the space between the iliac crest and the 12th rib.

Ischial Tuberosity. A number of structures have their attachments on the ischial tuberosity. T ese include the ischial bursa, the semimembranosus tendon, the sacrotuberous ligament, the biceps femoris and semitendinosus tendons, and the tendons of the quadratus femoris, adductor magnus, and inferior gemellus. T e ischial tuberosity is best palpated in the side-lying position with the hip flexed to 90 degrees (see Chapter 29). T is position moves the gluteus maximus upward, permitting direct palpation at the tuberosity. T e ischial bursa is located on the inferior and medial aspect of the ischial tuberosity. A diagnosis of ischial bursitis is usually based on a history of pain with sitting on a hard surface and finding tenderness with palpation of the ischial tuberosity.

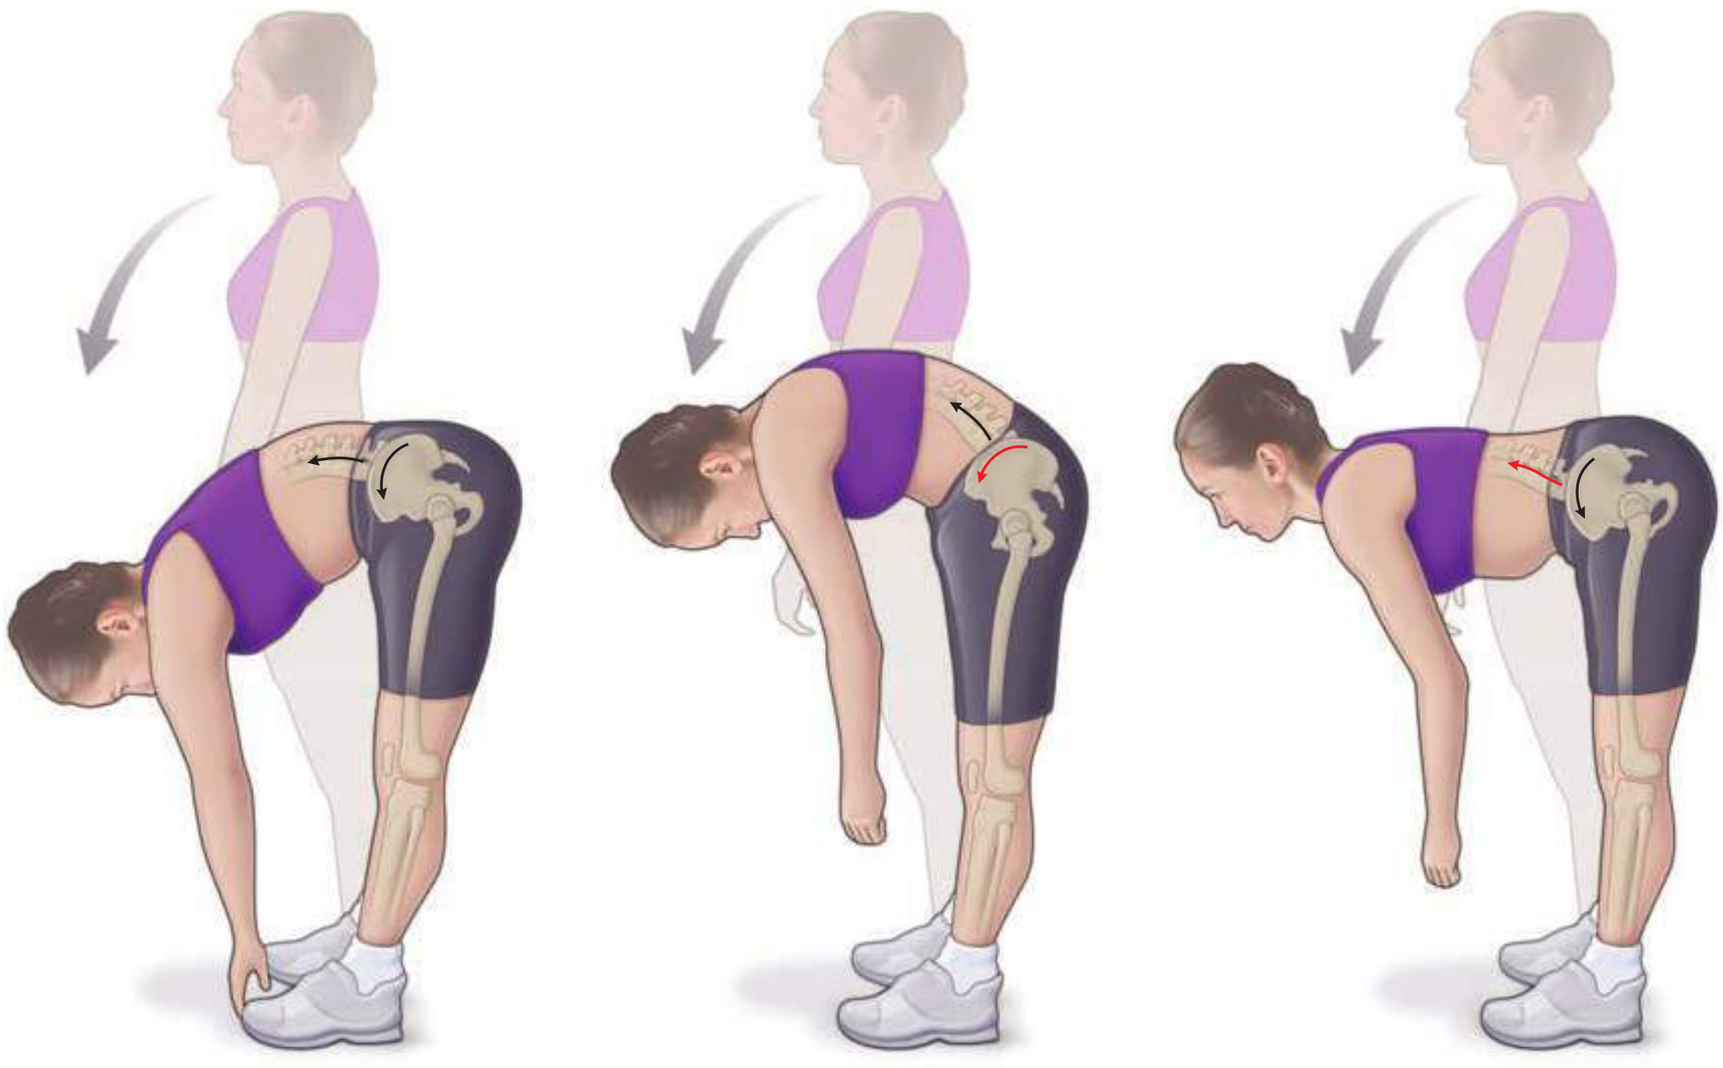
Sciatic Nerve. One of the most important structures to palpate in this area is the sciatic nerve. It can be located by palpation at a point halfway between the greater trochanter and ischial tuberosity. Tenderness of this nerve can be produced by a piriformis muscle spasm or by direct trauma, referred to as piriformis syndrome (see Chapter 5).

Active, Passive, and Resistive Tests

T e clinical procedures for performing ROM measurements vary and disagreement exists about the accuracy of visual estimates compared to goniometer measurements. A study by Holm et al.[189] comprising 25 patients (6 M, 19 F; mean age 68.5 years, range 46–76 years) with osteoarthrosis of the hip, verified both clinically and radiologically, examined the reliability of goniometric measurements and visual estimates of hip ROM. Hip ROM measurements (abduction VIDEO, adduction VIDEO, extension VIDEO, flexion VIDEO, and internal VIDEO/external rotation VIDEO) were recorded by four different teams on the same day and were repeated 1 week later. Teams 1, 2, and 3 consisted of physiotherapists using standardized goniometric measurements. Team 4 involved an experienced orthopaedic surgeon making the assessments from visual estimates only. With the exception of abduction ($p = 0.03$), there were no significant differences between the measurements recorded on the first and second occasions for the same teams. T e coefficient of variance was 5.5% for flexion (lowest) and 26.1% for extension (highest). Reproducibility was best for flexion. T ere was also high reliability when all the arcs of motion were summed up (abduction + adduction + extension + flexion + internal/external rotation). With the exception of internal rotation, there were highly significant differences between the teams when two people performed the measurements compared to the values measured by a single individual. Concordance, expressed as the standardized agreement index, between visual estimates made by one individual (the orthopaedic surgeon) and goniometric measurements made

by two experienced physiotherapists, was 0.77–0.83, which indicates good agreement.

Bierma-Zeinstra et al.[190] performed a study to compare the reliability of measurements of hip motions obtained with two instruments, an electronic inclinometer and a two-arm goniometer, and to investigate whether the two instruments, and different body positions, produce the same measurement data. Maximal active and passive hip movements were measured simultaneously with both instruments, in nine subjects during 10 consecutive measurements at short intervals. The results from the study demonstrated the following[190]:



- The intraobserver variability was lower with the inclinometer in measurements of passive hip rotations.
- The two instruments showed equal intraobserver variability for hip movements in general.
- The inclinometer showed lower interobserver variability in the measurements of active internal rotation.
- More rotational movement was measured with the two-arm goniometer and more extension and flexion with the inclinometer. Also, more rotational movement was found in the prone position compared to the sitting and supine positions.

The study concluded that the inclinometer is more reliable in measurements of hip rotation; for hip movements, in general, the two-arm goniometer is just as accurate when used by only one observer; and the two instruments, and some positions, are not interchangeable during consecutive measurements.[190]

During the examination of the ROM, the clinician should note which portions of the ROM are pain free and which portion causes the patient to feel pain. The screening of active and passive lumbar motion is indicated for all patients with a potential hip pathology. An assessment of the lumbopelvic rhythm (see Chapter 28) can alert the clinician to the primary area of a particular limitation. Active trunk motion in all planes and manual overpressure at end ranges should be administered to fully clear the lumbar spine. During normal forward bending, the patient should be able to touch their toes without bending the knees and with a flattening of the lordosis (Fig. 19-20). However, if the hamstrings are adaptively shortened, toe touching, cannot be accomplished even with a flattening of the lordosis. If the tightness is located in the LB, as the patient bends forward, no flattening of the lordosis occurs, and the patient is unable to touch the toes even with good hamstring flexibility. If lumbar screening reproduces the patient's hip symptoms, then further spine evaluation is warranted. The sacroiliac joint should be evaluated in hip patients with complaints of posterior hip or buttock pain (see Chapter 29).

The capsular pattern of the hip appears variable and is an unreliable method for determining the presence of OA when used alone.[167] Twinges of pain with active motions may indicate the presence of a loose body within the joint. At the end of available AROM, passive overpressure is applied to determine the end-feel. The normal ranges and end-feels for the various hip motions are outlined in Table 19-5. Abnormal end-feels common in the hip include a firm capsular end-feel before an expected end range; empty end-feel from severe pain, as in the sign of the buttock; and a bony block in cases of advanced OA.[21] Horizontal abduction and adduction of the femur occur when the hip is in 90 degrees of flexion. Since these actions require the simultaneous, coordinated actions of several muscles, they can be used to assess the overall strength of the hip muscles.

Resisted testing of the muscles that cross the hip joint (Table 19-4) is performed to provide the clinician with information about the integrity of the neuromuscular unit, and

A Normal lumbar and hip flexion

B Limited hip flexion and excessive lumbar flexion

C Limited lumbar flexion and excessive hip flexion

FIGURE 19-20 Lumbopelvic rhythm.

to highlight the presence of muscle strains (see "Systems Review").[191]

If the history indicates that repetitive motions or sustained positions cause the symptoms, the clinician should have the patient reproduce these motions or positions.[192]

Cl INICAl PEARl

In the child, pain and loss of range at the hip joint should always alert the clinician to the possibility of transient synovitis, Legg–Calvé–Perthes disease, or a slipped femoral capital epiphysis (see Chapter 30).

In addition to reports of pain and overall ROM, the clinician also notes information about weakness, joint end-feel, palpation of the moving joint, and muscle tightness.

Flexion. T e six muscles primarily responsible for hip flexion are the iliacus, psoas major, pectineus, rectus femoris, sartorius, and TFL (Table 19-4). T e primary hip flexor is the iliopsoas muscle.

Hip flexion motion can be tested in sitting or supine, first with the knee flexed (Fig. 19-21) and then with the knee extended. With the hip flexed and the knee extended, normal hip flexion should be 80 degrees with knee extension to 20 degrees.[193] With the hip flexed, the ROM should be approximately 110–120 degrees. More hip flexion should be available with the knee flexed.

Resisted tests are then performed.

- To test the strength of the iliopsoas, the patient is seated with the thigh raised off the bed and resistance is applied by the clinician VIDEO.
- T e action of the sartorius muscle, which flexes, abducts, and externally rotates the hip, is tested by asking the patient to bring the plantar aspect of the foot toward the opposite knee VIDEO. T e clinician applies resistance at the medial malleolus and at the lateral aspect of the thigh to resist flexion, abduction, and external rotation.

A painless weakness of hip flexion is rarely a good sign. Although it may indicate a disk protrusion at the L1 or L2 level, these protrusions are not common. A more likely scenario is compression of the nerves by a neurofibroma or a metastatic invasion. Pain with the active motion or resisted tests should prompt the clinician to examine the contractile tissues individually. Passive stretching can also produce pain in a contractile structure.

FIGURE 19-21 Hip flexion with knee flexed.

FIGURE 19-22 Hip extension.

Extension. T e primary hip extensor is the gluteus maximus (Table 19-4). T e hamstrings also serve as hip extensors. Hip extension also involves assistance from the adductor magnus, gluteus medius, and minimus, and indirect assistance from the abdominals and the erector spinae.[194]

T e patient is positioned in prone or over the end of a table. As the clinician monitors motion at the pelvis to ensure the lumbar spine does not extend, the patient is asked to lift the thigh toward the ceiling (Fig. 19-22). With a normal recruitment pattern, the order of firing should be gluteus maximus, opposite erector spinae, and then the ipsilateral erector spinae and hamstrings.[185] Poor recruitment patterns are demonstrated as follows:

1. An initial activation of the hamstrings and erector spinae with a delayed contraction of the gluteus maximus. T e biceps femoris has a tendency to become shortened and overactive, resulting in delayed activation of the gluteus maximus.[195]
2. T e erector spinae initiate the movement with a delayed activity of the gluteus maximus. T is would lead to little if any, an extension of the hip joint, as the leg lift would be achieved by an anterior pelvic tilt and a hyperextension of the lumbar spine. T is is a very poor movement pattern.

T e normal ROM for hip extension is approximately 10–15 degrees. Reduced hip extension with the knee flexed can be the result of a number of reasons, including

- adaptive shortening of the iliopsoas, characterized by an increased lumbar lordosis, an externally rotated lower extremity, and a noticeable groove in the ITB in standing[196];
- a hip flexion contracture.

As before, the pelvis is monitored, and the patient is asked to raise the thigh off the table. T e strength of the gluteus maximus is tested with the knee flexed (Fig. 19-23) VIDEO. T e role of the hamstrings at the hip can be tested with the knee extended. By observing the patient's shoulder during this test, the recruitment pattern can be analyzed. T e

FIGURE 19-23 Hip extension with knee flexed.

opposite shoulder should be seen to rise from the bed. With the abnormal pattern, the same shoulder rises from the bed. Patients who use this abnormal recruitment pattern will often have well-developed thoracic musculature on the posterior aspect and, as a result, develop problems at the thoracolumbar junction.[185]

Resistance is then applied by the clinician. A strong and painful finding with resisted hip extension may indicate a grade I muscle strain of the gluteus maximus or hamstrings. It may also indicate gluteal bursitis or a lumbosacral strain. The strength of the medial and lateral hamstrings is also tested using resisted knee flexion, with the patient positioned in prone (see Chapter 20).

CLINICAL PEARL

Although hip extensor strength in the elderly has been identified as the primary predictor of walking ability, physical performance, and balance, assessment of hip extensor strength in this population is commonly overlooked, as the presence of pain, contractures, and reduced mobility often limits the ability of the elderly patient with hip or spine impairment to adopt the prone position.[149] In these situations, the clinician should modify the testing position to accommodate the patient.

Abduction/Adduction. Hip adduction (Fig. 19-24) and abduction (Fig. 19-25) ROM can be tested in supine or side lying making sure that both ASIS are level, and the legs are perpendicular to a line joining the ASIS.

Abduction. The patient is positioned in supine. The clinician monitors the ipsilateral ASIS, and the patient is asked

FIGURE 19-24 Hip adduction ROM using antigravity position.

to abduct the leg. The abduction motion is stopped when the ASIS is felt to move. The prime movers of this movement are the gluteus medius/minimus and the TFL. The quadratus lumborum functions as the stabilizer of the pelvis. The strength of the hip abductors can be tested against gravity in the side-lying position VIDEO, or in standing:

- Standing. The patient is positioned in standing with both lower extremities in 50 degrees of knee flexion and 30 degrees of hip flexion. The clinician places the palm of each hand on the lateral aspects of the patient's thighs before asking the patient to push outward against the hands. This is weight-bearing method of assessing hip abductor muscle performance has been shown to be a reliable method to assess hip muscle strength.[159]
- Side lying.[39] The patient is positioned in side lying on the nontested side, with the trunk in neutral alignment and the pelvis perpendicular to the testing surface. The nontested hip and knee are flexed. The patient's tested limb is placed in hip abduction, neutral rotation, and neutral flexion/extension. The clinician then monitors for compensation as the patient holds the test position. If the patient can maintain the test position for three seconds without compensation, resistance may be applied. The clinician places one hand on the iliac crest to prevent the pelvis from rotating or tilting and uses the other hand to place resistance at the distal thigh or ankle (depending on

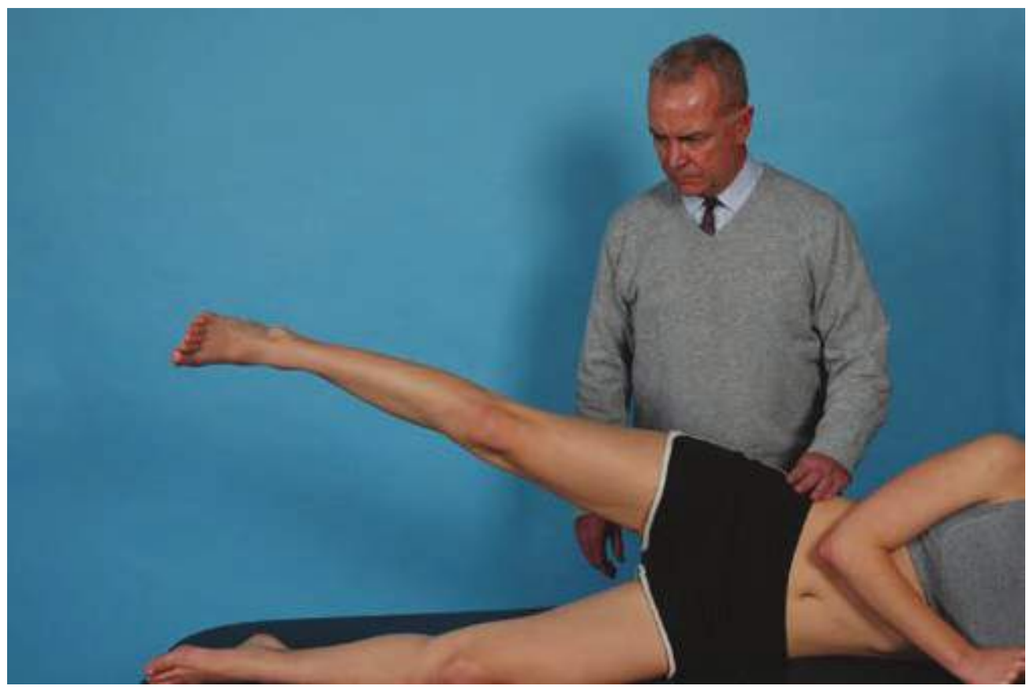


FIGURE 19-25 Hip abduction ROM.

the strength of the clinician/patient) in the direction of femoral adduction.

T e correct sequence of firing for the hip abductors in side lying should be gluteus medius, followed by the quadratus lumborum and TFL after approximately 15 degrees of hip abduction. Altered patterning demonstrates the following:

1. External rotation of the leg during the upward movement, indicating an initiation and dominance of the movement by the TFL, accompanied by a weakness of the gluteus medius/minimus. T e TFL has a tendency to become shortened and overactive.[195]
2. Full external rotation of the leg occurs during the leg lift, indicating a substitution of hip flexion and iliopsoas activity for the true abduction movement. If the piriformis is shortened and overactive, the external rotation of the leg is reinforced.[195]
3. A lateral pelvic tilt at the initiation of movement, indicating that the quadratus lumborum, which has a tendency to become shortened and overactive, is both stabilizing the pelvis and initiating the movement.[195] T is is indicative of a very poor movement pattern.

Adduction. Hip adduction is tested with the patient supine and with the uninvolved leg adducted over the other leg or held in flexion (Fig. 19-24). As before, the ASIS is monitored for motion, indicating the end of the range for adduction. T e primary hip adductor is the adductor longus. Adaptive shortening of the hip adductors can theoretically result in inhibition of the gluteus medius, a decrease in frontal stability, ITB tendinopathy, and anterior knee pain. Pain can be referred from the hip adductors into the anterolateral hip, groin, medial thigh, the anterior knee, and medial tibia. Pain in these regions with passive abduction, or active adduction, may indicate a strain of one of the adductors. T e cause of the pain can be differentiated between the two-joint gracilis and the other hip adductors (longus, brevis, and pectineus) in the following manner. T e patient is positioned in supine, with the tested leg over the edge of the table, monitored by the clinician. T e clinician places the involved hip into the fully abducted position, and the knee is flexed (Fig. 19-26). If no pain is reproduced with this maneuver, the patient is asked to extend the knee (Fig. 19-27), thereby bringing in the gracilis

FIGURE 19-26 Differentiating hip adductor muscles—knee flexed.

FIGURE 19-27 Differentiating hip adductor muscles—knee extended.

and implicating it if the pain is now reproduced. T is can be confirmed with resisted hip adduction and knee flexion. If the other adductors are implicated, this can be confirmed with resisted adduction (longus and brevis) or resisted hip adduction and hip flexion (pectineus).

T e strength of the hip adductor muscle group can also be tested in side lying VIDEO, by flexing the uninvolved leg over the tested leg or by supporting the upper leg and then applying resistance. T is position also stretches the hip abductors and can be a source of pain in the case of an iliotibial band friction syndrome (ITBFS).

A strong and painful finding with resisted adduction is usually the result of an adductor longus lesion, whereas a painless weakness with resisted abduction is often found in a palsy of the fifth lumbar root because of a disk herniation at the same level.

Internal and External Rotation. Although a number of muscles contribute to external rotation of the femur (Table 19-4), six muscles function solely as external rotators.[60] T ese are the piriformis, gemellus superior, gemellus inferior, obturator internus, obturator externus, and quadratus femoris. Normal ROM for hip external rotation is approximately 40–60 degrees. Excessive external rotation of the hip may indicate hip retroversion.

T e major internal rotator of the femur is the gluteus minimus, assisted by the gluteus medius, TFL, semitendinosus, and semimembranosus. T e internal rotators of the femur are estimated to be only approximately one-third the strength of the external rotators.[118] Normal ROM for hip internal rotation is approximately 30–40 degrees. Excessive internal rotation of the hip may indicate hip anteversion.

Internal and external rotation of the hip can be measured with the patient in a variety of positions[39]:

- Patient seated. T e patient is positioned sitting with the hip at 90 degrees of flexion. T e sitting position assists in stabilizing the pelvis, and the pelvis should be closely monitored to avoid pelvic movement. T e hip to be measured is placed at 0 degree of abduction, and the contralateral hip is placed in about 30 degrees of abduction. T e reference knee is flexed to 90 degrees, and the leg is passively moved to produce hip rotation. T e tibiofemoral joint must be controlled to prevent motion (rotation or abduction/adduction), which could be construed as hip rotation.[197] T e motion is stopped

when the clinician reaches a firm end-feel or when pelvic movement is necessary for additional movement of the limb. Limited internal rotation ROM when the hip is flexed to 90 degrees has been associated with bony impingement due to femoroacetabular impingement.[198]

- Patient prone. T e patient is positioned prone with the feet over the edge of the bed. T e hip being measured is placed in 0 degree of abduction, and the contralateral hip is placed in about 30 degrees of abduction. Manual stabilization is applied to the pelvis to prevent pelvic movement and also at the tibiofemoral joint to prevent motion (rotation or abduction/adduction), which could be construed as hip rotation.[197] T e reference knee is flexed to 90 degrees, and the leg is passively moved to produce hip rotation. T e motion is stopped when the clinician reaches a firm end-feel or when pelvic movement is necessary for additional movement of the limb.
- Patient supine. T e patient is positioned in supine, with the leg in 90 degrees of hip flexion and 90 degrees of knee flexion. Hip internal rotation (IR) (Fig. 19-28) and external rotation (ER) (Fig. 19-29) is then assessed.

If an asymmetry exists between the two positions, such that more ROM is available in the prone position compared with supine, a muscle restriction is likely present.[199] When the asymmetry of internal rotation ROM is much greater than the external rotation range in both the hip flexed and hip extended positions, structural anteversion may be present.[199] If retroversion is present, the range of external rotation is greater than the range of internal rotation in both the flexed and extended positions of the hip.[199]

It is important to remember that if an athlete is not getting enough rotation at the hip joint, compensation will occur with increased motion through the lumbar spine, the latter of which has a limited capacity for rotation. In addition, a decrease in hip rotation may create an increased shear force through the pubic symphysis, increasing the risk for developing osteitis pubis.[200]

FIGURE 19-28 Supine hip IR.

FIGURE 19-29 Supine hip ER.

Once the ROM measurements have been established, the strength of the internal rotators VIDEO and external rotators VIDEO is then assessed.

Functional Assessment

In addition to gait analysis, the function of the hip can be assessed through observation during functional activities such as sit to stand, or through use of a self-report measure, which allow a patient to rate his or her capacity to perform ADL. Table 19-14 outlines a functional assessment tool for the hip.

Other tests that can be used include[39]:

- T e Harris Hip Rating Scale (Table 19-15) is the most commonly used functional outcome assessment for the hip after total hip arthroplasty. T e Modified Harris Hip Score (MHHS)[178] is a disease-specific self-report questionnaire with questions related to pain and functional ability that excludes the clinician's judgment of deformity and ROM which allows the patient to complete the questionnaire independently.
- Copenhagen Hip and Groin Outcome Score (HAGOS).[201] T is was developed to assess patient's hip and groin disability in a young, active patient. T e HAGOS is a disease-specific self-report questionnaire with the following six separately scored subscales: pain, other symptoms, physical function in daily living, function in

TABLE 19-14 Functional Tests of the Hip

Starting Position	Action	Functional Test
Standing	Hip flexion: lift foot onto an 8-in/20-cm step and return	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor Zero repetitions: nonfunctional
Standing	Hip extension: sit in a chair and return to standing	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor Zero repetitions: nonfunctional
Standing	Hip abductors: lift leg to the articular surfaces balance on one leg while keeping pelvis level	Hold 1–1.5 minutes: functional Hold 30–59 seconds: functionally fair Hold 1–29 seconds: functionally poor Cannot hold: nonfunctional
Standing	Hip adductors: walk sideways 6 m	6–8 m one way: functional 3–6 m one way: functionally fair 1–3 m one way: functionally poor 0 m: nonfunctional
Standing	Hip internal rotation: test leg off floor (holding onto object for balance if necessary), internally rotate non–weight-bearing hip	10–12 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor Zero repetitions: nonfunctional
Standing, facing closed door	Hip external rotation: test leg off floor (holding onto object for balance if necessary), externally rotate non–weight-bearing hip	10–12 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor Zero repetitions: nonfunctional

Data from Palmer ML, Epler M. Clinical Assessment Procedures in Physical Therapy. Philadelphia, PA: JB Lippincott; 1990.

sport and recreation, participation in physical activities, and hip-related quality of life.

- The International Hip Outcome Tool (iHOT-33).[202] The iHOT-33 is a disease-specific self-report questionnaire developed specifically for young, active adults with symptomatic hip disease that has questions related to the following domains: symptoms and functional limitations, sports and recreational physical activities, job-related concerns, and social, emotional, and lifestyle concerns.
- The Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) (see Chapter 20).
- Hip Disability and Osteoarthritis Outcome Score (HOOS).[203] The HOOS is a disease-specific self-report questionnaire that can be used for individuals with various types of hip pain. The HOOS includes all questions from the WOMAC, along with additional items thought to be useful in detecting limitations in high-level activities, such as running, squatting, and pivoting. The current version (version 2) includes 40 items to assess five domains: symptoms (stiffness and ROM), pain, function in daily living, function in sport and recreation, and hip-related quality of life. The HOOS may be preferred to the WOMAC due to its reduced ceiling effect compared to the WOMAC. Additionally, the WOMAC score can be calculated from the HOOS questionnaire if desired.
- The 30-second chair stand. Participants are asked to rise from a seated position to a standing position, with their arms folded across their chest, as many times as possible in 30 seconds. The number completed is recorded for this test.[204]
- The 20-cm step test. Participants are asked to step up onto and down from a step 20 cm in height as many times as possible. The involved lower extremity acts as the working lower extremity so that the patient steps up with the involved lower extremity and down with the uninvolved lower extremity. The number completed is recorded for this test. The test is discontinued if the maximum number of 50 steps is reached.[205]

Functional tests for the more athletic population can include double-leg squatting, single-leg balance, single-leg squat, and the various hop tests outlined in Chapter 4.

Examination of Movement Patterns

Some of the movement patterns were assessed in the "Active, Passive, and Resistive Tests". One further test is described here.

TABLE 19-15 Harris Hip Rating Scale

Harris Hip Function Scale

(Circle one in each group)

Pain (44 points maximum)

None/ignores	44
Slight, occasional, no compromise in activity	40
Mild, no effect on ordinary activity, pain after unusual activity, uses aspirin	30
Moderate, tolerable, makes concessions, occasional codeine	20
Marked, serious limitations	10
Totally disabled	0

Function (47 points maximum)

Gait (walking maximum distance) (33 points maximum)

1. Limp:	
None	11
Slight	8
Moderate	5
Unable to walk	0
2. Support:	
None	11
Cane, long walks	7
Cane, full time	5
Crutch	4
Two canes	2
Two crutches	0
Unable to walk	0
3. Distance walked:	
Unlimited	11
Six blocks	8
Two to three blocks	5
Indoors only	2
Bed and chair	0

Functional activities (14 points maximum)

1. Stairs:	
Normally	4
Normally with banister	2
Any method	1
Not able	0
2. Socks and tie shoes:	
With ease	4
With difficulty	2
Unable	0
3. Sitting:	
Any chair, 1 hour	5
High chair, ½ hour	3
Unable to sit ½ hour any chair	0
4. Enter public transport:	
Able to use public transportation	1
Not able to use public transportation	0

Absence of deformity (requires all four) (four points maximum)

1. Fixed adduction <10 degrees	4
2. Fixed internal rotation in extension <10 degrees	0
3. Leg-length discrepancy less than 1¼ in	
4. Pelvic flexion contracture <30 degrees	

Range of motion (five points maximum)

Instructions

Record 10 degrees of fixed adduction as "–10 degrees abduction, adduction to 10 degrees"

Similarly, 10 degrees of fixed external rotation as "–10 degrees internal rotation, external rotation to 10 degrees"

Similarly, 10 degrees of fixed external rotation with 10 degrees further external rotation as "–10 degrees internal rotation, external rotation to 20 degrees"

Permanent flexion

(1) _____

	Range	Index Factor	Index Value*
A. Flexion to	_____ degrees		
(0–45 degrees)		1.0	
(45–90 degrees)		0.6	
(90–120 degrees)		0.3	
(120–140 degrees)		0.0	
B. Abduction to	_____ degrees		
(0–15 degrees)		0.8	
(15–30 degrees)		0.3	
(30–60 degrees)		0.0	
C. Adduction to	_____ degrees		
(0–15 degrees)		0.2	
(15–60 degrees)		0.0	
D. External rotation in extension to	_____ degrees

Comments:

Data from Harris WH. Traumatic arthritis of the hip after dislocation and acetabular fractures. Treatment by mold arthroplasty: An end-result study using a new method of result evaluation. J Bone Joint Surg. 1969; 51:737–755.

Trunk Curl Up. The global core musculature includes links to the extremities and prime movers, the latter of which generate power from the stable platform provided by the local core musculature (see Chapter 28). The transversus abdominis and oblique muscles act as a contractile bandage, pulling the anterior portions of the blades of the ilia toward each other, which in turn increases the pressure on the anterior portions of the sacroiliac joint, stabilizing the pelvis in an upright posture.[9] This test assesses the patient's ability to sit up from a supine position and the relationship between the transversus abdominis, oblique, and iliopsoas muscles. The patient is positioned in supine with the hips and knees flexed, both feet flat on the bed.

The patient is then asked to perform a sit-up while actively plantar flexing their ankles, thus removing the effect of the iliopsoas.[194] The patient progressively flexes the spine, starting at the cervical region, until the lumbar region is flexed. As soon as the iliopsoas becomes involved in the motion, the patient's feet will lift from the bed. Normally, the patient should be able to curl up so that the thoracic and lumbar spines are clear of the bed before the feet lift. A patient in excellent condition can complete a full sit-up without the feet lifting from the bed.

Passive Accessory Movements

Because of the extreme congruency of the joint partners at the hip joint, this is a difficult area to assess with any degree of accuracy, especially as the glides that occur are very slight. Unless otherwise indicated, the patient is positioned supine with the hip in its resting position. The clinician can wrap a belt around the patient's pelvis and the treatment table to help stabilize the pelvis.

Distraction. A joint distraction can be used to assess for pain and any hypomobility at the hip joint. The patient's thigh is grasped by the clinician as proximal as possible, and a distraction force is applied along the line of the femoral neck (Fig. 19-30).

Leg Traction. The clinician grasps the patient's ankle and applies a longitudinal force along the length of the leg (Fig. 19-31).

Posterior Glide. The clinician stands on the medial side of the patient's thigh. A belt can be placed around the clinician's shoulder and under the patient's thigh, to help hold the weight of the lower extremity. The clinician places one hand on the distal thigh of the patient and the other hand on the anterior surface of the patient's proximal thigh (Fig. 19-32). Keeping the elbows extended and flexing the knees, the clinician applies a force through the patient's hip in a posterior direction (Fig. 19-32).

Anterior Glide. The patient is positioned prone, with the trunk resting on the table, their thigh over the edge, and the opposite foot supported (Fig. 19-33). The clinician stands on the lateral side of the patient's thigh. A belt can be placed around the clinician's shoulder and under the patients thigh to help hold the weight of the lower extremity. Using one hand, the clinician grasps the patient's lower leg. The other hand of the clinician is placed posteriorly on the proximal thigh of the patient, just below the buttock (Fig. 19-33). Keeping the elbows extended and flexing the knees, the clinician applies a force through the proximal hand in an anterior direction.

FIGURE 19-30 Hip joint distraction.

Inferior Glide. The patient is positioned with the hip and knee each flexed to 90 degrees and the lower leg placed against the clinician's shoulder. The clinician grasps the anterior aspect of

FIGURE 19-31 Leg traction for hip.

FIGURE 19-32 Posterior glide of the hip.

the proximal femur as far proximally as possible with one hand. An inferior glide is imparted using the hands while simultaneously rocking the patient's thigh into flexion (Fig. 19-34).

Neurological Tests

For sensation testing, the clinician should be aware of the dermatomal pattern as well as the areas supplied by the peripheral

FIGURE 19-33 Anterior glide of the hip.

FIGURE 19-34 Inferior glide of the hip.

nerves (inferior femoral cutaneous nerve, lateral cutaneous nerve of the thigh, and posterior femoral cutaneous nerve).

Paresthesia or anesthesia is not commonly found in the buttock, hip, or groin region because of the degree of dermatome overlap. However, paresthesia in the "saddle" region should be considered indicative of a sign of cauda equina compression.

Special Tests

Special tests are merely confirmatory tests and should not be used alone to form a diagnosis. T e results of these tests are used in conjunction with the other clinical findings to help guide the clinician. To assure accuracy with these tests, both sides should be tested for comparison.

Quadrant (Scour) Test. T e quadrant or scour test is a dynamic test of the inner and outer quadrants of the hip joint surface.[206]

T e patient is positioned in supine, close to the edge of the bed, with their hip flexed and foot resting on the bed. T e clinician places one hand on the top of the patient's knee. T e patient's hip is placed in 90 degrees of flexion, with the knee being allowed to flex comfortably. From this point, the clinician adducts the hip to the point at which the patient's pelvis begins to lift off the bed, to assess the inner quadrant (Fig. 19-35). At the end range of flexion and adduction, a compression force is applied to the knee along the longitudinal axis of the femur. From this point, the clinician moves the hip into a position of flexion and abduction to examine the outer quadrant. T roughout the entire movement, the femur is held midway between internal and external rotation, and the movement at the hip joint should follow the smooth arc of a circle. An abnormal finding is resistance, apprehension, or pain felt anywhere during the arc. T e pain can result

FIGURE 19-35 Scour test.

from compression of, or stress to, a number of structures including[206]

- the articular surfaces of the hip joint;
- the labrum;
- the hip joint capsule;
- the insertion of the TFL and the sartorius;
- the iliopsoas muscle;
- the IPB and neurovascular bundle;
- the insertion of the pectineus;
- the insertion of the adductor longus;
- the femoral neck.

T e resistance may be caused by capsular tightness, an adhesion, a myofascial restriction, or a loss of joint congruity. Given all of the possible diagnoses, extreme care must be taken when interpreting the results of this test. Of the various studies that have looked at the Scour test, most have had poor study designs. Given the wide range of possible diagnoses with a positive finding, and the variety of patients this test is used with, bias is likely to result.

FABER or Patrick's Test. T e FABER (flexion, abduction, external rotation) test (Fig. 19-36) is a screening test for hip, lumbar, or sacroiliac joint dysfunction, or an iliopsoas spasm (see Chapter 29). If this position recreates groin pain, then iliopsoas and/or intra-articular hip pathology may be present.[33] Posterior hip joint pain in this position may indicate a ligamentum teres injury and/or posterior hip impingement.[33]

FADIR or Hip Flexion, Adduction, Internal Rotation Impingement Test. T is position, sometimes referred to as the anterior impingement test, will typically provoke intra-

FIGURE 19-36 FABER test.

articular hip pathology at the anterior superior region of the acetabulum, the most common site of a femoral acetabular impingement (FAI) and a labral tear.[33,207] T e patient is positioned in supine, and the hip and knee are flexed to 90 degrees. Maintaining the hip at 90 degrees of flexion, the hip is then internally rotated and adducted as far as possible. T e patient is asked what affect the motion has on symptoms. T e test is considered positive if the patient reports a production of, or increase in, the anterior groin, posterior buttock, or lateral hip pain consistent with the patient's presenting pain complaint. If the test is negative, the test is repeated with the hip placed in full flexion. Beck et al.[208] assessed 19 subjects with the clinical diagnosis of femoroacetabular impingement, based on clinical examination, radiographs, and magnetic resonance arthrogram (MRA). T ey found that all 19 subjects had a positive FADIR test corresponding to intraoperative dynamic impingement and labral lesions in the anterosuperior region of the hip joint.[39]

Posterior Impingement Test. T is test is designed to provoke intra-articular hip pathology (FAI) at the posterior aspect of the acetabulum. T e patient is positioned in supine so that both legs hang over the end of the bed in knee flexion. T e patient is asked to hold one knee against the chest while the clinician moves the other leg into a combination of maximal hip extension and external rotation. A positive test is associated with pain occurring in the buttock or groin during this maneuver.[209]

Log-roll Test. T e patient is positioned in supine with the hip and knee in 0 degree of extension. T e hip is passively rotated internally and externally, while the clinician ensures the rotation is occurring at the hip and not at the knee or ankle. T e clinician notes any side to side difference in external rotation ROM. T e test is positive for ligamentous laxity when the involved hip demonstrates greater external rotation ROM and the uninvolved hip or reproduces anterior pain.[210] One study[211] assessed the intertester reliability of the log-roll test in people seeking care for intra-articular, nonarthritic hip joint pain. T e clinicians demonstrated 80% agreement and a kappa value of 0.61 (95% CI: 0.48, 0.84), indicating substantial[212] reliability.[39]

Dial Test. T is test, which is used to help detect injury to the hip joint capsule associated with instability is similar to the log-roll test.[213] T e patient is positioned in supine and the clinician places both hands on the patient's thigh and tibia before maximally internally rotating the patient's hip. T e clinician

FIGURE 19-37 Puranen–Orava test.

then releases the limb, allowing the hip to return to its resting position in external rotation. A positive test is indicated if the hip external rotation is beyond 45 degrees, and a firm end-feel is not present.

McCarthy Sign. This test is used to help diagnose a labral tear.[214] The patient is positioned in supine, and the clinician moves the patient's hip from a position of flexion, adduction, and internal rotation to one of extension, abduction, and external rotation. The reproduction of mechanical symptoms, such as a click or clunk, or the reproduction of anterior pain, is indicative of a positive test.

Hamstring Provocation Tests. These tests are commonly used to assess whether a patient has sustained a tear of the hamstrings[215]:

- Puranen–Orava. This test entails actively stretching the hamstring muscles in the standing position with the hip flexed to about 90 degrees, the knee fully extended, and the foot supported on a solid surface (Fig. 19-37). A positive finding is an exacerbation of the patient's symptoms.
- Bent-knee stretch test. The patient is positioned in supine, and the hip and knee of the symptomatic limb are then maximally flexed. The clinician then slowly straightens the patient's knee while keeping the hip flexed. A positive finding is an exacerbation of the patient's symptoms.
- Modified bent-knee stretch test. The patient is positioned in supine with the lower extremities fully extended. The clinician grasps the symptomatic limb behind the heel with one hand and at the knee with the other. The clinician maximally flexes the hip and knee and then rapidly straightens the knee (Fig. 19-38A–C). A positive finding is an exacerbation of the patient's symptoms.

FIGURE 19-38 Modified bent-knee stretch test.

- Taking off the shoe test.[216] In standing, and the patient is asked to take off the shoe on the involved side with the help of his/her of the shoe (Fig. 19-39). While performing this maneuver, the hindfoot of the involved leg must press the longitudinal arch of the noninvolved foot. The affected leg during the maneuver is an approximately 90 degrees of external rotation at the hip and 20–25 degrees of flexion at the knee. A positive finding is the feeling of a sharp pain

FIGURE 19-38 (Continued)

over the injured biceps femoris. This test has a reported specificity of 100% for hamstring injury.[216]

- AROM test. There are two parts to this test. The patient is positioned in prone and is asked to actively extend the hip with an extended knee. In the second part of the test, the patient is again positioned in prone but this time is asked to flex the knee as far as he/she can. A positive finding is the reproduction of the patient's concordant pain with either test.
- PROM test. There are two parts to this test. The patient is positioned in supine. Using one hand, the clinician stabilizes the pelvis by grasping the iliac crest and, using the other hand, passively flexes the patient's hip allowing the knee to flex from the tension placed on the hamstrings and gravity. With pressure applied proximal to the knee joint, the normal end-feel for hip flexion is soft owing to the approximation of the quadriceps with the abdomen.

FIGURE 19-39 Taking off the shoe test.

In the second part of the test, the patient is again positioned in supine but with the hip flexed to 90 degrees, and the knee flexed in a relaxed position. The clinician passively extends the lower leg (knee) to a firm muscle tension end point. A positive finding is the reproduction of the patient's concordant pain with either test.

- Resisted ROM test. There are two parts to this test. The patient is positioned in prone, with the knee extended and the pelvis stabilized by pressure on the iliac crest from the clinician. An isometric break test is performed at end-range hip extension, with a resistance applied to the popliteal fossa. In the second part of the test, the patient is again positioned in prone with the knee extended. The clinician performs an isometric break test with the knee flexed by providing resistance over the Achilles tendon at 10, 45, and 90 degrees of knee flexion unless contraindicated. A positive finding is the reproduction of the patient's concordant pain with either test.
- Composite clinical assessment. There are three parts to this test:
  1. Passive straight-leg raise. With the patient's lower extremity completely relaxed, the clinician lifts the lower extremity off the bed with the knee fully extended. The degree of hip flexion is measured with a bubble goniometer.
  2. Active knee extension. The patient's thigh is vertical with the posterior distal aspect of the thigh, resting lightly against a frame (or held by a belt), assisting to keep the thigh perpendicular to the bed. With the ankle relaxed in plantarflexion, the patient is asked to actively extend the knee while maintaining light contact with the horizontal part of the frame/belt. A temporary myoclonus of alternating contraction and relaxation of the quadriceps and hamstring muscle groups tends to occur at the maximum angle of active knee extension. At this point, the patient is instructed not to force the leg past the point of initial mild resistance. The patient is then asked to slightly flex the knee until the myoclonus ceases. At the first point at which the shaking ceases, the angle between the vertical and the tibia is recorded using an inclinometer.
  3. Manual muscle testing. Manual muscle testing in the prone position is performed by asking the patient to lift his/her heel by bending his/her knee to the point at which the toe is off the bed. The patient is asked to hold that position while a gentle, steadily increasing resistance is applied to the heel (about 15 degrees of knee flexion). A positive finding is a reproduction of the patient's concordant pain/stiffness during any one of the three tests.

CLINICAL PEARL

A study by Cacchio et al.[217] examined the Puranen–Orava, bent-knee stretch, and modified bent-knee stretch tests and found all three to be of potential value in assessing chronic proximal hamstring tears in athletes. However, the authors recommended that the findings be used in conjunction with other objective measures, such as MRI.

In addition to the provocative tests, the passive motions of the hip can be examined with the innominate stabilized. T e hip motions and their respective innominate motions in parenthesis are outlined in Table 19-6.

Hamstring Flexibility Test. In contrast to the provocation tests, this hamstring test was developed to determine safe return to sports for athletes with an acute hamstring strain as a complement to the common clinical examination.[218] Before attempting this test, the patient must demonstrate normal hamstring strength for manual muscle testing in prone at 90, 45, and 0 degrees of knee flexion then the patient is positioned in supine with one leg strapped to the table and with the other leg placed in a knee extension splint. T e leg in the knee extension splint is taken through a ballistic straight-leg raise to the maximal ROM while monitoring for apprehension and insecurity. T e hip ROM is compared with the uninjured side. In the 2010 study, active flexibility was found to be greater (23%) than passive flexibility. In the athletic population, the injured leg showed smaller (8%) active, but not passive, flexibility than the uninjured leg. Average insecurity estimation using a VAS scale (0–100) was 52 (range 28–98) for the injured and 0 for the uninjured leg, respectively.[218]

Craig Test. T e Craig test is used to assess femoral anteversion/retroversion. T e patient is positioned in prone with the knee flexed to 90 degrees. T e clinician rotates the hip through the full ranges of hip internal and external rotation while palpating the greater trochanter and determining the point in the range at which the greater trochanter is the most prominent laterally. If at this point the angle is greater than 8–15 degrees in the direction of internal rotation, when measured from the vertical and long axis of the tibia, the femur is considered to be in anteversion.[127,130,199,219]

One study[219] showed this test to be accurate to within 4 degrees of intraoperative measurements, for the assessment of femoral anteversion/retroversion and was more accurate than radiographic measurement techniques.

Flexion–Adduction Test. T is test is used as a screening test for early hip dysplasia.[220] T e patient is positioned in supine, and the hip is passively flexed to 90 degrees and in neutral rotation while maintaining the contact of the patient's pelvis to the bed. From this position, the clinician monitors the pelvis and the hip is passively adducted (Fig. 19-40). T e resultant end-feel, restriction, discomfort, or pain is noted and compared with the normal side. A positive test for an early sign of hip dysplasia is the inability to adduct the flexed hip past midline toward the opposite hip. Although Woods and Macnicol[220] found the sensitivity to be 100% with this test, the test was performed on adolescents and demonstrated many design flaws.

Supine Plank Test. T is test is used to detect hamstring weakness or injury. T e patient is positioned in supine, resting on his or her arms and heels. T e patient is asked to elevate the pelvis while maintaining their body weight on the arms and heels (Fig. 19-41). T e patient is then asked to alternately lift one leg at a time. T e test is positive for weakness if pelvic collapse or rotation occurs, or for injury if pain occurs at the ischial origin or in the hamstring musculature.

Trendelenburg Sign. T e Trendelenburg sign indicates a weakness of the gluteus medius muscle during unilateral

FIGURE 19-40 Flexion–adduction test.

weight bearing.[221] T is position produces a strong contraction of the gluteus medius, which is powerfully assisted by the gluteus minimus and TFL, in order to keep the pelvis horizontal. For example, when the body weight is supported by the left foot (Fig. 19-19), the left hip abductors contract both isometrically and eccentrically to prevent the right side of the pelvis from being pulled downward by gravity.

T e clinician crouches or kneels behind the patient so that the eyes are level with the patient's pelvis, and ensures that the patient does not lean to one side during the testing. T e patient is asked to stand on one limb by flexing the opposite hip to approximately 30 degrees. T e patient may use a light touch with the ipsilateral upper extremity for balance, or the clinician may provide gentle manual pressure to maintain balance and reduce any trunk shift. Once balanced, the patient is asked to raise the nonstandard pelvis as high as possible. From the

FIGURE 19-41 Supine plank test.

posterior view, the clinician observes the angle formed by a line that connects the iliac crest and a line vertical to the testing surface. If the patient can maintain the elevation of the hip of the nonstance side for 30 seconds, the test is considered negative. A positive Trendelenburg sign is indicated if one of the following criteria are met[39]:

1. T e patient is unable to hold the elevated pelvic position for 30 seconds
2. No elevation is noted on the nonstance side
3. T e stance hip adducts, allowing the pelvis on the nonstandard side to drop downwardly below the level of the stance side pelvis (Fig. 19-19). A goniometer may be used to quantify the amount of pelvic movement by placing the axis of the goniometer on the ASIS, the stationary arm along an imaginary line between the two ASIS landmarks, and the moving arm along the anterior midline of the femur.[222]

A false-negative may occur if the patient is allowed to shift his or her trunk too far laterally over the stance limb (reverse Trendelenburg sign) in an attempt to prevent the contralateral pelvis from dropping and to reduce the demand on the hip abductors. A number of dysfunctions can produce the Trendelenburg sign. T ese include superior gluteal nerve palsy, lumbar disk herniation, weakness or tear of the gluteus medius, and advanced degeneration of the hip. T us, if used in isolation, this test has little diagnostic value.

Pelvic Drop Test. T e patient is asked to place one foot on a 20-cm (8-in) stool or step and to stand up straight. T e patient then lowers the non–weight-bearing leg to the floor (Fig. 19-42). On lowering the leg, there should be no arm abduction, anterior or pelvic motion, trunk flexion, or any hip adduction or internal rotation occurring at the weight-bearing

FIGURE 19-42 Pelvic drop test.

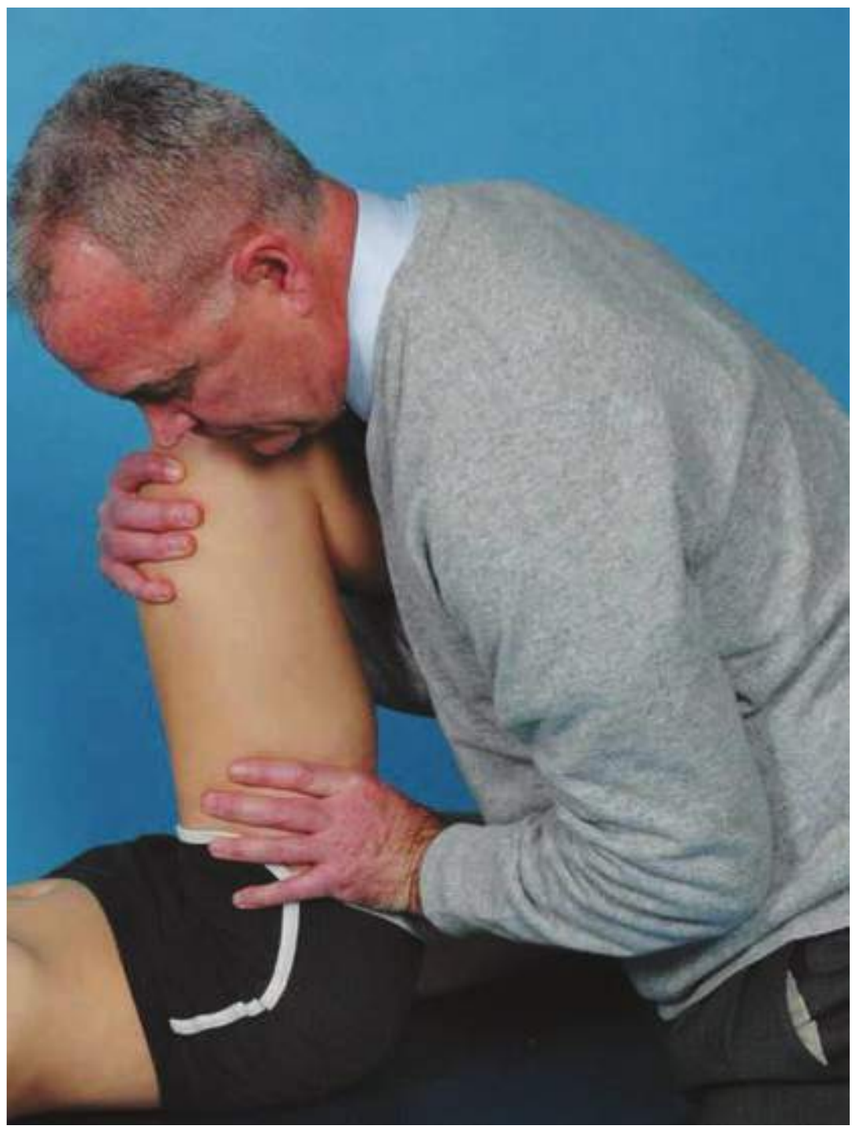

FIGURE 19-43 Piriformis stretch.

hip. T ese compensations are indications of weak external rotators or an unstable hip.

Piriformis Compression of the Sciatic Nerve. Piriformis compression of the sciatic nerve can be reproduced by maximally stretching the piriformis muscle.[174] T e patient lies supine with both legs flat on the examination table. T e clinician raises one leg and positions it in maximum flexion of the hip and knee. T e hip is then internally rotated and fully adducted (Fig. 19-43). Pain radiating down the leg constitutes a positive test for piriformis syndrome (see Chapter 5).

Stinchf eld's Test. Stinchfield's test, sometimes referred to as the resisted straight-leg raise test, is designed to help determine the source of a patient's back, buttock, groin, and/or leg pain. T e patient is positioned in supine and asked to lift their leg, without bending the knee, to about 30 degrees. If this maneuver does not reproduce any pain, the clinician applies pressure downward on the patient's raised leg, in an attempt to extend the flexed hip, while the patient resists the force (Fig. 19-44). Pain produced either with or without resistance is assessed for location. If the pain is felt in the groin or anterior thigh, it is considered to arise from the hip; if from the buttock or lumbar spine, the sacroiliac joint or lumbar spine is the likely source. Stinchfield's test should not be confused with the straight-leg raise test used to detect neuromeningeal problems (see Chapter 11). Stinchfield's test is not dependent on the range obtained but rather on the location of symptoms. T e only manner in which the two diagnoses could be confused is if a lumbar lesion was producing a restriction of the SLR at or below 30 degrees, but other signs and symptoms would help differentiate between the two. Unfortunately, Stinchfield's test has not been subjected to criteria validity research, so no sensitivity or specificity numbers are available.

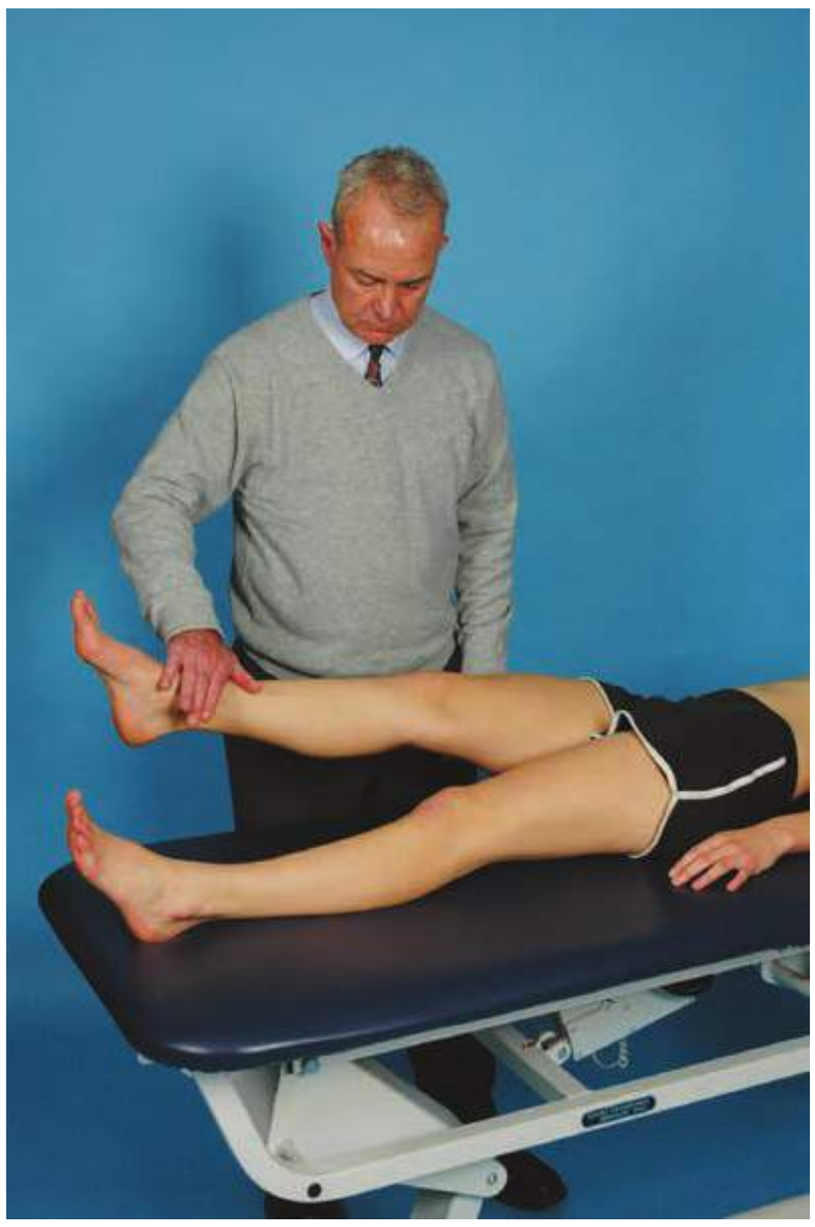

FIGURE 19-44 Stinchfield's test.

FIGURE 19-45 Auscultatory patellar-pubic percussion test.

Auscultatory Patellar-Pubic Percussion Test. The auscultatory patellar-pubic percussion test is used when there is a suspicion of an occult hip fracture.[223–225] The patient is positioned in supine, and the clinician places the head of a stethoscope over the pubic symphysis. With the lower extremities extended and positioned symmetrically, the clinician taps (percusses) each patella with a finger or reflex hammer and compares the generated sound (Fig. 19-45). The percussion note should have symmetrical quality and intensity of sound. Any bony disruption along the conduction path (femur) will result in a diminished or muffled sound intensity of a duller quality. Reliability and validity of the technique have been demonstrated.[223] Tiru et al.[226] noted a positive predictive value of 0.98, sensitivity of 0.96, and specificity of 0.76. Although the study design was not without fault, the test does appear to have diagnostic value as a screening tool and as a diagnostic tool. Thus, a positive patellar-pubic percussion test should prompt referral for diagnostic imaging.[223]

Muscle Length Tests

Flexibility testing of the hip assesses muscle length in order to identify adaptive shortening or excessive flexibility. Two-joint muscles are most commonly affected and need to be evaluated due to the greater tendency to suffer a muscle strain or tendon injury in these groups.[11] Restrictions in motion limit functional capacity, negatively impact posture, decrease muscle strength (by adversely affecting the muscle length–tension relationship), and can have an adverse effect on muscle and joint biomechanics. Excessive flexibility, or increase muscle length, has been associated with reduced muscle force output and impaired performance.[227]

Thomas Test and Modified Thomas Test. The original Thomas test was designed to test the flexibility of the iliopsoas complex but has since been modified and expanded to assess a number of other soft tissue structures. Neither the original test nor the suggested variations have ever been substantiated for reliability, sensitivity, or specificity.

The original test involves positioning the patient in supine, with one knee being held to the chest at the point where the lumbar spine is felt to flex (Fig. 19-46). The clinician assesses whether the thigh of the extended leg maintains full contact with the surface of the bed. If the thigh is raised off the surface of the table, the test is positive. A positive test indicates a decrease in flexibility in the rectus femoris or iliopsoas muscles or both. One of the limitations of this test is that it merely

FIGURE 19-46 Thomas test demonstrating adaptive shortening.

determines the amount of hip extension possible at any given degree of pelvic flexion.[228] Another problem is that there are better methods of measuring the flexibility of the iliopsoas complex. For example, positioning the patient in prone, stabilizing the pelvis, and then extending the thigh. T e precise point at which the pelvis begins to rise marks the end of the hip motion and the beginning of pelvic and spine motion.

A modified version of this test is commonly used to help eliminate the effect of the lumbar curve. For the modified version, the patient is positioned in sitting at the end of the bed. From this position, the patient is asked to lie back, while bringing both knees against the chest. Once in this position, the patient is asked to perform a posterior pelvic tilt. While the contralateral hip is held in maximum hip flexion by the patient's hands, the tested limb is lowered over the end of the bed toward the floor (Fig. 19-47). If normal, the thigh should be parallel with the bed, in neutral rotation, and neither abducted nor adducted, with the lower leg being perpendicular to the thigh and in neutral rotation. T ere should be 100–110 degrees of knee flexion present with the thigh in line with the table.

If the thigh is raised compared to the table, a decrease in the flexibility of the iliopsoas muscle complex should be suspected. If the rectus femoris is adaptively shortened, the amount of knee extension should increase with the application of overpressure into hip extension.[194] If the decrease in flexibility lies with the iliopsoas, attempts to correct the hip position should result in an increase in the external rotation of the thigh.[194]

T e application of overpressure into knee flexion can also be used. If the increase in knee flexion produces an increase in hip flexion (the thigh rises higher off the bed), the rectus femoris is implicated, whereas if the overpressure produces no change in the degree of hip flexion, the iliopsoas is implicated.

T is test can also be used to assess the flexibility of the TFL if the hip of the tested leg is maximally adducted while monitoring the ipsilateral ASIS for motion. T ere should be 20 degrees of hip adduction available.

Two things must be remembered when interpreting the results of this test:

- T e criteria are arbitrary and have been shown to vary between genders and limb dominance and to depend on the types and the levels of activity undertaken by the individual.[229]
- T e apparent tightness might simply be normal tissue tension, producing a deviation of the leg because of an increased flexibility of the antagonists.
- As always, the cause of the asymmetry must be found (or at least looked for) and addressed.

Ely's Test. T is is a test designed to assess the flexibility of the rectus femoris. T e patient is positioned in prone, and the knee is passively flexed by the clinician (Fig. 19-48). If the rectus is tight, the hip flexes on the same side and the pelvis is observed to anteriorly rotate early in the range of knee flexion. T e other side is tested for comparison. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Ober Test. T e Ober test is used extensively to evaluate the flexibility of the TFL (see T omas test).[230] T e patient is placed in the side-lying position, and with the hip extended and abducted and the knee flexed to 90 degrees, the proximal part of the tested leg is released and allowed to drop passively

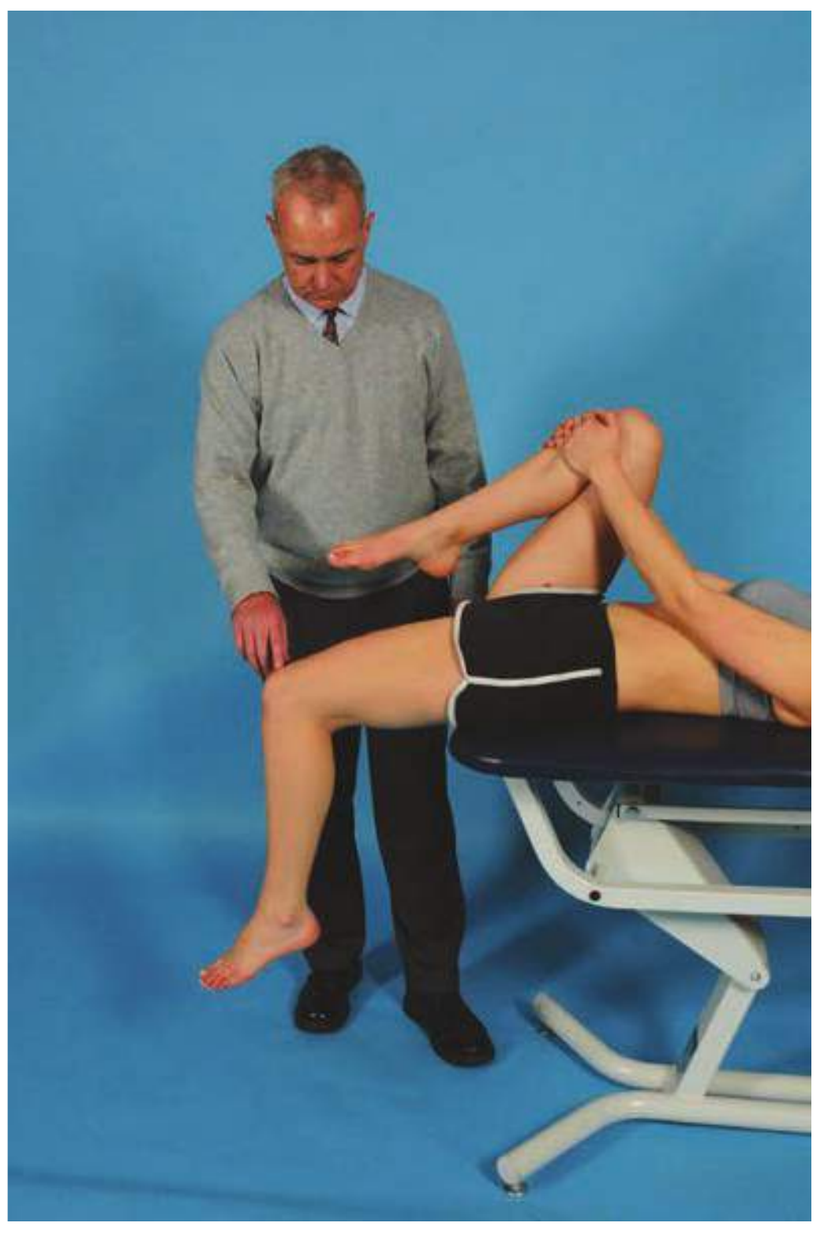

FIGURE 19-47 Modified Thomas test.

FIGURE 19-48 Ely's test.

FIGURE 19-49 Ober test.

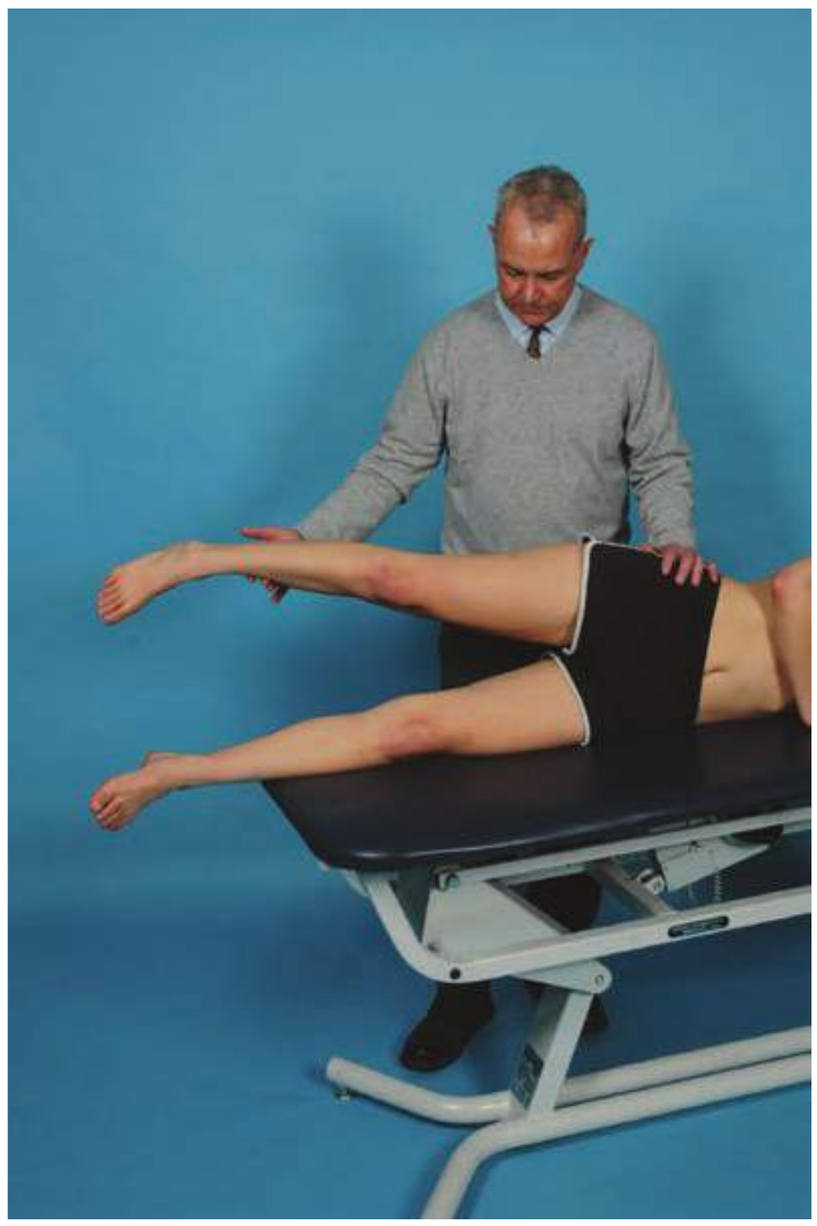

FIGURE 19-50 Modified Ober test.

(Fig. 19-49). The test is considered positive when the leg fails to lower. However, there have been some doubts expressed as to the reliability of the Ober test and to date, no diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.[231] Flexibility of the gluteus medius muscle and gluteus maximus muscle can be determined using this test by varying the angle of hip and knee flexion to bias the different muscle groups.[232] The gluteus medius can be assessed by flexing the knee while maintaining the hip in extension. The gluteus maximus can be assessed by flexing the hip and extending the knee and then asking the patient to roll the upper torso from the side-lying position to the supine position.

Modified Ober Test. The modified Ober test is performed in the same fashion as the Ober test except that the knee of the tested leg is extended (Fig. 19-50).[233] A study by Reese and Bandy[233] was performed to determine the intrarater reliability of the Ober test and the modified Ober test for the assessment of TFL flexibility using an inclinometer to measure the hip adduction angle and to determine if a difference existed between the measurements of TFL flexibility between the Ober and the modified Ober test. Sixty-one subjects, with a mean age of 24.2 (SD = 4.3) years, were measured during two measurement sessions over 2 consecutive days.[233] During each measurement session, subjects were positioned on their left side and, with an inclinometer at the lateral epicondyle of the femur, hip adduction was measured during the Ober test (knee at 90 degrees of flexion) and the modified Ober test (knee extended).[233] If the limb was horizontal, it was considered to be at 0 degree, if below horizontal (adducted), it was recorded as a positive number, and if above horizontal (abducted), it was recorded as a negative number. The ICC values calculated for the intrarater reliability of the repeated measurement were 0.90 for the Ober test and 0.91 for the modified Ober test.[233] Results of the dependent t test indicated a significantly greater ROM of the hip in adduction using the modified Ober test as compared to the Ober test.[233] The study concluded that the use of an inclinometer to measure hip adduction using both the Ober test and the modified Ober test appears to be a reliable method for the measurement of TFL flexibility, and the technique is quite easy to use.[233] However, given that the modified Ober test allows significantly greater hip adduction ROM than the Ober test, the two examination procedures should not be used interchangeably as a measurement of TFL flexibility.[233]

Straight-Leg Raise Test for Hamstring Length. The patient is positioned in supine with the legs staright and together resting on the table. The clinician stands on the side of the leg to be tested and grasps the patient's ankle with one hand while visually monitoring, or palpating the patient's opposite ASIS. With the patient's knee extended, the clinician lifts the patient's leg, flexing it at the hip until motion is detected at the ASIS (Fig. 19-51). The angle of hip flexion from the table is measured. The clinician returns the leg to the table and repeats the maneuver from the other side of the table with the other leg. The hamstrings are considered shortened if a straight leg cannot be raised to an angle of 80 degrees from the horizontal while maintaining the other leg straight.[185] Any limitation of flexion is interpreted as being caused by adaptively shortened hamstring muscles.

This straight-leg raise test may also be used as a screen for adverse neural tension, particularly of the sciatic nerve (see Chapter 11), and to differentiate between a hamstring

FIGURE 19-51 Straight-leg raise test for hamstring length.

lesion and a sciatic nerve lesion by adding ankle dorsiflexion (Fig. 19-52)—adding dorsiflexion places tension through the sciatic nerve but does not alter hamstring length.

90–90 Straight-Leg Raise. Hamstring length can also be assessed with the patient positioned in supine and the tested leg flexed at the hip and knee to 90 degrees. From this position,

FIGURE 19-52 Straight-leg raise test with ankle dorsiflexion.

FIGURE 19-53 90–90 Straight-leg raise.

the patient is asked to extend the knee of the involved side without extending the hip (Fig. 19-53). A measurement of knee motion is taken at the first resistance barrier.

Piriformis. T e FAIR (flexion, adduction, and internal rotation) test is designed to detect compression of the sciatic nerve by the piriformis (see Chapter 5). T e patient is positioned in side lying or supine with the involved extremity by the clinician. Holding the patient's knee, the clinician brings the involved extremity into a position of hip flexion, adduction, and internal rotation (Fig. 19-54). If pain is elicited at a point corresponding to the intersection of the sciatic nerve and the piriformis during this test, the result is considered positive.[234,235] T e FAIR test has been demonstrated to have a sensitivity of 0.88, a specificity of 0.83, a +LR of 5.2, and a −LR of 0.14.[234,236]

l eg-l ength Discrepancy

T e tests used to detect the presence of a leg-length discrepancy are described in Chapter 29.

Fulcrum Test

T e fulcrum test[237] is used to test for the presence of a stress fracture of the femoral shaft. T e patient is positioned in sitting, with their knees bent over the edge of the bed and feet dangling. T e clinician positions his or her arm under the thigh to be tested and moves it proximal to distal, as gentle pressure is applied to the thigh with the clinician's hand (Fig. 19-55). A positive test is when the patient reports sharp pain or expresses apprehension when the fulcrum arm is placed under the fracture site. T e fulcrum test has not been subjected to criteria validity research, so no sensitivity or specificity numbers are available.

FIGURE 19-54 FAIR test.

Diagnostic Imaging

The standard radiographic views of the hip include anteroposterior views and axial or frog leg views (see Chapter 7).

INTERVENTION STRATEGIES

The hip joint and surrounding tissues are prone to a number of common conditions, including joint dysfunction, soft tissue injuries, impingement syndromes, and muscle imbalances of strength and flexibility. Also, because of the high potential of symptom referral from other regions to this area, any intervention for the hip joint must take the entire lower kinetic chain (lumbar spine, pelvis, and lower extremities) into consideration.

FIGURE 19-55 Fulcrum test.

The techniques to increase joint mobility and soft tissue extensibility are described in the "Therapeutic Techniques".

Acute Phase

During the acute phase, the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are applied as appropriate. Elevation of the hip joint is usually not applicable or possible. The goals of the acute phase include

- protection of the injury site;
- restoration of pain-free ROM in the entire kinetic chain;
- improvement of patient comfort by decreasing pain and inflammation;
- retardation of muscle atrophy;
- minimization of the detrimental effects of immobilization and activity restriction[238–243];
- maintenance of general fitness;
- independence with a home exercise program.

The promotion and progression of healing usually involves a decrease in weight bearing with rest and/or modification of activities, or through the use of an assistive device. Assistive devices are often used to offset the load through the hip joint and to promote a symmetric gait pattern.[114,244] The use of a walker for maximum functional ambulation and safety may be required for some patients, particularly those with poor balance.[114]

The use of shoes with specially made cushion heels may further aid in diminishing the pain associated with weight bearing.

According to patient tolerance, the clinician should also attempt to remove any other stresses to the hip joint such as joint restrictions in the lumbar spine or sacroiliac joint, and any muscle imbalances.

The approach during this phase may depend on the specific tissue involved:

- Contractile tissue lesions are treated with rest, gentle friction massage, submaximal isometric exercises (glut sets, quad sets, ham sets), pain-free range-of-motion exercises (heel slides, supine hip abduction/adduction), and with appropriate modalities. Whenever possible, active exercises are performed within a functional context.
- Articular lesions are best treated by placing the joint in the open-packed position (flexion, abduction, and external rotation) and with grade I and II joint mobilizations.

A progressive stretching program is initiated for those muscles that are prone to adaptive shortening (the hip flexors, short hip adductors, sartorius, piriformis, rectus femoris, hamstrings, TFL, and ITB), and those that are prone to be weak or inhibited (glutei muscles and the lumbar erector spinae). Initially, the stretches can be performed using the milder techniques of post-isometric relaxation techniques and myofascial release before progressing to other techniques (see "Therapeutic Techniques" section) as symptoms subside. The stretch positions used are those that are used for testing muscle length. Self-stretching is taught to the patient at the earliest opportunity.

Balance and coordination retraining activities are usually performed in some form of weight bearing (sitting then standing), provided that there are no contraindications (pain

FIGURE 19-56 Reduced double-limb support.

or instability) to weight bearing.[114] Simultaneous contraction of hip extensors and abductors in weight bearing is the normal coactivation pattern used in early stance phase of gait.[114,186] Once the patient is able to weight bear, these exercises are initially performed with reduced double-limb support (Fig. 19-56) and then progressed to full single-leg support as the patient progresses (Fig. 19-57). Once the static weight-bearing exercises

FIGURE 19-57 Full single leg support on soft surface.

can be performed, sit–stand transfers and gait activities are introduced. Functional exercises, such as sit–stand–sit, require simultaneous activation of hip muscles coordinated with other trunk and limb patterns normally used to accomplish the activity.[114] Gait-training procedures during this phase involve the use of manual contacts at the pelvis to guide and stretch and to apply joint approximation or resistance to help promote the development of appropriate patterns of neuromuscular control.

The essential components of normal swing-phase gait to develop are

- posterior rotation of the pelvis during swing-phase flexion of the hip;
- a pelvic dip (drop) of no more than approximately 5 degrees on the side of swing limb;
- flexion of the hip to a maximum of 30 degrees (activation of hip flexors) with simultaneous knee flexion and dorsiflexion.

While standing, active hip flexion with adduction, combined with knee flexion, and dorsiflexion simulates the normal swing phase of gait and promotes balance control in weight bearing on the contralateral stance leg. A multi-hip machine can be introduced as the hip muscles become stronger.

Cardiovascular fitness can be maintained during this phase using an upper body ergometer. If tolerated, a stationary bicycle can be used.

Functional Phase

Once there is no pain, and when the ROM is equal to that of the uninvolved limb, the patient progresses to the functional stage. The patient should also be able to perform normal walking and daily activities without pain. The goals of the functional phase include

- restoring normal joint kinematics;
- improving muscle strength to within normal limits;
- improving neuromuscular control;
- restoring normal muscle force couple relationships.
- Return to normal function or athletic performance as appropriate.

The following exercises are recommended during this phase:

- Quadruped exercises incorporating rocking forward and backward. These exercises help to stretch the joint capsule and apply joint compression.
- Lunging (Fig. 19-58) VIDEO, squatting (Fig. 19-59) VIDEO, and hip circumduction (Fig. 19-60). These exercises increase functional ROM and strength while simultaneously stretching the capsule.
- Open-chain exercises using cuff weights or tubing may be used to develop strength and endurance of all of the hip musculature VIDEO (Fig. 19-61). The exercises are initially performed using concentric contractions and then advanced to eccentric contractions using a variety of speeds and resistance.

FIGURE 19-58 Lunge.

FIGURE 19-60 Hip circumduction.

- Strengthening of the hip flexors. T e straight-leg raise (Fig. 19-62) is a common exercise prescribed to strengthen the hip flexors. However, it is important to remember that there is significant force placed through the hip joint when the iliacus and psoas are weak.[9] If this weakness is present, increased force is placed on the gluteus minimus, adductor longus, pectineus, sartorius, TFL, and rectus femoris.[9]
- Strengthening of the hip extensors—gluteus maximus.[59] Despite the variety of exercises available to focus on

FIGURE 19-59 Squat.

FIGURE 19-61 Hip abduction with T-band.

the gluteus maximus, attention must be given to power, endurance, and eccentric control due to the varied functions of this muscle and the impact proper exercise will have on return to function.[59] A good introductory exercise to progressively strengthen the gluteus maximus is the body bridge progression starting with the body bridge (Fig. 19-63) and then progressing to the side body bridge (Fig. 19-64), and then the supine bent-knee bridge,

FIGURE 19-62 Straight-leg raise.

FIGURE 19-63 Body bridge.

FIGURE 19-64 Side-body bridge.

FIGURE 19-65 Supine bent-knee bridge.

where the patient lies supine with the hips and knees flexed, and the feet resting on the table and then raises the trunk until it is parallel with the thighs (Fig. 19-65) VIDEO. A variety of other bridging exercises exist, including unilateral bridging exercises (Fig. 19-66) VIDEO. Manually applied resistance can be superimposed on the pelvis or thighs to generate maximal muscular tension in the contracting muscles.

- Strengthening of the hip extensors—hamstrings. Careful exercise selection, including endurance-based and eccentric exercises, is important when rehabilitating the hamstrings.[59] T e exercise progression should include:
  - Supine bent-knee bridge walkouts. Bridge walkouts are completed once the patient is in the bridge position. In a controlled fashion, the patient ultimately walks the feet out while maintaining the bridge position at the hips. Once the patient reaches the end of the ROM, the patient returns the starting position (Fig. 19-67 and Fig. 19-68).
  - T e supine single-leg chair bridge (Fig. 19-69 and Fig. 19-70).
  - Unilateral good mornings with rotations (Fig. 19-71 and Fig. 19-72).
  - Lunges with torso rotations (Fig. 19-73).

FIGURE 19-66 Unilateral bridging.

FIGURE 19-67 Supine bent-knee bridge walkouts—start position.

FIGURE 19-68 Supine bent-knee bridge walkouts—end position.

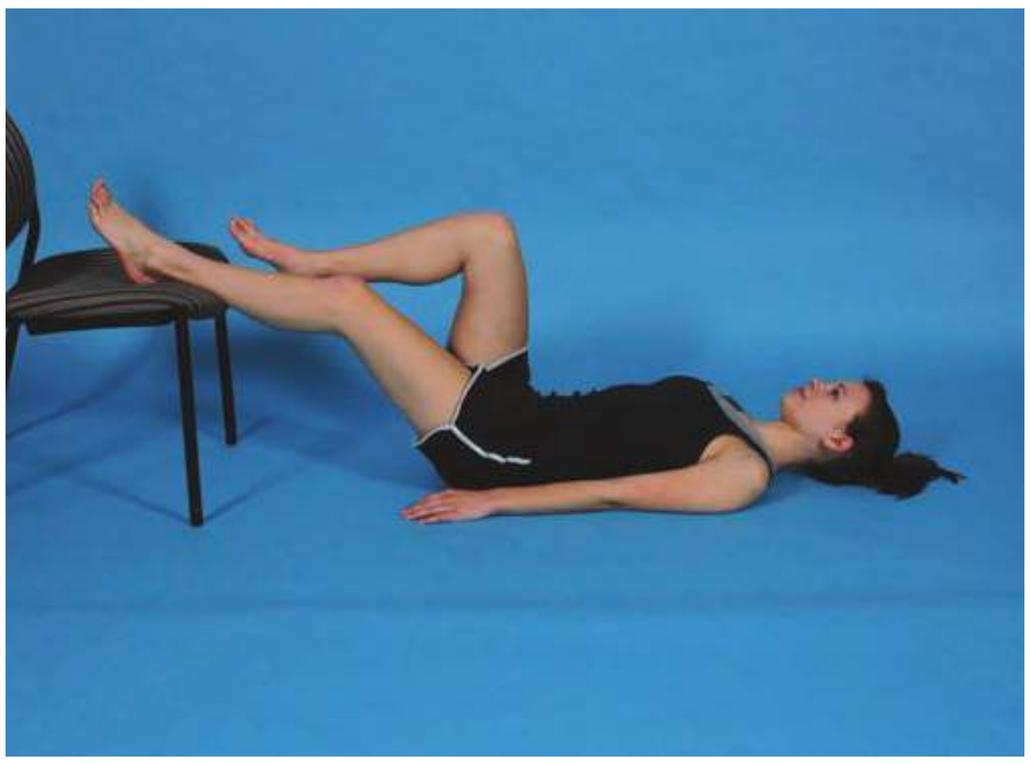

FIGURE 19-69 Supine single-leg chair bridge—start position.

- Hamstring lowers (Nordic drop curls). T is exercise involves the patient slowly lowering the trunk down toward the bed in a controlled fashion and using their arms to brace their fall once unable to control the eccentric movement (Fig. 19-74).
- Prone foot catches with ankle weight. T e patient lies prone with the hip flexed at the edge of the table and an ankle weight around the ankle. T e patient is asked to lift the leg until parallel with the table and then to drop the leg quickly while trying to slow the fall and pause just before the foot hits the floor.
- Prone hip extension with ankle weight. It is important to remember that during prone hip extension, the largest forces through the hip occur when the gluteus maximus is weakened.[9] T e patient is positioned in prone with the hip extended off the edge of the bed for full ROM. T e patient lifts the leg parallel to the floor and then drops and catches the leg before it touches the floor.
- Grapevine stepping (Fig. 19-75) VIDEO. T e grapevine stepping exercise, using the right leg as an example, is performed by asking the patient to stand with the feet

FIGURE 19-70 Supine single-leg chair bridge—end position.

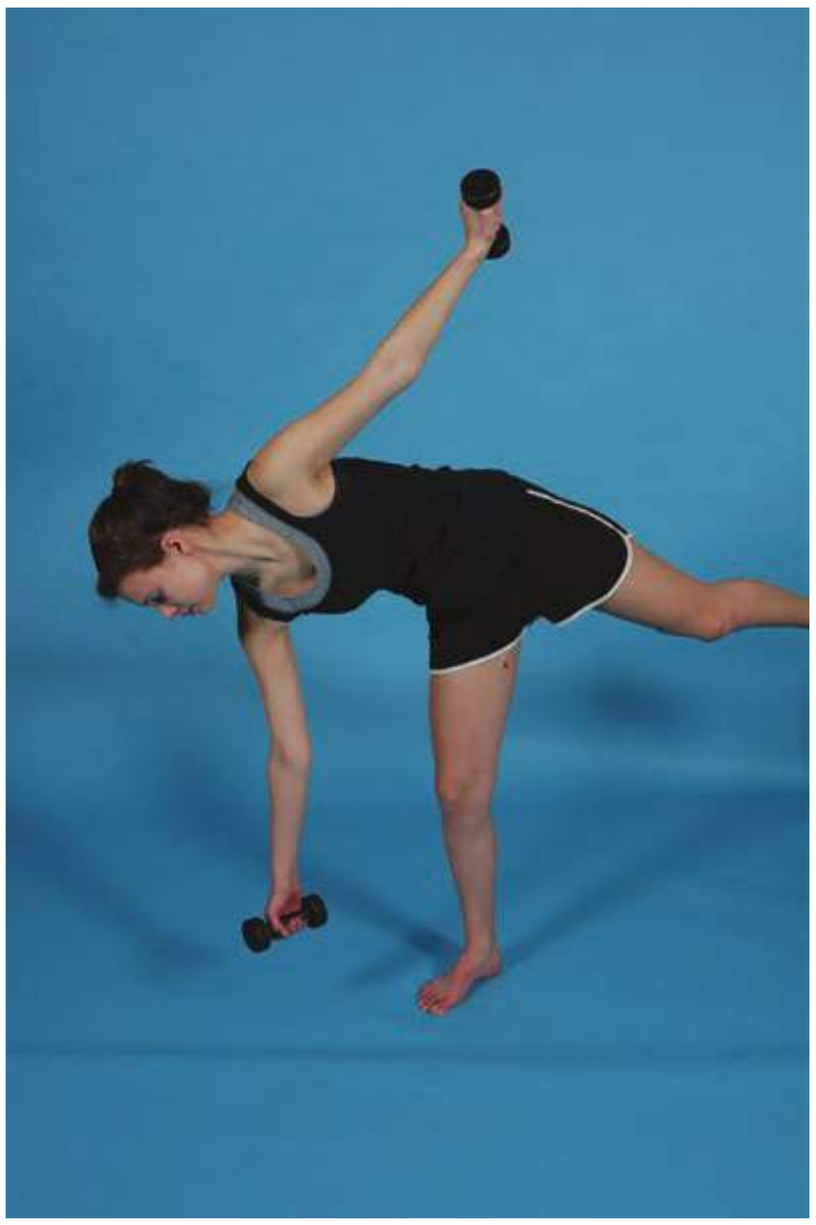

FIGURE 19-72 Unilateral good mornings with rotations.

FIGURE 19-74 Hamstring lowers.

together. The patient is then asked to take one step to the right, and then using the left leg to step behind and slightly to the right of the right foot, thereby crossing the left leg behind the right leg. The left foot should be pointed toward the right heel, but not directly behind it (Fig 19-75). The patient is then asked to take a step to the right with the right foot, and then to move the left foot so that the feet are together again. The routine is then repeated. The exercise is then performed moving to the left.

FIGURE 19-73 Lunge with torso rotations.

FIGURE 19-75 Grapevine stepping.

- Strengthening of the hip adductors.[59] This muscle group requires specific exercise selection to increase the strength of what is the most vulnerable of the four hip quadrants due to its decreased mechanical advantage. Exercises for this region require activation in the transverse plane due to the key role as complex plays in controlling hip and trunk rotation. The performance of bilateral lower extremity activities necessitates simultaneous activation of the abductor muscles to control femoral-on-pelvic and pelvic-on-femoral movements.[50] For example, this activation pattern occurs when sidestepping over a puddle, where the stance limb incorporates pelvic-on-femoral stabilization and eccentric activation of the abductors to maintain control, while the contralateral mobile limb uses femoral-on-pelvic and chain movement coupled with eccentric firing of the adductor pulling the body into the direction of the limb clearing the puddle. The close relationship and proximity of the hip adductors and trunk musculature in injuries like athletic pubalgia also necessitate the inclusion of eccentric and endurance-based exercises to enhance stabilization to complete pain-free function.
- Strengthening of the gluteus medius muscle is often an important component of the hip rehabilitation program. The primary function of these muscles is to abduct the limb away from the midline during open-chain activity and to maintain a level pelvis during closed-chain activities, such as walking.[59] The greatest amount of hip joint compressive force comes from the muscular activation of the hip abductor group and this force is necessary to maintain frontal plane stability during activities such as gait.[50] Compensation due to weakness of the hip abductors has significant consequences and should be immediately addressed with exercises that facilitate strength, endurance, and stabilization of the lateral quadrant muscles.[59] Recommended exercises include the side bridge, sidestepping, wall squat, forward stepup, quadruped upper and lower extremity lift, and standing hip abduction (weight bearing on the target/opposite extremity). Additionally, the gluteus medius can be strengthened in side lying, with the upper leg in slight hip extension and external rotation VIDEO (Fig. 19-76), the pelvic rise and drop exercise (Fig. 19-77), which also strengthens the quadratus lumborum, stool rotations (Fig. 19-78) and the clam shell exercise progression (Figs. 19-79 to 19-82). Once the clam exercise can be performed without resistance, the following theraband progression can be used: clamshell in supine (Fig. 19-83), clamshell in side lying (Fig. 19-84), and clamshell bridge (Fig. 19-85).[245] A neutral pelvis position is advocated to optimize recruitment of the gluteus maximus and gluteus medius during the clam exercise.[246] An increase in the hip flexion angle increases activation of the gluteus medius.[246] In contrast, TFL activity is relatively low and generally unaffected by variations of the clam exercise.[246] One of the challenges when trying to isolate the gluteus medius is the presence of the TFL, which in addition to being a hip abductor, is also an internal rotator of the hip. If the goal of rehabilitation is to preferentially activate the gluteal muscles while minimizing TFL activation, then the clam, sidestep, unilateral bridge, and both quadruped and hip extension exercises appear to be the most appropriate.[247]

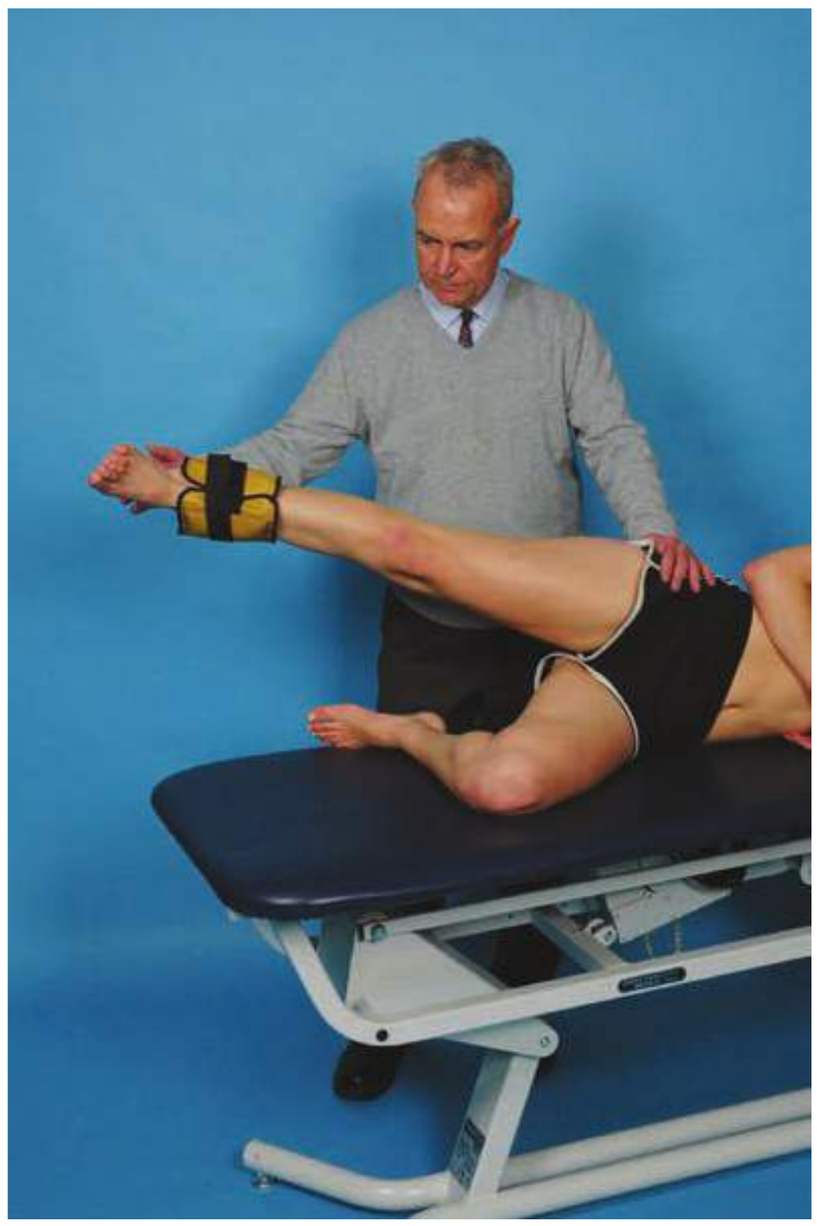

FIGURE 19-76 Gluteus medius strengthening.

CLINICAL PEARL

In those individuals with acetabular undercoverage, biasing the posterior fibers of the gluteus medius with strengthening exercises may be most beneficial.[9]

- T e stationary bicycle can be used to increase lower extremity strength, endurance, and range during repetitive reciprocal movements of the lower extremities.[114] EMG analysis of lower limb muscles during pedaling has shown that the highest peak of activity for the gluteus maximus and biceps femoris muscles (as hip extensors) occurs during the pedal downstroke.[248] Stationary bicycling has also been found to be as effective for increasing ROM at the hip joint as static stretching.[249] T e stationary bicycle is a convenient mode of exercise for home use; however, the use of vigorous protocols should be carefully monitored for cardiac effects, especially in light of the fact that both blood pressure and heart rates have been found to increase markedly during this type of exercise.[114,250]
- Pool walking, swimming, and kicking may also be incorporated if available.
- Enhancing core stability. Core stability, which is the cornerstone of athletic participation, is the body's capacity to maintain or resume a position or trajectory following perturbation.[251,252] Core stability may be assessed and trained in many ways (see Chapter 28) including the following:
  - Side plank with leg raise (Fig. 19-86).
  - Stirring the pot using a Swiss ball (Fig. 19-87A,B).

FIGURE 19-86 Side plank with leg raise.

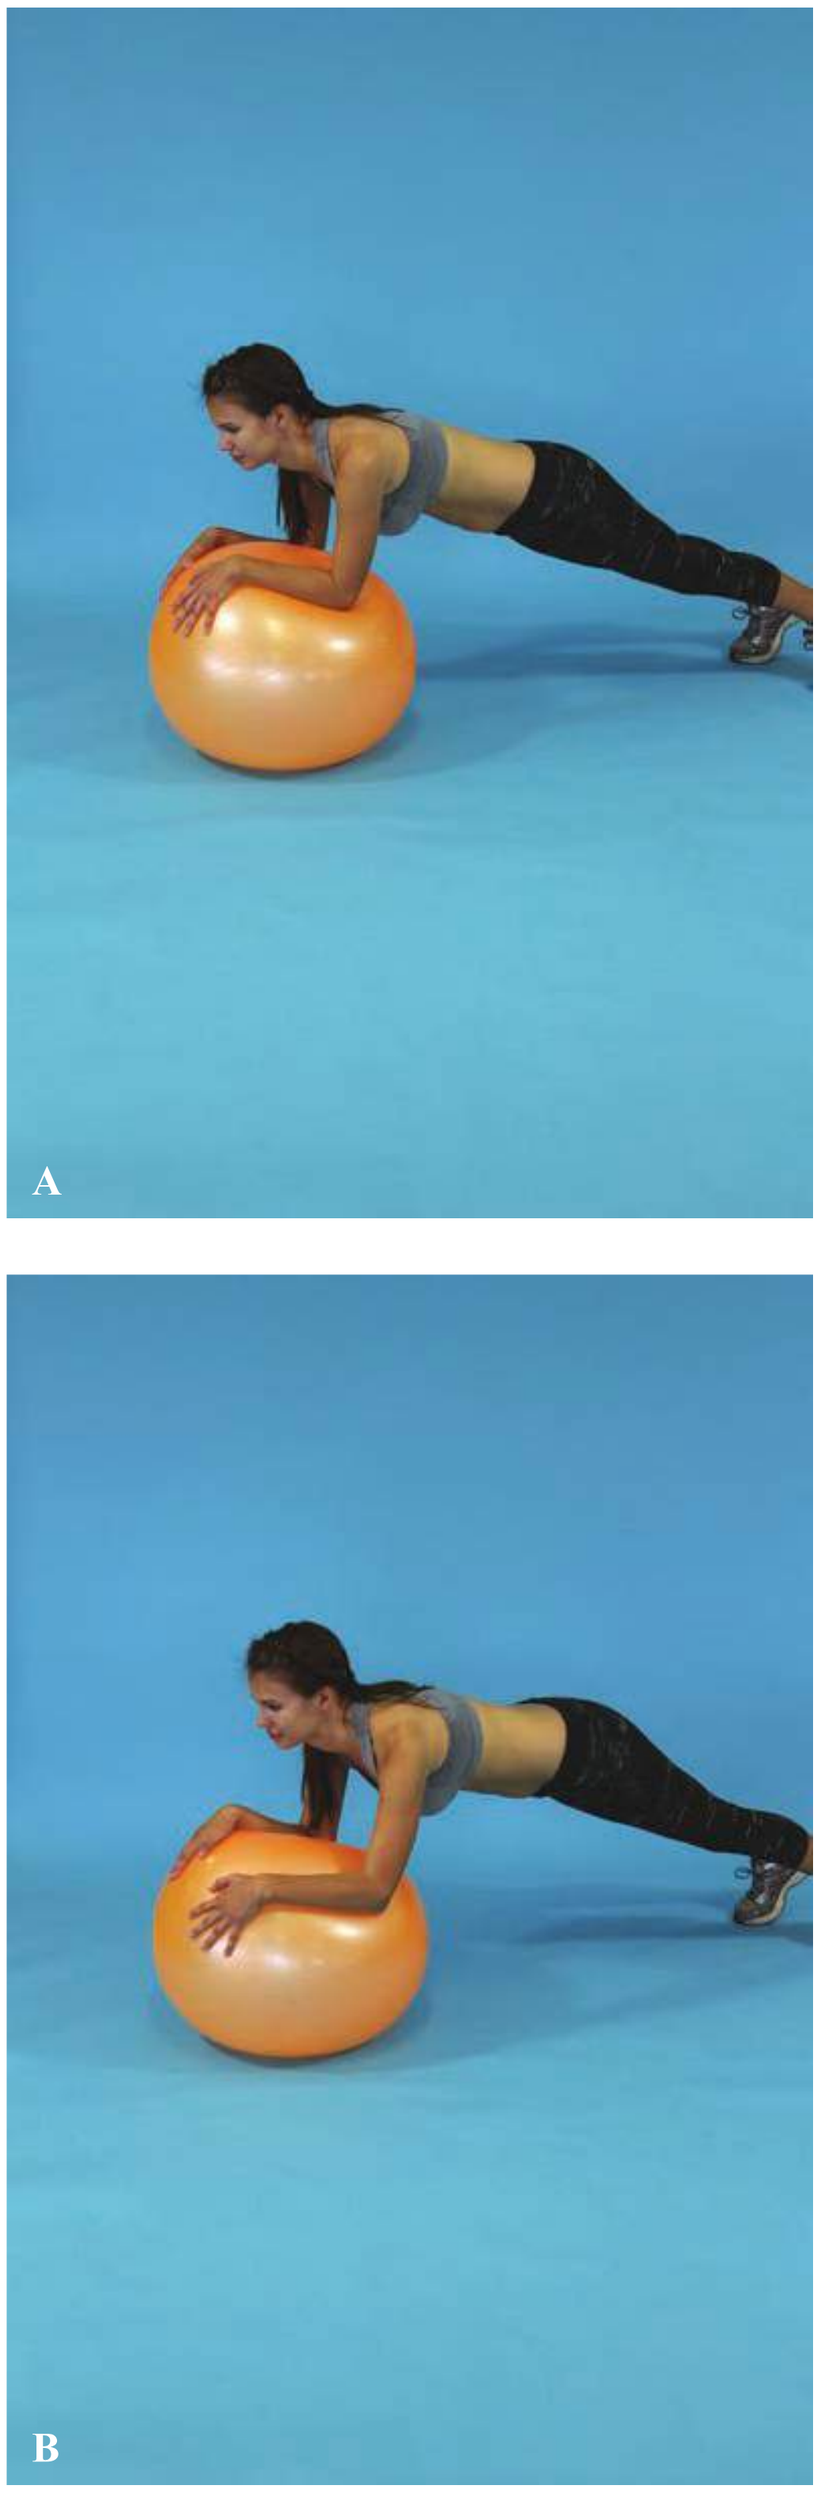

FIGURE 19-87 Stirring the pot using a Swiss ball.

  - Medicine ball throws (Fig. 19-88).
  - Boxing drills (Fig. 19-89).
- Neuromuscular reeducation exercises for the hip. T ese are prescribed to emphasize specific movement patterns and sequencing of muscle contractions. T ese exercises demand a high level of control and coordination.[253–256]

FIGURE 19-88 Medicine ball throws.

Ambulation activities can be used initially, progressing to more difficult unilateral extremity exercises.

- Task-oriented exercise programs (work hardening). These should be instituted for the patient who intends to resume a type of employment that requires a predetermined level of work performance.

FIGURE 19-89 Boxing drills.

- Exercise progressions for the returning athlete. These exercise programs attempt to incorporate activities that simulate the actual circumstances and patterns of contraction used in the sport.[114,257] Examples of two such protocols are outlined in Tables 19-16 and 19-17. In order to decrease joint loading, the returning athlete should be encouraged to use a mid- to forefoot initial contact instead of heel contact.[9] One study[153] found an inverse relationship between step rate and vertical excursion, braking impulse, and step length, with significantly less joint loading with a 5% or 10% increase in step rate, which were most likely due to decreased step length.[9] The functional strengthening programs for athletes should focus on the hip abductors and external rotators to decrease knee adduction moments during the single-leg stance.[258] In addition, particularly in those athletes involved in sprinting activities, the clinician must address hamstring rehabilitation and ensure correct pelvic positioning so that the hamstrings are not unduly stressed by an abnormal anterior pelvic tilt. Due to the fact that the hamstrings do large amounts of negative work during end-phase swing while sprinting,[259] and the fact that the biceps femoris has the highest amount of peak strain during activity,[259] rehabilitation of the hamstrings should involve a high degree of focus on eccentric strengthening.

Practice Pattern 4A: Primary Prevention/Risk Factor Reduction for Skeletal Demineralization

Idiopathic Transient Osteoporosis of the Hip

Osteoporosis is the most prevalent bone disease among the aging population, and osteoporotic hip fractures account for substantial morbidity, mortality, and healthcare costs.[260] Two types of osteoporosis are distinguished on the basis of age of presentation[261] and differing rates of loss of cortical or trabecular bone.[262] Type I is characterized by vertebral fractures in postmenopausal women at about the age of 65 years; type II may occur in both sexes at about 75 years of age and produces mainly osteoporotic hip fractures.[262]

Men with osteoporosis of the hip are likely to have an underlying metabolic abnormality contributing to bone loss. The most common etiologies in men are hypogonadism, alcohol and corticosteroid use, anticonvulsant use, malabsorption syndromes, hyperthyroidism, and neoplasias.[263] Many factors have been cited for women, including decreased bone mass with an accelerated loss after menopause, parity, smoking, alcohol consumption, various medications, and diet. Although the reasons are unclear, in male patients either hip may be involved, whereas, in women, the left hip is involved much more frequently.[264]

Hip pain begins spontaneously, without an antecedent history of trauma. The condition is aggravated by weight bearing. The symptoms may become severe enough to result in a limp. The clinical findings are self-limiting and resolve in 2–6 months without permanent sequelae.[264] Biopsy of the synovium reveals normal findings or slight (mild, minimal, or equivocal) chronic inflammation.[265]

Radiographic findings are characteristic and become apparent within weeks or months of the onset of clinical

TABLE 19-16 Return to Sport for Runners Following Soft Tissue Injury

Aerobic capacity and endurance

Cycling

- Incorporating appropriate warm-up and cool-down intervals, cardiovascular conditioning may be performed on stationary bicycle as symptoms permit or regular.
- Attention to proper bike fit is important, as hip and back pain may result from improper biking biomechanics.
- If biking has not been used as a cross-training method in the past, an appropriate base building period is necessary:
  - 3–5 minute warm-up at 70–90 rpm, at 55–65% of age-estimated maximum heart rate.
  - 10–15 minutes at 80–90 rpm, at 70–75% of age-estimated maximum heart rate, building this phase at no more than 3–5 minutes per session, as symptoms and cardiovascular condition permit.
  - 3–5 minute cool-down at 70 rpm, at 55–65% of age-estimated maximum heart rate.

Aqua jogging

- Deep-water jogging has been shown to be an effective mode of cross-training for runners, with good specificity of carryover.
- Use of a flotation device (Wet Vest) will enhance the comfort of beginners.
- Appropriate warm-up and cool-down intervals should be incorporated, as well as a base building period if this is an unfamiliar activity.

Running

As soon as symptoms permit, a return to running should be initiated. This should consist of level-ground or treadmill running at first, at a speed that brings the heart rate no higher than 60% of age-estimated maximum (warm-up pace), for durations that do not exacerbate symptoms (generally less than 15 minutes). As symptoms permit, duration (mileage) should be increased by no more than 10% per week. Once a substantial base of mileage has been built with no return of symptoms, the addition of speed-specific training may be incorporated. This may consist of "fartlek" (short bursts of acceleration within a longer run) or "tempo" (runs of longer duration at or near race pace), or it may be more regimented intervals using a track and stopwatch.

- For marathoners, the distance covered on any interval may range from 400 m at 10K race pace to 3–5 miles at marathon race pace.
- For shorter-distance runners, the intervals would be relatively shorter. For example, a 10K racer may do intervals of 100–400 m at 5K-race pace and 400 m up to 2 miles at 10K-race pace.

Speed-specific intervals should be performed no more than once per week initially and should be pursued cautiously. Total speedwork distance should make up no more than 10% of total weekly mileage.

Additional strengthening may be obtained with the incorporation of hill repeats.

Specific hill training should be performed no more than twice per week and pursued cautiously.

- Monitoring of heart rate will assist in avoiding excessive speed on the uphill.
- Maintaining proper form on the downhill will reduce risk of impact injuries.
- To avoid overuse injury, periodization of mileage, terrain, interval training, proper footwear, etc., is crucial. For example, the following beginning marathon training schedule demonstrates good periodization of intensity, duration, and terrain:
  - Sun: 10 miles at 70% of age-estimated maximum heart rate on rolling trails.
  - Mon: 3 miles at 70% of age-estimated maximum heart rate on rolling hills.
  - Tues: 6 miles at 70% of age-estimated maximum heart rate on rolling hills.
  - Wed: Off or alternate form of training (e.g., swimming and biking).
  - Thurs: 5 miles, consisting of 1-mile warm-up, 2–3 miles of interval work at 80–85% of age-estimated maximum heart rate, and 1-mile cool-down (track).
  - Fri: 3 miles at 70% of age-estimated maximum heart rate on flat pavement.
  - Sat: Off or alternate form of training.

Balance/proprioceptive re-education

Balance/reach drills

The following exercises are performed at three to five sets of 10–15 reaches:

- Unilateral stance balancing, reaching one or both arms in various directions to maximum distance, avoiding use of other leg for counter-balance. Additional challenges can be added by holding a light weight or medicine ball or by using resistive tubing.
- Anterior reach: the anterior reach stimulates hamstrings, soleus, gastrocnemius, and hip/back extensors (depending on height of reach).
- Posterior overhead reach: the posterior overhead reach stimulates the gluteals, quadriceps, and hip/back extensors.
- Rotational reach to side: this reaching exercise stimulates the gluteals, quadriceps, trunk stabilizers, hip abductors, and abdominals.

TABLE 19-16 Return to Sport for Runners Following Soft Tissue Injury (Continued)

Strengthening

Open kinetic chain exercises

The following exercises are performed using weight machines, cuff weights, or resistive tubing, at three to five sets of 15–18 repetitions:

- Hip flexion
- Hip extension
- Hip abduction
- Hip adduction

Closed kinetic chain functional exercises

The following exercises are performed: three to five sets of 15–18 repetitions, observing for deterioration of proper form because of fatigue.

Squats. Progression is made from mini-squats to deeper squats as symptoms permit, with additional challenges from additional weight.

Lunges. Progression is made from straight anterior/posterior and lateral lunges to rotational lunges as appropriate, increasing distance lunged or using additional weight as appropriate.

Step-ups/step-downs. Variations are made with step height and direction of step (lateral, anterior, posterior, or rotational) as appropriate, with additional challenges of increasing distance from step or use of additional weight as appropriate.

Flexibility

Flexibility exercises

These exercises are performed once the athlete has warmed up, for example, after walking at least 3–5 minutes, or after a warm shower or bath. Emphasis should be on proper technique and form. The stretch should be held for at least 15–30 seconds.

The patient performs three to five repetitions of each stretch on both sides on a regular basis.

- Gastrocnemius/soleus
- Hamstrings
- Quadriceps
- Gluteals
- Psoas

Data from Schunk C, Reed K. Clinical Practice Guidelines. Gaithersburg, MD: Aspen; 2000.

findings. Osteoporosis is not usually found in the acetabulum but may be seen in the femoral neck. Progressive and marked osteoporosis of the femoral head is identified on plain radiographs.[265] The joint space is normal and the femoral subchondral bone is usually intact.

The differential diagnosis includes avascular necrosis, OA, septic arthritis, and rheumatoid arthritis.[265] The intervention for osteoporosis is discussed in Chapter 5.

Practice Pattern 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated With Connective Tissue Dysfunction

Osteoarthritis

OA of the hip, which is a disease of the entire joint complex and the surrounding musculature, is one of many causes of hip and groin pain in older patients. It is important to identify patients with symptomatic OA correctly and to exclude conditions that may be mistaken for, or coexist, with it.[171,172]

The overall rate of hip OA in the United States is between 3% and 5%, with an incidence of between 47 and 88 per 100,000 individuals.[266] Studies in the natural history of hip OA clearly demonstrate heterogeneity of disease progression and the lack of universal agreement as to the definition of progression of hip OA. Most define progression by radiological features such as loss of joint space, osteophytes, and sclerosis.[267,268] However, the demonstration of a correlation between radiographic features and clinical symptoms is not easy in OA: factors differentiating symptomatic OA from asymptomatic disease are unknown.[269] The two clinical sequelae of OA are joint pain, joint stiffness, and functional impairment.

Hip OA, which can eventually result in structural and functional failure of the joint, usually begins insidiously, although in a few cases it may start abruptly. Consequently, although patients with hip OA share the same pathology, they present with varying combinations of underlying impairments.[270] The development of OA at any joint site depends on a generalized predisposition to the condition and abnormalities of biomechanical loading, which act at specific joints.[271] Individual risk factors, which may be associated with a generalized vulnerability to the disorder, include family history, obesity, and hypermobility of the joint.[272] Those that reflect local biomechanical insults include minor trauma to an already diseased joint, abnormalities of joint shape, and physical activity.[272]

The pain of hip OA can vary greatly in both its site and its nature, sometimes making early diagnosis difficult.[273] Periarticular pain that is not reproduced by passive motion suggests an alternate etiology such as bursitis, tendinopathy, or periostitis. The distribution of painful joints also helps to distinguish OA from other types of arthritis, because MCP, wrist, elbow, ankle, and shoulder arthritis are unlikely locations for OA, except after trauma. The pain may be felt in the buttock, groin, thigh, or knee and varies in character from

TABLE 19-17 Return to Sport Following Osteitis Pubis

Phase I

1. Static adduction against soccer ball placed between feet when lying supine; each adduction is held for 30 seconds and is repeated 10 times.
2. Abdominal sit-ups performed both in straight direction and in oblique direction. The patient performs five sets to fatigue.
3. Combined abdominal sit-up and hip flexion (crunch). The patient starts from supine position and with a soccer/basketball placed between knees. The patient performs five sets to fatigue.
4. Balance training on wobble board for 5 minutes.
5. One-foot exercises on sliding board, with parallel feet as well as with a 90-degree angle between feet. Five sets of 1-minute continuous work are performed with each leg, and in both positions.

Phase II (from third week)

1. Leg abduction and adduction exercises in side lying. The patient performs five series of 10 repetitions of each exercise.
2. Low-back extension exercises while in prone over the end of treatment table. The patient performs five series of 10 repetitions.
3. One-leg weight-pulling abduction/adduction standing. The patient performs five series of 10 repetitions of the exercise for each leg.
4. Abdominal sit-ups both in straightforward direction and in oblique direction. The patient performs five sets to fatigue.
5. One-leg coordination exercise, flexing and extending knee and swinging arms in same rhythm (cross-country skiing on one leg). The patient performs five sets of 10 repetitions for each leg.
6. Skating movements on sliding board. This is performed five times for 1-minute continuous work.

Data from Holmich P, Uhrskou P, Ulnits L, et al. Effectiveness of active physical training as treatment for long-standing adductor-related groin pain in athletes: Randomised trial. Lancet. 1999; 353:439–443.

a dull ache to sharp and stabbing. The C sign (Fig. 19-90) may be encountered when asking the patient describe the location of the pain—the patient will cup the hand above the greater trochanter with the thumb posterior and the fingers gripping deep into the anterior groin when describing deep interior hip pain.[274] The discomfort associated with hip OA is generally related to activity and the bouts of pain can last for several hours.[273] Stiffness of the hip is usual, particularly after inactivity, and can be the presenting feature. Symptoms that include prolonged morning stiffness (greater than 1 hour) should raise suspicion of inflammatory arthritis, such as RA. As the disease progresses, the patient experiences difficulty in climbing stairs with the involved leg and may have difficulty in donning socks or stockings.[275] In advanced cases of the disease, the patient may complain of severe pain that is present at night or during rest, and there is a marked decline in the participation of recreational activities.

OA is characterized by progressive biomechanical joint changes, including degeneration and loss of articular cartilage, joint capsule contracture, loss of periarticular flexibility, and increased intracapsular pressure.[276] Early physical signs include restriction of internal rotation and abduction or flexion of the affected hip, with pain at the end of the range.[273] Cyriax and Russell[277] described a typical capsular pattern of motion loss of the hip that included flexion, abduction, and internal rotation. However, more recent literature has challenged this concept of capsular pattern motion loss that is associated with OA.[167] The most common losses of motion seen with hip OA are internal rotation and flexion.[278] Birrell et al.[168] noted that as the number of restricted planes of hip motion increases, the specificity, or ruling in of the diagnosis of hip OA, increases. As specificity increases, sensitivity, or the ruling out of a diagnosis of hip OA, decreases in those patients with mild-to-moderate and severe OA of the hip.[168,173] This is trade-off, where sensitivity decreases while specificity increases, is common with sensitivity and specificity.[173] The diagnostic value of decreased ROM in the hip is best when present in two or three planes of motion (positive likelihood ratio of 2.5–5), as compared to just one plane of motion (positive likelihood ratio of 1.9).[168,173]

FIGURE 19-90 The C sign.

A diagnosis of hip OA can usually be confirmed by radiography; joint space width of 2.5 mm or less indicates substantial loss of cartilage in the hip joint, and osteophytes, subchondral bone sclerosis, or cysts are usually present.[273] As mentioned, though, radiographs can be misleading because of the relative insensitivity of their findings with clinical signs and symptoms. Two separate studies by Bierma-Zeinstra et al.[279] and Altman et al.[280] examined the relationship between patients with clinical signs and symptoms of hip OA and radiographic findings. The clinical diagnosis of early hip OA according to Bierma-Zeinstra et al.[279] includes such variables as decreased external rotation, no pain aggravation with sitting, and over 60 years of age. The criteria from the Altman et al. study included hip internal rotation less than 15 degrees and an age of over 50 years. Diagnostic measurement properties, like sensitivity, specificity, and likelihood ratios, are probabilistic statistics; consequently, false-positive and false-negative results will always be potentially possible.[173]

The narrowing of the joint space associated with OA could potentially slacken the supporting ligaments, rendering them less effective and producing changes in proprioceptive input. Indeed, OA of the hip has been associated with deficits in a patient's proprioception and balance.[281,282] The joint space narrowing may also result in a relative decrease in the length of the muscles that cross the hip joint, which could feasibly

result in a mechanical disadvantage of the muscles that act on the hip joint. In addition, OA of the hip can have many manifestations in neighboring joints, particularly the lumbar spine and the foot. T is is likely because the joint stiffness associated with the disease diminishes the amount of rotation available at the hip, forcing the lumbar spine and foot to compensate for this loss.

Any treatment for hip OA needs to address the modifiable musculoskeletal and functional impairments that are associated with activity limitations in the absence of a cure for the disease.[283] Systematic reviews have concluded that exercise reduces the pain and disability associated with hip OA. Weigl et a1.[284] showed that strengthening exercises, flexibility, relaxation, and endurance training decreased pain and improved physical function in patients with OA.[173] van Baar et al.[285] showed that exercise improved function and reduced pain in patients with hip OA, but later found that the beneficial effect of exercise declined over time.[173,286] Research on the use of manual physical therapy in the treatment of hip OA is limited. Hoeksma et al.,[287] in a randomized clinical trial comparing the effectiveness of two different therapy programs in a group of patients with hip OA, demonstrated the superiority of manual physical therapy plus exercise over exercise alone for improving pain and ROM. MacDonald et al.,[288] in a case series describing the outcomes of individual patients with hip OA treated with manual physical therapy and exercise reported that all patients exhibited reductions in pain and increases in PROM, as well as a clinically meaningful improvement in function. T e inherent limitations of the case series, however, do not allow for the identification of a cause-and-effect relationship. Further research, including randomized clinical trials, is necessary to uncover the exact effect of manual physical therapy and exercise in the treatment of hip OA.[288]

Based on the above research, the primary goals of treatment are to relieve pain, maintain joint function and mobility, reduce joint swelling, reduce the risk of disease progression, and to modify risk factors, particularly obesity. As with the intervention of other joints, it is standard practice to perform objective assessments of physical function (using both physical performance and self-report measures) to obtain a picture of patient status prior to initiating any intervention. T ese assessments serve as a baseline value for estimating changes over time.

Intervention in the earlier stages includes:

- Patient education and empowerment through advice about what patients can do for themselves, joint protection advice, and the benefits of physical therapy. Patients are often frightened that use of the hip will "wear out" an already damaged joint and feel they need "permission" to use it.[273] Evidence suggests that the involved joint will benefit from regular loading to help maintain its integrity (see below).
- Modalities for muscle relaxation, pain relief, and anti-inflammation. It has been proposed that excessive muscular contractions can lead to cartilage wear in people with hip OA resulting in abnormal loading of the hip.[270] T eoretically, adaptively shortened structures around the hip could also cause abnormal loading. It is, therefore, important to include retraining of the hip abductor muscles to regain optimal control of these structures.
- Strengthening exercises for the trunk stabilizers and the major muscle groups of the hip region, especially the gluteus medius.
- Stationary cycling. T is exercise can be used to optimize the benefits of the manual therapy, enhance aerobic capacity, and help strengthen the lower extremities.
- Balance and proprioception training. High rates of falls have been reported among people with chronic musculoskeletal pain of any cause and people with hip OA.[289] T e causes of these falls are thought to be balance impairments that are related to deficits in knee extensor strength and decreased lower limb proprioception.[290] T us, gait, neuromuscular, and balance retraining exercises should be included.
- Manual techniques. T ese should include techniques to mobilize the joint and techniques to passively stretch the hip joint capsule. Since alternating periods of joint compression and decompression are thought to be the mechanism by which joint cartilage is lubricated, techniques that add compression and distraction may assist in the stimulation of synovial fluid flow.[288,291] Two common techniques can be used[290]:
  - Long-axis distraction with thrust. T e patient is positioned in supine, and the hip is positioned in 15–30 degrees of flexion, 15–30 degrees of abduction, and slight external rotation, the clinician performs 3–6 thrusts at the beginning of the first set, then performs oscillations, preferably using a seat belt, in the remaining 3–6 sets.
  - Seatbelt glide, or distraction mobilizations. T e patient is positioned in supine with the hip flexed to 15–30 degrees, abducted to 15–30 degrees of abduction, and slightly externally rotated. T e clinician applies 3–6 sets of oscillatory passive accessory mobilization forces inferiorly or laterally to the proximal thigh.

Following these techniques, a stretching program into flexion, abduction, and external rotation should be initiated to help counteract the typical capsular pattern. T e FABER position, or cross-legged sitting where appropriate, is ideal for this. In addition to mobilizations for the hip joint, lumbar spine mobilization techniques should also be included due to the fact that low back pain may occur as a consequence of hip OA, and the fact that a loss of lumbar spine mobility in the frontal plane may adversely affect normal weight shift during gait.[292–295]

- Home exercise program. T e home exercise program should include strengthening exercises for the hip abductors and quadriceps, stretching exercises for the hip extensors, flexes, abductors, and external rotators, and a progression of functional neuromuscular balance/gait drills.[290] T e level of difficulty for each of these exercises should be individually based.

Patients need to learn an appropriate balance and intersperse periods of activity with rest, as prolonged or heavy activity involving the diseased hip may cause further damage.[296]

There is no evidence for the involvement of any dietary factor in the etiopathogenesis of hip OA.[273] However, it is possible that obesity may accelerate progression or cause more pain. A reduction in weight can significantly improve a patient's symptoms, increase mobility, and improve health status.[297] Many people with arthritis of the spine or legs are more comfortable wearing trainers or other shoes with good shock-absorbing properties than they are in regular footwear. Sorbithane and other shock-absorbing insoles, which are available in sports and shoe shops, may be helpful.[273]

Finally, the patient should be advised

- to engage in adequate warm-ups before exercising;
- to pay attention and respect the limitations of their body and not exercise if in discomfort;
- not to use medication to cover up pain from exercising;
- to increase general levels of physical activity, such as low-to-moderate intensity walking with or without an assistive device. A simple walking stick can make a big difference, reducing loading on a hip by 20–30%, but attention must be given to its length, characteristics, and use. In most cases, it will be most beneficial if it is held on the uninvolved side of the body and that it comes to the top of the pelvis and has a good ferrule and comfortable handle.[273] In addition, cycling, and/or swimming can be included as appropriate.[290] Contact sports and activities such as jogging, which can cause repetitive high impact loading of the hip, are probably best avoided.[296]

Rheumatoid Arthritis

Rheumatoid arthritis is a systemic, inflammatory, and chronic disorder of unknown etiology, which is characterized by periods of exacerbation and remission, and which eventually results in destruction of the joint surfaces and progressive disability.[275]

In the early phases of the disease, systemic manifestations such as malaise, weight loss, and ability fatigue are seen.[275] The patient typically experiences vague pain and stiffness in the hip, especially when arising from bed in the morning. With time, the stiffness and pain become more severe and persistent and is accompanied by protective muscle spasms. Eventually, a hip flexion contracture develops.

Conservative intervention involves pharmacologic management and active exercises of the hip within the limits of the pain to preserve joint motion and maintain good muscle tone.[275] The activity modifications outlined for OA of the hip are also advocated during periods of remission. The patient is instructed on joint protection skills and to take frequent breaks.

Total Hip Arthroplasty

The THA is a common procedure performed in cases of severe joint damage resulting from OA, rheumatoid arthritis, displaced femoral neck fractures, and aseptic necrosis.[298] Arthroplasty of the hip may be categorized as a THA or a hemiarthroplasty. In a THA, the articular surfaces of both the acetabulum and femur are replaced. This is involves either replacement of the femoral head and neck (conventional THA) or replacement of the surface of the femoral head (resurfacing THA); both procedures also replace the acetabulum. In contrast to a THA, a hemiarthroplasty involves replacement of the articular surface of the femoral head without any surgical alteration to the acetabular articular surface. Two main types of hemiarthroplasty exist:

- Unipolar. This is procedure involves replacement of the femoral head and the neck and tends to be used for less active and older patients who are unlikely to outlive the hip implant.
- Bipolar. This is procedure involves replacement of the femoral head and neck. Either the acetabular is replaced by an acetabular cup (bipolar hemiarthroplasty), or the surface of the femoral head is replaced (resurfacing hemiarthroplasty).

CLINICAL PEARL

A proximal femoral osteotomy is a procedure that relies on maintaining the biological integrity of the femoral head as the preservation of the blood supply to the femoral head is of the utmost importance. The proximal femoral osteotomy is commonly used for the treatment of hip fracture nonunions and malunions and in cases of congenital and acquired hip deformities. The postsurgical rehabilitation protocol is similar to that of the total joint replacement.

Ankylosing Spondylitis

Ankylosing spondylitis (AS), also known as Marie–Strümpell disease or rheumatoid spondylitis, is a form of inflammatory arthritis, usually characterized by initial involvement of the sacroiliac joints, later involvement of the spinal joints, and occasional involvement of the hip joints and other joints of the body (refer to Chapter 5).[275] The patient is usually between 15 and 40 years, and AS affects one to three per 1,000 people. Although males and females are affected evenly, mild courses of AS are more common in the latter.[299] Clinical findings in the hip may include an early capsular pattern of motion restriction.

An exercise program is particularly important for these patients to maintain functional outcomes (see Chapter 5).[300] The goal of exercise therapy is to maintain the mobility of the involved joints for as long as possible and to prevent stiffening. A strict regime of daily exercises, which include positioning and spinal extension exercises, breathing exercises, and exercises for the peripheral joints must be followed. Several times a day, the patient should lie prone for 5 minutes to help maintain hip and spinal extension, and they should be encouraged to sleep on a hard mattress and avoid side lying. Swimming is the best routine sport.

Osteonecrosis of the Femoral Head

Osteonecrosis, or avascular necrosis of the femoral head, is a condition in which there are progressive ischemia and secondary death of osteocytes or bone cells of the femoral head, resulting in the collapsing of bone of the femoral head and the later development of degenerative arthritis.[275] Osteonecrosis of the femoral head is described in more detail in Chapter 5.

Nonarthritic or Intra-articular Hip Disease

Nonarthritic or intra-articular hip disease, also referred to as chronic hip joint pain (CHJP) is a major cause of hip dysfunction in young adults that leads to significant activity limitations.[301] Diagnoses associated with CHJP include structural instability, chondral lesions, ligamentous teres tears, acetabular labral tears, and FAI. It should be noted that these conditions are not necessarily mutually exclusive, and at times may be related to each other.[39] Without proper management, conditions associated with CHJP may progress to hip OA. Diagnoses of nonarthritic hip joint conditions are made by clinicians based on a combination of imaging and clinical findings, even though there is no consensus on the diagnostic criteria to rule in or rule out a specific condition.[39] Potential differential diagnoses include referred pain from lumbar facet disorders and/or lumbar disk disorders, sacroiliac joint dysfunction, pubic symphysis dysfunction, lumbar spinal stenosis, nerve entrapment (lateral femoral cutaneous nerve of the thigh, obturator), hip osteoarthrosis, iliopsoas tendinopathy/bursitis, adductor strain, obturator internus strain, inguinal hernia, sports hernia (athletic pubalgia), stress fracture (proximal femur or pelvic), avulsion injury (sartorius or rectus femoris tendon), gynecological disorders, neoplasm, osteomyelitis, septic arthritis, rheumatoid arthritis, prostatitis, and metabolic bone disease. In the younger population, Legg–Calvé–Perthes disease and slipped capital femoral epiphysis should be considered.

CLINICAL PEARL

One proposed mechanism of injury in persons with CHJP is repetitive hip rotation with axial loading:[28,302]

- Repetitive hip internal rotation may contribute to increasing compressive forces in the anterior hip joint, leading to mechanical impingement and subsequent injury to the acetabular labrum and articular cartilage.[303]
- Repetitive external rotation may result in an accumulation of tensile stresses to the capsuloligamentous structures and acetabular labrum, leading to injury and potentially microinstability of the hip.[28]

Structural Instability

Hip instability, which may be traumatic, atraumatic, or secondary to bony or soft tissue abnormality, may be defined as an extraphysiologic hip motion that causes pain with or without the symptom of hip joint unsteadiness.[304] Traumatic hip instability can be caused by a hip dislocation or subluxation, which occurs posteriorly in 90% of cases.[213] Immediately following a dislocation, the lower extremity is typically in a position of adduction, internal rotation, and flexion, and is observed to be shorter than the uninvolved side.[11] Reduction should occur rapidly by a trained individual following appropriate diagnostic evaluation for fracture.[11] Microinstability of the hip, defined as the inability to keep the femoral head centered within the acetabular fossa without subluxation of the joint, may occur for a variety of reasons. Factors associated with structural instability of the hip joint include a shallow acetabulum, an excessive femoral anteversion, and in the presence of Ehlers–Danlos, Marfan, or Down syndrome, which all produce generalized laxity.[9,305] When combined with repetitive forceful activities, these characteristics have been associated with the development of a labral tear as the labrum attempts to maintain the congruent relationship between the femur and the acetabulum. This is particularly true in the presence of a compromise to the static stabilizers, including the capsule, iliofemoral ligament, and the labrum, which may create compensation to the iliopsoas and hip abductors.[9]

The clinical presentation of atraumatic hip instability typically involves the following[11]:

- An insidious onset of anterior hip or groin pain that may be exacerbated by end-range hip extension and external rotation.[11]
- No motion loss, but excessive motion may be observed, especially in hip external rotation and extension.
- A positive dial test (see "Special Tests") may be present.
- Tenderness may be noted in the anterior aspect of the hip and protective muscle guarding may be observed.

Atraumatic hip instability is evaluated using both standard radiographs and MRI or MRA.[11]

Chondral lesions

A chondral lesion is typically associated with a tear of the acetabular labrum, and little is known about the prevalence of isolated chondral lesion. Chondral lesions have been reported in younger, more active individuals as a source of hip pain.[306,307] The cause of such a lesion is thought to involve acute overloading through impact sustained by a blow to the greater trochanteric region.[308]

ligamentum Teres Tears

As described previously in the chapter, the ligamentum teres may function as an intrinsic joint stabilizer that resists hip joint subluxation forces. Injury to this structure may be classified as follows[11]:

- A ligament tear (partial or complete). A ligament tear can occur in the case of a hip dislocation or subluxation. Hip instability may be associated with a traumatic tear with severe cases reporting a giving way during weight bearing.
- Ligament hypertrophy (degenerative tearing). This type is more common in individuals who perform repetitive hip external rotation and extension motion under an axial load as is observed in ballet dancing and figure skating.[309]

Isolated injuries to the ligamentum teres are generally considered rare, and the correlation between injuries to the ligamentum teres and clinical presentation is not well understood.[39] Clinical findings include[39]:

- Anterior groin pain for generalized hip joint pain.
- Pain is reproduced with the FADIR or FABER test.
- Reports of mechanical symptoms such as popping, locking, or snapping of the hip.
- There may be reports of feelings of instability, and the sensation of instability when squatting.

Acetabular labral Tear

Labral tears of the hip are more common than previously thought. In patients with mechanical hip pain, the prevalence of labral tears has been reported to be as high as 90%.[21,310,311] In studies of people with a tear of the labrum, researchers have attributed the injury to a variety of causes.[74] Mechanical impingement and/or instability of the femoroacetabular joint are believed to be common causes of labral chondral pathology. Direct trauma, sporting activities, and certain movements of the hip, including torsional or twisting movements have been cited to cause labral tears.[74] However, a large percentage of labral tears are not associated with any known specific event or cause and may occur insidiously.[305] Two common types of scenarios have been recognized:

1. A young person with a twisting injury to the hip, usually an external rotation force in a hyperextended position.
2. An older person with a history of hip and/or acetabular dysplasia, or the result of repeated pivoting and twisting.

Acetabular labral tears represent the most common cause for mechanical hip symptoms. In a recent study, they were found to be the cause of groin pain in more than 20% of athletes presenting with groin pain.[312]

Labral tears can be classified according to location, etiology, and type[313]:

- Location. With respect to location, tears can be anterior, posterior, or superior (lateral) although anterior and anterosuperior tears appear to be the most common.[313] Anterior labral tears are also common in patients with a degenerative hip disease or acetabular dysplasia. T e most likely reason for the prevalence of anterior labral tears is that this region is subjected to higher forces or greater stresses than other regions of the labrum.[74] Because of the anterior orientation of both the acetabulum and the femoral head, the femoral head has the least bony constraint anteriorly and relies instead on the labrum, joint capsule, and ligaments for stability.[74]
- Etiology. Tears can be degenerative, dysplastic, traumatic, or idiopathic. Degenerative tears can also be seen in association with inflammatory arthropathies. Traumatic labral tears often present with immediate sharp pain and mechanical symptoms such as catching, locking or clicking.[11] In the cases of an insidious onset, a dull type pain is described as intermittent sharp pain occurring with certain movements; typically, hip internal or external rotation.[314]
- Type. Labral tears have been classified into four types: radial flap (the most common type), radial fibrillated, longitudinal peripheral (least common), and abnormally mobile.[314] Seldes et al.[45] classified acetabular labral tears into type 1 and type 2 on the basis of their anatomical and histological features.
  - Type 1 tears consist of a detachment of the labrum from the articular cartilage surface. T ese tears tend to occur at the transition zone between the fibrocartilaginous labrum and the articular hyaline cartilage.[44] T ey are perpendicular to the articular surface and, in some cases, extend to the subchondral bone.
  - Type 2 tears consist of one or more cleavage planes of variable depth within the substance of the labrum.[44]

Both types of tears are associated with chondrocyte proliferation and hyalinization of the labral fibrocartilage along the edges of the defect. All labral tears are associated with increased microvascularity within the substance of the labrum at the base of the tear adjacent to the labrum's attachment to bone.[44] Osteophyte formation is also sometimes seen in labral tears.

Diagnosis can often be made on the basis of the history and physical examination although the diagnosis is often delayed or is often misdiagnosed.[169] T is is largely due to the fact that labral tears can have a variety of clinical presentations associated with a wide degree of clinical findings.[44]

- History. Since a labral lesion produces a decrease of pressure within the joint and causes an increase in the laxity of that joint, symptoms of a labral tear are usually mechanical: buckling, catching, twinges, clicking, locking, instability, and painful clicking. T ere may or may not be a history of trauma. In the presence of a recalled incident, the trauma can vary from severe to very mild.[44] T e injury is usually caused by the hip joint being stressed while in rotation. T e pain is mainly in the anterior groin (most commonly) but can be in the lateral or posterior thigh and/or medial knee region.[44] It can have an acute onset or be gradual, and it is common for it to be sharp with a clicking, snapping, catching, or locking sensation.[44] Activities that involve forced adduction of the hip joint in association with rotation in either direction tend to aggravate the pain.[44]
- Physical examination. On examination, ROM of the hip may or may not be limited, but, in those cases where it is not limited, there may be pain at the extremes.[44] T ere is little information regarding the sensitivity, specificity, or likelihood ratios associated with a single clinical test or a cluster of tests in diagnosing a labral tear.[314] Generally speaking, the combined movement of flexion and rotation causes pain in the groin. More precisely, the specific maneuvers that may cause pain in the groin[315,316] include.

Cl INICA1 PEAR1

Hip internal rotation with overpressure and the FABER test have been shown to demonstrate the highest sensitivity, compared to the resisted straight-leg raise and scour test in identifying intra-articular hip pain.[317]

- flexion, adduction, and internal rotation of the hip joint (impingement test/scour test) while it is held in at least 90 degrees of flexion and at least 15 degrees of adduction—positive with anterior—superior tears, anterior labral tears, and iliopsoas tendinopathy;
- passive hyperextension, abduction, and external rotation (with posterior tears), with the patient lying supine at the edge of the table; a positive finding with this test is apprehension or exquisite pain and suggests anterior hip instability, an anterior labral tear, or posteroinferior impingement;

- resisted straight-leg raise test;
- flexion of the hip with external rotation and full abduction, followed by extension, abduction, and internal rotation (anterior tears)[318];
- extension, abduction, and external rotation brought to a flexed, adducted, and internally rotated position (posterior tears).[318]

Strength deficits may or may not be present in patients with an acetabular labral tear. In general, the clinician should suspect an acetabular labral tear when a patient has the following combination of signs and symptoms:

- no restrictions in ROM
- normal radiographs
- complaints of a long duration involving anterior hip or groin pain and clicking
- pain with passive hip flexion combined with adduction and internal rotation
- pain with an active straight-leg raise[74]

The diagnosis is typically confirmed with MRA, MRI, and intra-articular anesthetic injections.[11]

The appropriate physical therapy intervention for a patient with an acetabular labral tear has yet to be established.[74] Conservative intervention has traditionally included bed rest with or without traction, followed by a period of protected weight bearing and use of nonsteroidal anti-inflammatory medication. Lewis and Sahrmann[74] recommend the use of key elements of the examination to develop a plan of intervention (Table 19-18). Operative treatment consists of arthrotomy or arthroscopy with resection of the entire labrum or the portion of the labrum that is torn. Postoperatively, the protocol can be divided into three phases[301,312]:

Phase 1 (days 1–7):

- Weight bearing to tolerance with crutches.
- Isometric quadriceps, gluteal sets.
- AROM in all planes of motion.
- Closed-chain bridging, weight shifts, and balancing exercise.

TABLE 19-18 Conservative Intervention for Acetabular Labral Tears Based on Examination Findings

Examination	Intervention
Positions and movement tests	Standing alignment, particularly noting the presence of hip hyperextension, as evident in the hyperextension or pelvic posterior tilt, or both In a sitting position, femoral motions accompanying the extension Precision of both active and passive hip flexions In the prone position, the pattern of hip extension as an indication of the relative participation of the hamstring and gluteus maximus muscles Effect of passive knee flexion on femoral motion in the prone position Pattern and range of hip rotation in prone and sitting positions; this assessment includes asymmetric ranges, suggesting the presence of femoral anteversion or retroversion In the quadruped position, the alignment of the hip joint and the presence of symptoms both while in the position and when rocking backward toward the heels
Muscle strength (force-generating capacity of muscle) and pattern of control	Hip abductor, gluteus maximus, iliopsoas, and deep external rotator muscles when not painful; the deep external rotator muscles are best tested with the hip flexed
Muscle length and stiffness	Medial and lateral hamstring muscles
Gait assessment	Particularly noting a lack of appropriate knee flexion at heel strike and early stance phase, prolonged foot flat during stance, and knee hyperextension that causes hip hyperextension Walking with the hip in external rotation as an improper correction of femoral anteversion
Modification of functional activities	Avoid sitting - with knees lower than hips - with legs crossed or sitting on legs so that the hip is rotated - on the edge of the seat and contracting hip flexor muscles - with pressure on the femur, which can cause forces into the hip joint; instead, the pressure should be on the ischial tuberosity When getting up from a chair that is behind a desk or out of the car, patients should avoid pushing or rotating the pelvis on a loaded femur When walking on a treadmill, patients must be careful not to let the moving tread contribute to excessive hip hyperextension Patients should avoid weight training of quadriceps femoris and hamstring muscles and avoid any exercises causing hip hyperextension

Data from Lewis CL, Sahrmann SA. Acetabular labral tears. Phys Ther. 2006; 86:110–121.

- Open-chain standing abduction, adduction, flexion, and extension with no resistance.
- Avoidance of straight-leg raise exercises.

Phase 2 (weeks 2–3):

- Progress to ambulation without crutches and normalize gait.
- Progress ROM exercises to gradual end-range stretch within tolerance.
- Stationary bike, if tolerated.
- Open-chain above the knee-resistive theraband or light pulley exercises.

Phase 3 (weeks 4–6):

- Continue flexibility exercises.
- Progress resisted strengthening and closed-chain exercises. Emphasis is placed on hip and lumbopelvic stabilization, correction of hip muscular imbalance, and biomechanical control.[319]
- Functional, and sports-specific functional, activities introduced as tolerated.

Femoral Acetabular Impingement

FAI occurs when there is an abnormal contact between the femoral head/neck and the acetabular rim.[320] FAI has been associated with labral and chondral damage.[209] The presence of a slipped capital femoral epiphysis has also been noted to cause FAI.[321]

Three types of FAI have been described based on the bony morphology of the acetabulum and the femoral head: cam and pincer.[314,322]

- Cam. Cam impingement occurs when there is a structural abnormality of the femur due to a bony overgrowth of the femoral neck, which causes an abutment against the acetabular rim and the chondrolabral junction. This deformity causes abnormal contact between the femur and the acetabulum, particularly when hip flexion is combined with adduction and internal rotation. The cam impingement has been implicated in the etiology of anterosuperior labral and chondral lesions.
- Pincer. The pincer type of impingement is caused by a bony abnormality of the acetabulum due to an increase in the size of the acetabular rim, effectively creating a deeper hip socket. This is overcoverage can be general (coxa profunda) or local anterior (acetabular retroversion).
- A combination of the cam and pincer impingements (mixed type), which is likely the most common category.[323]

Pincer impingements are thought to be more common in middle-aged women participating in athletics, while cam impingements are more common in young athletic males. Both forms of FAI can cause damage to the acetabular chondrolabral structures as the hip joint moves through the extremes of joint motion, due to repetitive bony impingement on either the acetabular labrum or the articular cartilage surfaces due to the bony incongruity.[324]

Although this condition can occasionally be asymptomatic, common clinical findings include the following[39]:

- Pain, which is described as aching or sharp, in the anterior hip/groin and/or lateral hip/trochanter region. The pain is usually worse with prolonged hip flexion positions and rotational activities.
- Pain with activities such as walking, pivoting, and recreational exercise.
- Reports of mechanical symptoms such as popping, locking, or snapping of the hip.
- Anterior hip pain is typically aggravated by prolonged sitting (i.e., riding in a car) and is reproduced with FADIR test.
- Loss of certain hip ranges of motion. The hip should be tested for flexion, extension, adduction, and abduction ROM maximums. With the hips flexed to 90 degrees and the pelvis stabilized, the maximal internal and external rotation should be noted. A common finding is a limitation of hip internal rotation (less than 20 degrees with the hip at 90 degrees of flexion), as well as a decrease in hip flexion, and hip abduction.[33] In a study by Philippon et al.[325], the FADIR (anterior impingement) test (see "Special Tests") was positive in 99% of individuals with FAI.

Suspicions can be confirmed with radiographic findings, which are considered to be the gold standard for diagnosis of FAI.

loose Bodies

In advanced cases of OA, the hip joint becomes susceptible to a chondral injury with subsequent loose bodies of cartilage or bone (ossified and nonossified) within the joint. These injuries can occur both traumatically and nontraumatically, with the latter related to articular or synovial disease processes.[11] The traumatic type is caused by excessive shear stress across the articular surface.[11] If the loose body is large enough, it will cause a distraction in the joint, which will produce muscle inhibition and problems with gait and weight bearing.

The patient typically reports sudden leg pain twinges with weight bearing and periodic giving away of the leg. Clinical findings include a springy end-feel in the hip during passive hip extension (the close-packed position of the joint), which is often painless.

Byrd and Jones[169] reported that MRA was highly sensitive for detecting articular cartilage injury in the hip compared to plain MRI. Once confirmed, the intervention usually involves arthroscopic techniques to remove the loose body.

Hip Arthroscopy

The arthroscopic management of hip disorders has continued to increase over the past decade as the number of patients with hip complaint continues to grow. Intra-articular hip pathologies that were once managed with an open surgical hip dislocation can now be managed through minimally invasive, arthroscopic techniques, generally in an outpatient setting. The most common conditions treated by hip arthroscopy include cartilage lesions, labral tears, FAI, the snapping hip, and loose bodies.

Postoperative hip rehabilitation following arthroscopic surgery can be broken down into four phases[33]:

1. Initial rehabilitation. T is phase begins immediately following surgery and usually continues until about 4 weeks postoperatively (6 weeks for more complex procedures). T e primary goal of this phase is to protect the repair tissue and facilitate healing. A postoperative brace is often used to maintain motion restriction and protect the joint and is normally required for 10–14 days. Weight-bearing restrictions are procedure dependent. Criteria to advance to phase 2 includes ROM at 75–80% of the uninvolved side, straight-leg raise without quadriceps lag, unilateral weight bearing without pain with a level pelvis, and a normalized gait pattern without an assistive device.
2. Intermediate rehabilitation. T e goals for this phase are the continued protection of the repair tissue, restoration of full ROM, utilization of a normal gait pattern, and an increase in the muscular strength of the hip girdle, quadriceps, hamstring group, and core. Criteria to advance to phase 3 include the ability to perform normal ambulation without a compensatory patterns secondary to gluteus medius weakness, full hip ROM in accordance with the demands of daily activity, normalized gluteal timing, 5/5 manual muscle strength in the involved lower extremity, and good neuromuscular control during single-leg squat at 90-degree knee flexion with the involved limb.
3. Advanced rehabilitation. Goals for this phase consist of restoration of muscular strength and endurance, cardiovascular fitness, and optimization of neuromuscular control, balance, and proprioception. To complete this phase, the patient must demonstrate full pain-free ROM, hip flexion strength greater than 70% of the uninvolved side, and hip adduction, abduction, extension, internal rotation, and external rotation strength greater than 80% of the uninvolved side.
4. Functional/sports-specific rehabilitation. T is phase is characterized by agility and plyometric drills performed in multiple planes with an emphasis on lateral bounding and weight-bearing rotation over the hip to mimic optimal function and gauge readiness to return to sport.

Integration of Practice Patterns 4C and 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Muscle Performance Because of Impaired Muscle Performance and Connective Tissue Dysfunction

Snapping Hip (Coxa Sultans)

Multiple etiologies for snapping hip (coxa sultans) exist. T e etiologies are categorized as extra-articular (internal/medial, external/lateral, or posterior) or intra-articular.[326,327]

Extra-articular

1. T e internal/medial type has been attributed to
   a. the iliopsoas snapping over structures just deep to it as it moved medially and laterally from end-range flexion to extension, namely the femoral head, and iliopectineal eminence, which produces a snapping in the anterior groin region.[328–331] Internal snapping hip syndrome can be asymptomatic in some cases, therefore not requiring treatment;
   b. stenosing tenosynovitis of the iliopsoas insertion.[332]
2. T e external/lateral causes include snapping of the ITB or gluteus maximus over the greater trochanter.[328,333] Pain over the greater trochanter, at the attachment of the hip abductors or along the posterior ITB, may be associated with this condition.[11] T is condition is more common in females with a wide pelvis and prominent trochanters and is exacerbated by running on banked surfaces.[334]
3. T e posterior type has been attributed to occur with ischiofemoral impingement, as a result of a narrowed ischiofemoral space, although the true etiology of this rare entity is unknown.[335]

Intra-articular. T e intra-articular causes have included synovial chondromatosis, loose bodies, fracture fragments, and FAI, which may lead to labral tears and articular cartilage injury.[336–339] Snapping of the iliofemoral ligament over the anterior femoral head has also been described,[329,340,341] as has snapping of the long head of biceps origin over the ischium ("Snapping Bottom").[342]

When no cause can be identified, as in most patients, the condition is classified as a myopathy of idiopathic origin.

Particular areas of attention during the examination include observation of genu recurvatum, leg length, knee flexion contracture, overpronation of the foot, hip flexion contracture, and the amount of internal or external rotation of the lower extremity during static standing. With an internal snapping hip of the iliopsoas, the clinician can bring the hip into a flexed position, while maintaining knee extension and then abduct and extend the hip down to the side and back around to neutral. T is circumferential motion will typically reproduce a click or snap of the iliopsoas tendon.[33]

T e intervention is based on etiology with all forms initially employing nonoperative management. Activities that initiate or aggravate the painful snapping should be modified or avoided altogether. For example, if an imbalance of the TFL or iliopsoas is producing the symptoms, the intervention is focused on prevention, which includes increasing the flexibility of the soft tissues, and the correction of any strength imbalances. If the flexibilty of the ITB is decreased, the emphasis is on stretching the ITB. Cross-training exercises can be used to maintain aerobic condition and strength during the recovery. Corticosteroid injections can also be used to identify the source of the pain as well as reduce pain if the patient is unable to tolerate the exercise prescription.[343] As with most musculoskeletal injuries, surgery is generally reserved for cases that have not responded to 3–6 months of standard nonoperative management.[344]

Flexion Contracture

A flexion contracture at the hip is a common occurrence. Hip flexion contractures can result from

- adaptive shortening of the iliopsoas muscle or rectus femoris muscles;
- contracture of the anterior hip capsuloligamentous complex.

These changes to the soft tissue and connective tissues around the hip can result from OA, injury, or sustained postures involving hip flexion.

The resulting anterior rotation of the pelvis shifts the weight bearing of the hip to a thinner region of hyaline cartilage, in both the femur and the acetabulum, and places the hip extensors in a state of low-level tension.[21]

Flexion contractures can be diagnosed using the Thomas test (see "Special Tests").

The intervention for the contracture is based on the cause. Adaptive shortening of the contractile tissues may be addressed using muscle energy, passive stretching, and myofascial techniques. Stretching of the capsuloligamentous complex is accomplished by grade III distraction mobilizations and by prolonged stretching.

Movement Impairment Syndromes of the Hip

Three of the movement impairment syndromes detailed by Sahrmann in her excellent book, Movement Impairment Syndromes,[182] are described. The intervention for these syndromes focuses on the correction of muscle imbalances. The adaptively shortened structures are stretched, and the weak muscles are strengthened.

Femoral Anterior Glide Syndrome. The characteristic findings for this condition result from an insufficient posterior glide of the femoral head during hip flexion. Typically, the patient complains of groin pain, particularly during hip flexion, gait, and running. The consequences of this syndrome are

- stretching of the anterior joint capsule and tightening of the posterior structures resulting in excessive hip extension ROM;
- an increase or decrease in the length of the hip external rotators;
- a decreased posterior glide of the femoral head;
- a decrease in length of the TFL on the involved side;
- weakness and lengthening of the iliopsoas on the involved side;
- a dominance of hamstring activity over gluteus maximus activity, both of which are shortened.

Limited motion in the gluteus maximus causes increased tension on the IT band, which can result in a lateral knee pain, or trochanteric bursitis. If the hamstrings dominate as the hip extensors, they can dominate the stabilizing function by pulling posteriorly on the tibia to extend the knee in closed-chain activities, which alters the mechanics of the knee and may lead to overuse syndromes in hamstring tendons or anterior knee pain from imbalances in the quadriceps pull.

Hip Extension with Knee Extension Syndrome. The characteristic findings of this condition result from an insufficient participation of the gluteus maximus during hip extension or the quadriceps during knee extension. Typically, the patient complains of pain at the hamstring insertion site on the ischial tuberosity and along the muscle belly, particularly during resisted hip extension, knee flexion, or both. The consequences of this syndrome are

- a decrease in hip flexion because of the hypertrophy of the hamstrings;
- a dominance of hamstring activity over gluteus maximus activity;
- a weakness of the gluteus maximus and hip external rotators;
- a decrease in the length of the hamstrings;
- an increase in the frequency of hamstring strains.

The TFL and approximately one-third of the gluteus maximus insert into the ITB. A decrease in flexibility in either of these muscles can alter the tension transmitted to the ITB resulting in an ITB overuse syndrome or a patellofemoral impairment.

Femoral Accessory Motion Hypermobility. The characteristic findings of this condition result from early degenerative changes and increased compression at the hip joint because of stretching forces on the rectus femoris and hamstrings. Typically, the patient complains of pain deep in the hip joint and anterior groin that may extend along the medial and the anterior thigh, particularly during gait. The consequences of this syndrome are

- a slight antalgic gait;
- an internal rotation of the hip during single-leg stance;
- an external rotation of the hip with passive knee flexion in prone;
- a medial rotation of the femur with knee extension in sitting;
- a stiffer rectus femoris and hamstrings as compared to the iliopsoas and intrinsic hip internal rotators;
- an anterior hip joint pain with FABER test.

The relatively stiffer rectus femoris and hamstrings as compared to the iliopsoas may cause faulty hip mechanics or knee pain from overuse of these muscles as they cross the knee.

Integration of Practice Pattern 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Localized Inflammation

In addition to those conditions producing impaired ROM, motor function, and muscle performance attributed to inflammation, practice pattern E includes conditions that cause pain and muscle guarding without the presence of structural changes. Such conditions include

- sprains of the hip ligaments;
- strains of the hip muscles;
- periarticular syndromes: tendinopathy, bursitis, capsulitis, and tenosynovitis;
- contusions: hip pointer;
- pubalgia.

Overuse injuries of the hip result from repetitive microtrauma that leads to inflammation and local tissue damage in the form of cellular and extracellular degeneration. This tissue damage can be cumulative, resulting in myositis, bursitis, joint synovitis, cartilaginous degeneration, stress fractures, and neuropraxic or axonal nerve injury. Successful intervention requires a correct identification of the injury.

Hip Joint Sprains

The classic history of a hip joint sprain is a vigorous twisting of the lower extremity or trunk.[345] Clinical findings include an inability to circumduct the leg because of pain.[346]

Conservative intervention includes an ACE wrap hip spica. Crutches are used for PWB ambulation. The crutch walking continues until the patient is able to ambulate without pain.[347] The patient is progressed to strengthening and flexibility exercises, and the functional tests of hopping, sprinting, running backward, cutting, and pivoting in the athlete must be satisfactorily passed prior to return of play.[345]

Muscle Strains

First- and second-degree muscle strains are frequent injuries in sports activities.[114] The gluteus medius, adductors, ITB, iliopsoas, rectus femoris, rectus abdominis, and hamstrings muscles are commonly involved.

Gluteus Medius/Gluteus Minimus. Tendinosis and tears of the gluteus medius and gluteus minimus were a common finding in an MRI study of patients presenting with buttock, lateral hip, or groin pain.[348] Gluteus medius syndrome is manifested by tenderness to palpation of the gluteus medius muscle, which can be triggered by sudden falls, prolonged weight bearing on one extremity for long periods, activity overuse, or sporting injuries. Most commonly, this condition is observed in middle-aged women who have embarked upon a vigorous walking program, or who have started working out at a health club. Patients may present with pain that is transient and worsening over a time period, a Trendelenburg gait, a leg-length discrepancy, and weakness. These symptoms also affect runners, as there is tilting of the pelvis with running. Hip abduction strengthening should be avoided in the initial stages of gluteus medius syndrome because it only provokes tendinopathy. As the acute stage resolves, hip abductor strengthening is important and is best achieved in the aquatic environment.

Adductor. The hip adductor muscles, especially the adductor longus and magnus are the most frequent cause of muscle-induced groin region pain.[89,349] Adductor strains have been known to cause long-standing problems.[350]

There are a number of causative factors for an adductor strain, including fatigue or an abduction overload.[351] Laboratory studies have shown that strengthening exercises can protect these muscles from injury. [352]

Adductor strains are associated with running, jumping, and twisting activities, particularly when external rotation of the affected leg is an added part of the activity.[346] Soccer players with a history of forceful kicking are particularly vulnerable to an adductor strain. In fact, the incidence of groin pain among male soccer players is 10–18% per year.[353–355] Adductor muscle strains are also commonly encountered in ice hockey.[356–358] These sports require a strong eccentric contraction of the adductor musculature during competition.[359,360] Risk factors associated with adductor strains include an imbalance between strength and flexibility,[361] and an imbalance between adductor and abductor strength.[360]

The signs and symptoms that are easily recognizable[362]:

- Pain on palpation of the adductor tendons or their insertion on the pubic bone, or both
- Twinging or stabbing pain in the groin area associated with quick starts and stops
- Edema or ecchymosis several days postinjury
- Pain with passive abduction or manual resistance to hip adduction when tested in different degrees of hip flexion (0 degree [gracilis], 45 degrees [adductor longus and brevis], and 90 degrees [if combined with adduction, pectineus])
- A possible palpable defect in severe ruptures accompanied by muscle guarding

Groin strains are graded as a first-degree strain if there is pain, a minimal loss of strength and minimal restriction of motion; second degree if there is compromise to the strength of the muscle, but not including complete loss of strength and function; and third degree if there is complete disruption of the muscle tendon units, including complete loss of function of the muscle.[363] The differential diagnosis includes abdominal muscle strains, inguinal hernia, osteitis pubis, piriformis syndrome (see Chapter 5), and referred pain from the hip joint (osteoarthrosis), rectum, or lumbar spine.

Conservative intervention involves the principles of PRICEMEM in the acute stage (see Chapter 8). This is followed by heat applications, hip adductor isometrics, and gentle stretching during the subacute phase, progressing to a graded resistive program for the adductors, including concentric and eccentric exercises, PNF diagonal motions to promote balance strength and flexibility around the joint, and then a gradual return to full activity. As part of the rehabilitation program, any imbalance between the adductors, abductors, and the abdominals needs to be addressed. In addition, the clinician should examine the patient's technique in their required activity, as poor technique can overload and fatigue the adductors.

Sports Hernia. A sports hernia occurs when weakening of the muscles or tendons of the lower abdominal wall occur, but there is no palpable hernia. The symptoms of a sports hernia are characterized by pain during sports movements, particularly twisting and turning during single-limb stance.[364] The pain usually radiates to the adductor muscle region, although it is often difficult for patients to pinpoint. Any exertion that increases intra-abdominal pressure, such as coughing or sneezing can cause pain.[364] Currently, no clinical special test exists with a high degree of specificity to diagnose this condition, so the diagnosis is based on the patient's history and clinical signs when all other causes are ruled out. Conservative treatment usually involves a short period of rest followed by an exercise program focusing on abdominal strengthening. If the conservative approach fails, surgical repair is required.

Iliotibial Band Friction Syndrome. An ITBFS, which is an overuse injury most commonly associated with repetitive lower extremity activities, such as running or cycling, can manifest itself at the hip and at the knee (see Chapter 20). At the hip, an ITB contracture can lead to trochanteric bursitis by increasing compression and friction of the subgluteus maximus bursa between the ITB and the greater trochanter.[62] The primary cause of ITBFS in runners appears to be increased hip adduction and knee internal rotation. The knee internal

rotation may stem from either femoral external rotation or tibial internal rotation. [365] T e increased hip adduction may increase the eccentric demand on the hip abductors to compensate for greater internal hip adduction moment.[366] Several studies have suggested that pelvic and trunk motion in the coronal plane will be increased in this population, and given the potential for proximal compensations, pelvic and trunk motion should be assessed for abnormal movements during the dynamic examination of this group of patients.[367] T e classic test for ITB contracture is the Ober test. A comprehensive approach to soft tissue mobilization and hold/relax stretching of the ITB, rectus femoris, and iliopsoas should be included once the inflammation subsides to decrease the stresses on the bursa. A number of studies have demonstrated a successful return to pain-free running and increased hip abductor strength in patients with ITBFS after rehabilitation programs that included specific stretching of the ITB combined with specific strengthening of the hip abductors.[156,368] T e specific exercises to use include a coronal plane lunge (side lunge), a coronal plane lunge with contralateral reach, and a coronal plane lunge with medial reach.[367]

Iliopsoas. With the exception of the adductors and hamstrings, the iliopsoas is one of the most frequently strained muscles of this region.[369] T e mechanism of injury is forced extension of the hip while it is actively flexed. Clinical findings include

- complaints of pain with attempts at acceleration and high-stepping activities;
- increased pain with resisted hip flexion, adduction, and external rotation.[345]

Conservative intervention involves rest, ice, and compression during the acute phase, progressing to prone lying, heat, a graded resistive exercise program, and specific instructions on proper warm-up and cool-down. Recovery from this condition can be lengthy, and recurrences are frequent.

Rectus Femoris. Strains of the quadriceps most commonly occur during sports involving sprinting, jumping, or kicking. T e rectus femoris is the most commonly involved. Typically, the patient complains of local pain and tenderness in the anterior thigh, which may be gradual in onset or sudden during an explosive muscle contraction. Grade I strains result in pain with resisted testing and with passive stretching. Grade II strains cause significant pain with resisted testing and with passive and unopposed active stretching. Complete tears of the rectus feminists are rare and are usually associated with a palpable defect. During the initial period following injury, the principles of PRICEMEM are applied. Pain-free stretching and soft tissue mobilization are instituted early to preserve ROM. Straight-leg raises are initiated in the supine position and are progressed to long sitting. Short arc quad sets in pain-free ranges are progressed to full range as tolerated. Closed kinetic chain exercises at submaximal weight are initiated using short arcs before being progressed to full range. Both concentric and eccentric exercises are performed. Attention must be given to hip flexor and hamstring strength and flexibility to ensure correct muscular balance.

Rectus Abdominis. Rectus abdominis strains usually occur when the muscle is strongly contracting, as it is being moved into a stretched and lengthened position. T ese strains are common in such sports as tennis, wrestling, pole vaulting, weight lifting, and soccer. Abdominal strains are primarily the result of inadequate abdominal strength and/or incorrect technique.[345] As it may be difficult to differentiate this condition from an inflammation of one of the internal abdominal organs, a physician should be consulted whenever there is any doubt.[369]

T ese are difficult injuries to heal. Although mild strains may only take 2–3 weeks to heal, premature return to play can create large muscle ruptures, leading to hernia formation in the abdominal wall.[345]

Conservative intervention is the same as for other muscle strains and involves rest, ice, and compression during the acute phase, progressing to heat and gentle stretching, a graded resistive exercise program, and specific instructions on proper warm-up and cool-down. Training and retraining of the rectus abdominis should include half sit-ups, done slowly with the knees bent, to eliminate compensation by the iliopsoas.[345,369]

Hamstrings. T e hamstrings are the most commonly strained muscles of the hip,[346] with the biceps femoris being the most commonly injured hamstring. Strains of the hamstring muscle group can involve the muscle itself, the tendon, or a combination of both. Hamstring tears are typically partial rather than complete, and usually occur during the eccentric phase of muscle usage, when the muscle develops tension as it lengthens during activities that require sprinting with frequent directional changes and acceleration and deceleration. Specifically, they occur in end-range hip flexion with knee extension stretching movements. T e running-related hamstring injuries typically occur along and intramuscular tendon, or aponeurosis, and the adjacent muscle fibers of the biceps femoris.[370] Another type of hamstring injury, which involves the semimembranosus and its proximal free tendon, can occur during slower speed activities such as dance and yoga.[371] Hamstring injuries, which have a high recurrence rate, tend to require a prolonged recovery before an individual is able to return to his or her preinjury level of performance.[372]

A hamstring strain has a varied list of contributing factors including[347]:

- Previous hamstring injury. T ere is a strong correlation between a history of prior hamstring injury and recurrence. T is is likely because of the fact that the initial injury results in a loss of extensibility and a loss of eccentric strength.
- Degenerative joint disease *of* the lumbar spine. LB pain and injury result in restricted ROM and decreased hamstring extensibility. In addition, research has demonstrated that LB pain decreases proprioception and neuromuscular control of the lower extremities.
- Advancing age. It is not clear why injuries to soft tissues served by the L5 and S1 nerves, which supply the hamstring and calf muscles, have such a strong correlation with advancing age, whereas there is little or no correlation between age and the soft tissue injuries with an L2–L4 nerve supply. One could surmise that the lumbar nerve roots of L5 and S1 are more likely to be affected by

age-related spinal degeneration than the nerve supply of the quadriceps muscles (L2, L3, and L4).[373]

- Anterior pelvic tilt. A common finding is an anterior tilt of the innominate bones on the injured side that increases tension in the hamstrings and causes a relative lengthened position of their origin and insertion. T is altered pelvic position can also contribute to decreased hamstring strength. Cibulka et al.[374] researched manipulative treatment to correct an anterior innominate position in patients who had hamstring injuries. After only one treatment, isokinetic hamstring peak torque increased by 21.5% when compared with controls.[374] However, a functional improvement from this torque increase was not addressed. One of the reasons cited for the significantly increased incidence of hamstring injuries in black athletes is their pelvis tends to have an increased anterior tilt.
- Leg-length inequality. T e shorter leg can develop overly tight hamstrings.
- Anatomical arrangement. Being a biarticular muscle group means that the hamstrings are more susceptible to adaptive shortening[375] and can also be subjected to large length changes. Everyday movements, such as walking, squatting, and sitting, flexion of the hip and knee occur together, with opposing effects on hamstring length. In contrast, the knee is extended, and the hip is flexed in running and kicking, which places the hamstrings at longer lengths, thereby increasing the risk of muscle tears. Antagonists to prime movers, muscles that are used to control or resist motion, are also at a greater risk of injury than the prime movers themselves. While decelerating the body, these muscles contract while rapidly lengthening. T erefore, they are performing "eccentric contractions."
- Poor posture. For example, Janda's lower crossed syndrome, which is associated with adaptive shortening of the hip flexors and the erector spinae, weak/inhibited gluteal and abdominal muscles, an increased anterior pelvic tilt and a hyperlordosis of the spine.
- Muscle imbalance. Muscle balance is a term used to describe the relationship between either:
  - Agonist to antagonist muscle groups. T e hamstrings are directly antagonistic to the quadriceps during the first 160–165 degrees of leg extension but assume a paradoxical extensor action concurrent with initial contact.
  - T e relationship of agonist muscle groups between limbs (inhibited gluteus maximus).
  - Eccentric to concentric muscle ratios.
  - T e strength ratios between the hamstrings and trunk stabilizers.
- Decreased *flexibility*. Although there is little to no evidence to support this theory, decreased flexibility of the hamstrings has long been cited as the primary cause of hamstring injuries. In fact, the evidence has demonstrated that there is no correlation between passive hip flexion measurements and hamstring injuries provided that the minimum range is between 85 and 90 degrees. However, a differentiation must be made between active flexibility (the absolute range of movement in a joint or series of joints that is attainable in a momentary effort) and passive flexibility (the ability to assume and maintain extended positions) as research has shown that active flexibility is more closely related to sports achievement than is passive flexibility.

Cl INICAl PEARl

Jonhagen et al.[376] found decreased flexibility and lower eccentric hamstring torques in runners who sustained a hamstring strain when compared with uninjured subjects matched for age and speed.

- Hamstring strength. T e relationship between strength and the potential for a hamstring injury is not made clear in the studies available. While some rehabilitation and prevention programs based on strength and flexibility have been shown to reduce the seasonal incidence of hamstring injuries, muscle strength has not consistently been a good indicator of future risk of incurring a hamstring injury.[377] Many authors have commented on the limitations of isokinetic testing and the specificity of the types of training. Few studies have reported on the relationship between concentric and eccentric strengths and the frequency of hamstring injury, but those that have suggested that poor eccentric strength in the hamstring muscle group might be a causative factor in hamstring strains.[377] Zachazewski[378] commented that for a test to have predictive value it must incorporate some of the dynamic characteristics specific to that sport. Lephart et al.[379] stated that low peak torque values are not necessarily related to functional capacity.
- Precipitating activity. Most hamstring injuries occur while running at the end of the swing phase or at foot strike when the hamstrings are working to decelerate the limb while also controlling extension of the knee. At this point, the greatest muscle–tendon stretch is incurred by the biceps femoris, which may contribute to its tendency to be more often injured than the other two hamstring muscles during high-speed running.[248] With the forceful flexion of the hip and extension of the knee during the swing phase of sprinting, the hamstring muscle groups are put under extremely high loads in a lengthened position where they must change from functioning eccentrically, to decelerate knee extension in the late swing, to concentrically, becoming an active extensor of the hip joint. It has been proposed that this rapid changeover from eccentric to concentric function of the hamstring is when the muscle is most vulnerable to injury.[78] Kujala et al.[79] also suggested that, during this swing phase, the hamstrings are placed under extremely high loads in an elongated position.
- Inadequate warm-up. Although most clinicians prescribe warm-up and stretching to help reduce the incidence of muscle strains, the evidence supporting this idea is weak and largely based on retrospective studies.[380]
- Fatigue. In a study of professional soccer players, nearly half (47%) of the hamstring injuries sustained during matches occurred during the last third of the first and

second halves of the match. Kyrolainen et al.[381] looked at the recruitment pattern of leg muscles during different running speeds. T e greatest changes in muscle activity pattern were observed in the biceps femoris muscles as the speed increased from a slow jog to maximum speed.[78] Pinniger et al.[382] found that, when footballers became fatigued during sprinting, there was earlier activation of the biceps femoris and semitendinosus muscles. Asynchrony may be because of local muscle fatigue and/or neural fatigue as a result of "irritation or damage along the path of the nerve supplying the muscle."[78] General fatigue secondary to poor sleep patterns, stress, or suboptimal nutrition could result in central nervous system fatigue.[78]

- Poor coordination. Many hamstring strains occur during the last part of the swing phase or at heel strike, during which time the hamstrings work maximally eccentrically to decelerate the leg.

Other unsubstantiated predisposing factors include cleat design, playing surface, level of hydration, adverse neural tension, experience of the coach, and hormonal levels (abnormally low resting levels of testosterone and unfavorable testosterone/cortisol ratio during recuperation after exercise).[79,176,377,383,384]

It is likely that a combination of the aforementioned factors all play a role in hamstring injuries. Some of these factors are modifiable, others are not. T e modifiable factors include muscle imbalances between flexibility and strength, overall conditioning, and playing surface.

Clinical findings associated with hamstring injury may include some or all of the following:

- patient reports of a distinctive mechanism of injury with immediate pain during sprinting or while decelerating quickly.[345] In acute cases, the patient may report a "pop" or tearing sensation.
- tenderness elicited with passive stretching of the hamstrings (hip flexion with knee extension).
- Altered gait mechanics. T is finding may have prognostic value. One study[385] found that individuals taking more than 1 day to return to pain-free walking were four times more likely to take longer than 3 weeks to return to sports when compared with those walking pain-free within 1 day.
- posterior thigh pain, often near the buttock, which is worsened with resisted knee flexion and/or hip extension.
- tenderness to palpation, which is generally located at the muscle origin at the ischial tuberosity but may also be present in the muscle belly and distal insertions.
- Positive special tests specific for the detection of hamstring injuries.

Cl INICAl PEARl

A 2014 study,[386] using univariate analysis, reported that the clinical criteria associated with a full recovery time of >40 days were a visual analog scale (VAS) pain score of greater than 6, a report of a popping sound at the time of injury, pain during everyday activities for more than 3 days, bruising, and a ROM limitation of greater than 15 degrees as compared to the other side.

T ere are a number of systems used to grade tendon injuries, an example of which is given in Chapter 1. Hamstring strains can be graded using a simpler system according to findings[345]:

- Grade I: gait appears normal, but there is a pain with extreme range of a straight-leg raise.
- Grade II: antalgic gait or gait with a flexed knee. Resisted knee flexion and hip extension are both painful and weak.
- Grade III: usually requires the use of crutches for ambulation. In severe cases, ecchymosis, hemorrhage, and a muscle defect may be visible several days postinjury.

T e differential diagnosis for posterior thigh pain includes neoplasms, overt lumbar disk protrusions with definite signs of nerve root impingement, ischial tuberosity apophysitis, or an avulsion fracture. Examination of the lumbar spine is important because muscle injury may be related to referred pain with subsequent muscle inhibition and weakness.[387]

MRI and ultrasonography (US) are considered the criterion-reference standards for diagnosis of hamstring injuries.[388,389] However, both MRI and US are not practical alternatives for diagnosis due to the high incidence of this injury and the cost associated with these diagnostic tests.

Cl INICAl PEARl

Decreased hamstring muscle strength following injury is considered a consequence of structural disruption to myofascial tissue.[390] However, it is also influenced by inhibition associated with pain or subconscious fear of pain and recurrence.[85]

No consensus exists for rehabilitation of the hamstring muscles after strain. It is very likely that current clinical determinants of recovery, as measured during the physical examination (e.g., no pain, full ROM, and full strength), are not adequately sensitive enough to represent complete muscle recovery and readiness to return to sport. Despite differences in injury mechanisms and recovery time, current examination and rehabilitation approaches generally do not consider injury location (i.e., proximal free tendon injuries versus intramuscular tendon and adjacent muscle fibers) as part of the clinical decision-making process.[193,371] Most rehab programs are designed for injury to the muscular component because injury to the intramuscular tendon and adjacent muscle fibers initially present as more severe compared to proximal tendon injuries, but the latter usually involves a much longer recovery.[371]

T us, there are a number of key areas that require emphasis with the rehabilitation of hamstring injuries. T ese include:[391]

- Trunk stabilization. All movements begin at the lumbo-pelvic-hip complex otherwise known as the core. T e function of the core is to provide a stable base from which the muscles of the extremities, particularly the lower extremities, can work from. Sherry and Best[392] found significantly lower reinjury rates in athletes who completed a progressive agility and trunk stabilization program, compared to those whose rehabilitation programs focused on isolated hamstring strengthening

and stretching. The reasons for this are unclear. It may be because targeting muscles that control pelvic motion early in the rehabilitation process might facilitate recovery from injury and thereby minimize reinjury risk.[393] It may also be because, by providing a stable pelvic base from which the hamstrings can operate, unanticipated pelvic motions that the hamstrings have to accommodate to are reduced.

- Eccentric loading. Since in noninjured subjects, the performance of controlled eccentric strength training exercises has been shown to facilitate a shift in peak force development to longer muscle–tendon lengths,[193,394] eccentric exercises have been advocated in the rehabilitation of hamstring injuries.[193] These exercises should be performed in the outer ROM, that is, where the muscle is in a more lengthened position.[193] A recent prospective investigation determined through isokinetic testing that a strength imbalance (≥ 20% bilateral deficit) between the eccentric hamstrings (30 degrees per second) and concentric quadriceps (240 degrees per second) resulted in a fourfold increase in risk ratio of hamstring injury (risk ratio, 4.66; 95% confidence interval: 2.01–10.8) compared to a normal strength profile.[395] A number of eccentric strengthening protocols have been proposed that include such exercises as hamstring lowers, and the use of Yo-Yo™ flywheel ergometry. Although these protocols appear to decrease the severity of an initial injury, they tend to have an increased participant dropout rate because of the occurrence of muscle soreness and delayed onset muscle soreness (DOMS).[383,396,397]
- Soft tissue mobilization. During the acute phase of healing, the goal is to promote collagen synthesis. For chronic injury, the focus is to break up scar tissue. Recommended techniques include friction massage, myofascial release, active release technique, and augmented soft tissue mobilization therapy (ASTM) (see Chapter 10).
- Platelet-rich plasma therapy. Platelet rich plasma (PRP) typically consists of high concentrations of growth factors, including platelet-derived growth factor, transforming growth factor beta, vascular endothelial growth factor, and epidermal growth factor, all of which function in tissue regeneration.[398–400] Mejia and Bradley[400] reported that injecting professional football players with PRP 24–48 hours after sustaining hamstring strains reduced healing time and number of games missed. There were no complications with the injections and zero recurrences of hamstring strains.

The protocol outlined in Table 19-19 is recommended. Muscle imbalances of strength and flexibility are addressed with proper techniques to stretch and strengthen the hamstrings. Exercises to enhance eccentric loading include the supine bent-knee bridge walkout (Fig. 19-68), the supine single-limb chair bridge (Fig. 19-70), unilateral good mornings with rotations (Fig. 19-72), and increasing intensities of grapevine stepping (Fig. 19-76).

Finally, when appropriate, the biomechanical factors, including excessive anterior tilt of the pelvis, lumbar spine and sacroiliac joint dysfunction (trunk stabilization exercises), and leg-length discrepancies should be addressed and corrected.

CLINICAL PEARL

Rehabilitation of hamstring strains using progressive agility and trunk stabilizing exercises has been found to be more effective than a program emphasizing isolated hamstring stretching and strengthening.[392]

Because there is a great deal of variability in the rehabilitation time, anywhere from 2–3 weeks to 2–6 months, an athlete should not be permitted to return to full participation in sports until flexibility and strength ratios have been restored, and before plyometric and functional exercises are able to be performed pain free.[345,347]

Tendinopathy

Proximal Hamstrings. Proximal or high hamstring tendinopathy, which was initially referred to as "hamstring syndrome" is a relatively uncommon overuse injury in middle- and long-distance runners, cross-country skiers, and soccer players and, less commonly, in other running sports.[84] The mechanism of injury is not particularly clear; however, it is likely related to repetitive microtrauma, typically resulting from nonoptimal gait mechanics, muscular imbalances, or improper training.[401] Degenerative tendinopathy may include sciatic nerve compression, traction, or irritation. It can also develop insidiously after partial hamstring tears.[402] Due to the number of tissues that can generate posterior hip/buttock pain, proximal hamstring tendinopathy can easily be missed clinically. Typical complaints include a deep ache in the gluteal region that is often exacerbated with running, prolonged sitting on firm surfaces, or prolonged sitting in the proximal hamstring region.[403] The intervention involves controlled eccentric loading of the hamstrings, and lumbopelvic stabilization exercises. Trigger point dry needling has also been used.[401]

Rectus Femoris. Rectus femoris tendinopathy is typically sports related, resulting from acute or chronic overuse. The pain is usually located at the origin (ASIS), or just distal to it. The patient often complains of groin pain during sprinting or lifting the knee. In most cases, the cause is adaptive shortening of the rectus. The intervention involves stretching and transverse friction massage (TFM).

Iliopsoas. Tendinopathy of the iliopsoas complex almost always involves an overstretching of the muscle belly. The patient complains of groin pain, which can radiate into the anterior thigh. Resisted hip flexion and external rotation are often painful. In addition, passive hip flexion or passive hip extension/internal rotation are painful. The involved site is almost always just distal to the inguinal ligament, and just medial to the sartorius muscle. Conservative intervention involves TFM and stretching.

Bursitis

Trochanteric/Subtrochanteric. Trochanteric bursitis is the shared name given to inflammation of any one of the three trochanteric bursae. It has been suggested that trochanteric bursitis should be considered as a clinical diagnosis rather than an anatomical diagnosis because it cannot be distinguished from gluteal tendinopathy by signs and symptoms alone.[62] Trochanteric bursitis is the second most frequent

TABLE 19-19 Rehabilitation Protocol for Hamstring Injury

Phase	Protocol
I (acute): 1–7 days	Rest, ice, compression, and elevation to control hemorrhaging and minimize inflammation and pain Nonsteroidal anti-inflammatory drugs are an almost universally accepted treatment, and the only controversial aspect to their use is the appropriate timing of administration. The most common recommendation in the literature is short-term use (3–7 days), starting immediately after the injury. However, theoretically it would be beneficial to delay the treatment until 2–4 days after the injury, because they interfere with chemotaxis of cells, which is necessary for the repair and remodeling of regenerating muscle Early motion exercise is theoretically important to prevent or decrease adhesion within the connective tissue. Active knee flexion and extension exercises could be performed during the treatment with ice. It is important that the exercises are pain free to prevent further injury during the rehabilitation
II (subacute): day 3–3 weeks	Begins when the signs of inflammation (swelling, heat, redness, and pain) begin to resolve In this phase, it is important to continue muscle action to prevent atrophy and promote healing Regular concentric strength exercises can begin in this phase when the athlete has achieved full range of motion without pain The common recommendations in this stage include low to moderate intensity activities such as back and forth sidestep shuffles, back and forth grapevine exercises, and fast foot stepping in place Trunk stabilization exercises including the prone plank, side plank, and supine bent-knee bridge Balance exercises including standing single-leg balance progressing from eyes opened eyes closed and leaning forward slightly In this phase, other activities can be initiated to maintain cardiovascular fitness. This could be stationary bike riding, swimming, or other controlled resistance activities
III (remodeling); 3–6 weeks	To avoid the hamstring muscle becoming less flexible after the injury, hamstring stretching can begin in the third phase Moderate to high intensity exercise progressions of back-and-forth sidestep shuffles, back and forth grapevine exercise Low to moderate intensity back-and-forth the box a shuffle Rotating body bridge (hand plank) Supine bent-knee bridge with walkouts Single-leg windmill touches without weight Single-leg balance with forward trunk lean and opposite leg hip extension Eccentric strengthening can begin (see text)
IV (functional): 2 weeks to 6 months	The goal in this phase is return to sport without reinjury This is achieved by increasing hamstring strength and flexibility to the normal values for the individual athlete. Simultaneously, pain-free running activities are increased from jogging at low intensity to running and finally sprinting, each with an end phase of deceleration distance. Additional exercises include butt-kickers (jogging with heels hitting the butt with each step), kangaroo hops (bounding forward keeping both feet together). Pain-free participation in sports-specific activities is the best indicator of readiness to return to play
V (return to competition): 3 weeks to 6 months	When the athlete has returned to competition, the goal is to avoid reinjury. The focus should, therefore, be on maintaining stretching and strengthening

Data from Robinson KA. Tendinopathy and application to hamstring strain injuries. Orthop Phys Ther Prac. 2013;25(4):207–214.

cause of lateral hip pain, with a peak incidence occurring between 40 and 60 years of age,[91] and is more common in arthritic conditions and fibromyalgia and leg-length discrepancy.[62,404] It is also more common in females than males (2–4:1 ratio).[62]

The bursae can become inflamed through either friction or direct trauma, such as a fall on the side of the hip.

The history may reveal complaints of aching lateral thigh, groin, and gluteal pain, especially when lying on the involved side.[405] Although the pain is typically local to the hip region, it can radiate distally to the knee and the lower leg.

Objectively, the clinical findings include

- the reproduction of pain with palpation or with stretching of the ITB across the trochanter with hip adduction or the extremes of internal or external hip rotation;[406]
- that resisted abduction, extension, or external rotation of the hip are also painful;
- that there is often associated tightness of the hip adductors, which cause the patient's feet to cross the midline, resulting in increased stress on the trochanteric bursa.

Differential diagnosis should include[57,407]

- tendopathy of the gluteus medius or maximus muscles, with or without calcification;
- an inguinal and femoral hernia;
- an irritation of the L4–L5 nerve root;
- meralgia paresthetica;
- a "snapping" hip;
- lower spinal neoplasm;
- pelvic tumor;
- hip infection;
- avascular necrosis;
- stress fracture of the femur;
- bone or soft tissue tumor.

There is very little research on physical therapy interventions for trochanteric bursitis.[408] The intervention typically consists of the removal of the causative factors by stretching the lateral thigh tissues, especially the TFL and ITB, and emphasizing the flexibility of the external rotators, quadriceps, and hip flexors. Strengthening of the hip abductors and correction of any muscle imbalances between the adductors and abductors is also important. Other interventions include heat and ultrasound. TFM has also been advocated.[409] Orthotics may be prescribed if there is a biomechanical fault in the kinetic chain. A steroid injection into the area of tenderness over the greater trochanter may be useful in particularly intense or recalcitrant cases.

Iliopsoas/Iliopectineal. The IPB is located between the anterior aspect of the hip joint capsule and the musculotendinous junction of the iliopsoas. Iliopsoas bursitis seems to be underrecognized by the medical community despite reports that continue to be published. This may be because the entity often exists for years without being identified. The usual complaint is one of anterior hip or groin pain, which is aggravated by lumbar or hip hyperextension or power walking. In the older populations, psoas bursitis can mimic such conditions as hip joint pathology, an L2–L3 nerve root pathology, and meralgia paresthetica.

Objective findings are few, and they include

- pain with passive hip flexion and adduction at the end range;
- pain with passive hip extension and external rotation, which is increased if the hip flexors are resisted in this position;
- palpable tenderness of the involved bursa.

Conservative intervention consists of a stretching and strengthening program of the hip rotators and hip flexors. Johnston et al.[410] have published a conservative approach to iliopsoas bursitis, based on a retrospective study of nine patients with the condition. The recommended protocol consists of the following exercises:

- seated hip internal and external elastic resistance exercises;
- side-lying abduction/external rotation elastic resistance exercises;
- mini-squats, weight bearing on the affected leg;
- stretching of the hip flexor, quadriceps, and lateral hip/piriformis, and hamstring muscles.

Ischial. An ischial bursitis, also referred to as Weaver's bottom, involves two different bursae, one between the ischial tuberosity and the inferior part of the gluteus maximus belly, and the other between the tendons of the biceps femoris and semimembranosus. Inflammation of these bursae usually results from chronic compression or direct trauma.

Subjectively, the patient typically reports pain with sitting in a firm chair, almost as soon as the buttocks touch the chair. Ischial bursitis tends to affect thinner people more than obese individuals and women more than men. It is also common for cyclists.

Differential diagnosis should include lumbar nerve root impingement, hamstring syndrome, piriformis syndrome (see Chapter 5), and hamstring insertion tendopathy. These can be differentiated by using the history, palpation, and resistive testing, as patients with ischial bursitis generally will not complain of pain in the posterior thigh or demonstrate hamstring flexibility and strength inadequacies.

Conservative intervention is based on the cause, and typically involves relative rest, the use of a padded seat cushion, soft tissue massage, correction of hamstring strength and flexibility deficits, anti-inflammatory measures such as ice massage, and ultrasound.

Gluteal. Inflammation of the gluteal bursa, which is located above and behind the greater trochanter, and underneath the gluteus maximus and medius, is one of the most frequent causes of pseudoradicular pain in the lower extremity. The patient, who is usually in their fourth or fifth decade, typically complains of pain in the gluteal or trochanteric area, which may spread to the outer or posterior thigh, and down to the calf muscles and the malleolus. Unlike the pain caused by a lumbar disk lesion, the symptoms are not related to sitting, but only to walking and going upstairs. A typical pattern is a pain on passive internal rotation and abduction and resisted external rotation or abduction.

Conservative intervention is based on the cause and usually involves the use of a padded seat cushion, anti-inflammatory measures such as ice massage, and ultrasound.

Hip Pointer

A hip pointer is a subcutaneous contusion of the iliac crest resulting from a direct blow, usually at or near the ASIS. The contusion is graded from I to III, depending on the extent of the damage. Grade I hip pointers functionally limit the patient for about 5–14 days, while grade II and III hip pointers can functionally limit the patient for 14–21 days.

Usually, the patient reports point tenderness over the ASIS. The pain is increased with passive hip extension, resisted hip flexion, external rotation and abduction, active trunk motions, and with such activities as laughing, coughing, or sneezing.[345]

Early intervention within 2–4 hours is critical to avoid severe pain and limited trunk motion. The early intervention includes ice, compression, rest, and anti-inflammatory measures. Early motion exercises, which emphasize trunk side flexion to the side opposite the injury, should be initiated as tolerated and can be accompanied by transcutaneous electrical

nerve stimulation (TENS). As the symptoms subside, gentle-graded stretching exercises are added in addition to trunk-strengthening exercises. Especially effective exercises include long sitting, straight-leg raises with the hip externally rotated, as well as the PNF diagonal flexion adduction, external rotation to extension, abduction, and internal rotation.

Prophylactic prevention of the injury with adequate padding of the iliac crest using materials such as high-density foam and orthoplast is recommended.

Athletic Pubalgia

Athletic pubalgia is a collective term for all disorders that cause chronic pain in the region of the pubic tubercle and the structures attached to the pubic bone (inguinal region), including osteitis pubis, a chronic inflammatory and overuse condition of the pubic symphysis and adjacent ischial rami. A number of abnormalities in joints and muscles around the groin may increase the mechanical stress placed on the pubic region:

- limited hip ROM;
- increased adductor muscle tone;
- increased rectus abdominis tone;
- iliopsoas muscle shortening, often associated with hypomobility of the upper lumbar spine;
- lumbar spine/SIJ dysfunction;
- decreased lumbopelvic stability.

As its name suggests, athletic pubalgia typically results from a sports injury. In most cases, it occurs secondary to repetitive shear stress being transmitted to the soft tissue structures of the anterior pelvis during activities that require frequent rotation and pivoting.[11] It can also result from a single-leg movement, where the weight-bearing leg is rotated as the other leg performs a movement such as kicking, or during activities such as sprinting. The condition is rarely found in women—this may be because of variations in pelvic anatomy between men and women and strength differences or participation levels between genders.

Athletic pubalgia typically presents as lower abdominal pain with exertion, minimal to no pain at rest, and increased pain with activities that involve resisted hip adduction. After the initial pain, the pain disappears when the patient is warmed up, only to return, often more intensely, after the activity. Eventually, the pain will increase with exertion and only slightly diminish with rest.

In most cases, the pain is unilateral at onset, with progression to bilateral pain in about 40% of cases.[411] Examination findings include the following:

- Pain may be elicited with passive hip flexion when combined with hip adduction, or with passive abduction with a straight or bent knee. However, in some cases, ROM may appear normal.
- Point tenderness at the pubic tubercles, rectus abdominis insertion, adductor origin, and inferior pubic rami.
- Pain is intensified with sit-ups and resisted hip adduction.

Groin pain is a common complaint and can be ascribed to various disorders (Tables 19-20 and 19-21), necessitating a thorough knowledge of the differential diagnosis. Palpation of the relevant structures should help in locating the cause, as will resistive testing of the various muscles.

Once the diagnosis has been established, the conservative intervention should be causal:

- A period of relative rest and anti-inflammatory medications.
- TFM can be applied locally.
- Ultrasound, electrical stimulation, thermotherapy, and cryotherapy as appropriate.
- Stretching as tolerated to the muscles surrounding the injured area:
  - The short and long adductors.
  - Hip flexors (iliopsoas and rectus femoris).
  - Hip internal rotators.
  - Abdominals.
  - Gluteal muscles.
- Strengthening of the same muscle groups. The strengthening exercises are performed isometrically initially, and then concentrically and eccentrically, and finally isokinetically as appropriate.
- Core stability training. A particularly effective form of core strengthening for athletic pubalgia, developed by Alex McKechnie, uses diagonal elastic tubing resistance between the upper and lower extremities. These exercises combine a contraction of the pelvic floor and transversus abdominis muscles while performing activities such as squats (Fig. 19-59), lunges (Fig. 19-58), and sports-specific movements.
- Proprioception training.

Effective warm-ups and preparation before the sporting activity can play an important preventative role.

In cases of failed conservative intervention, which is common, surgical intervention (pelvic floor repair) or cessation of the offending activity becomes the patient's only choice.[411] Postsurgical rehabilitation uses many of the same exercises and modalities as in the traditional rehabilitation program outlined above.

Integration of Practice Patterns 4C, 4F, and 5F: Impaired Joint Mobility, Motor Function, Muscle Performance, ROM Associated with Spinal Disorders, Sign of the Buttock, Myofascial Pain Dysfunction (Referred Pain Patterns), and Peripheral Nerve Entrapments

If the tests and measures of the hip are negative for a hip disorder or a dysfunction of the lower kinetic chain, the clinician should examine the lumbar spine and sacroiliac joint, both of which can refer pain to this region.

Many internal disorders such as femoral and inguinal hernias, pelvic inflammatory disease, prostatitis, and nephrolithiasis can produce pain in the lower abdomen and groin region (see Chapter 5). These are all out of the scope of practice for the physical therapist, and proper referral to an internist, urologist, or gynecologist should be sought.

Sign of the Buttock

The sign of the buttock is a collection of signs that indicate the presence of serious pathology posterior to the axis of flexion and extension in the hip. Among the causes of the syndrome are osteomyelitis, fracture of the sacrum/pelvis, infections, sacroilitiis, gluteal hematoma, septic bursitis, ischiorectal abscess, tumor, and rheumatic bursitis. Typical findings include gross hip weakness with empty end-feel. The involved buttock looks larger. The seven signs of the buttock are

- a limited straight-leg raise;
- limited hip flexion;
- limited trunk flexion;
- a noncapsular pattern of hip restriction;
- painful and weak hip extension;
- gluteal swelling;
- an empty end-feel on hip flexion.

If the sign of the buttock is present, a medical referral is necessary.

Meralgia Paresthetica

Patients with meralgia paresthetica typically describe burning, coldness, lightning-type pain, deep muscle achiness, and tingling or frank anesthesia in the anterolateral thigh (see Chapter 5). There may also be local hair loss in the anterolateral thigh.[412] The symptoms may be exacerbated when the hip is extended, as in prone lying, or when standing erect. Sitting may relieve the symptoms in some patients but exacerbate them in others. Eventually, there may be no position that provides relief.[412]

The initial intervention of meralgia paresthetica is conservative, and patients may benefit from analgesics, NSAIDs, looser clothing, and weight loss.

Piriformis Syndrome

Piriformis syndrome is the result of entrapment of the sciatic nerve by the piriformis muscle, as it passes through the sciatic notch (see Chapter 5).

Entrapment of the Obturator Nerve

Compression of the anterior division of the obturator nerve in the thigh has been described recently as one possible cause for adductor region pain, and entrapment of this nerve has been documented by nerve conduction studies.[413] The fascia over the nerve is thought to contribute to compression of the nerve, or perhaps allow for the development of a compartment syndrome.[413]

Myofascial Pain Dysfunction

Myofascial pain is referred to the hip from the following muscles: quadratus lumborum, piriformis, gluteus minimus, and adductor longus.

Quadratus Lumborum. This muscle is perhaps one of the most overlooked sources of hip pain. The more superficial trigger points of this muscle refer pain to the lateral ilium and greater trochanter and may also refer pain into the groin in the region of the inguinal ligament. The tenderness in the trochanteric region can be misdiagnosed as trochanteric bursitis.

Clinical findings can include

- restriction of hip joint movements by lumbar spasm;
- trochanteric and buttock tenderness;
- a contralateral short leg;
- an ipsilateral flexed innominate.

Conservative intervention includes gentle, pain-free static stretching of the muscle, soft tissue techniques, and progressive strengthening.

Gluteus Minimus. Trigger points may be located in the posterior and anterior portions of this muscle. The posterior trigger point refers pain to the medial lower buttock and into the posterior thigh and calf. These trigger points have the potential to increase the tone in the hamstring and calf muscles. Stretching the gluteus minimus before hamstring and calf stretching allows these two muscles to lengthen much more readily. The anterior trigger point refers symptoms to the lower buttock, and down the lateral thigh and leg as far as the lateral malleolus, on occasion.

Conservative intervention includes gentle, pain-free static stretching of the muscle, soft tissue techniques, and progressive strengthening.

Adductor Longus. Trigger points in this muscle strongly refer to the anterior hip and anterior knee. Clinical findings include

- pain with resisted strength testing;
- positive FABER test for pain;
- marked restriction of hip abduction.

Conservative intervention includes gentle, pain-free static stretching of the muscle, soft tissue techniques, and progressive strengthening.

Practice Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, and ROM Associated with Fractures

Avulsions

Apophyseal avulsions of the pelvis and proximal femur occur most commonly to male athletes 10–20 years old, usually as the direct result of vigorous or uncoordinated activities such as kicking, jumping, hurdling, sprinting, and punting, involving the sartorius or TFL.[345,414]

Anterior Iliac Spine. The anterior iliac spine is a common site of the injury, especially during the middle-to-late teenage years when the iliac crest unites with the ilium. Clinical findings can include[415]

- point tenderness;
- crepitus;
- hematoma;
- limited hip motion;
- pain with resisted hip flexion and passive hip extension that increase pain at the site.

Conservative intervention includes ice and hip spica compression, followed by bed rest, progressing to crutch

ambulation and activity modification. Return to normal activity follows a period of strength, flexibility, and functional training.[345]

Hamstring Tendon. Complete and partial avulsions of the proximal hamstring tendon from the ischial origin are common during sporting activities that generate forceful hip flexion moments while the knee is extending.[416] The patient typically presents with a significant gait abnormality and an inability to fully extend the trunk and bear weight on the involved side.[416] These injuries are often treated with open surgical repair.

Ischial Apophyseal. This injury commonly occurs during the teenage years, especially 13–16 years, as the apophysis has the least amount of bony bridging or fusion at a time when the individual is the most active. The most common mechanisms of injury are sprinting and overzealous stretching. Common clinical findings include ischial tenderness and pain, especially when sitting. Ischial apophyseal avulsion fractures that are displaced less than 1 cm can be treated conservatively[416] by avoiding hamstring stretching and tension for several weeks to prevent further displacement and allow healing.[417]

Stress Fractures of the Femoral Neck/Head

Stress fractures result from accelerated bone remodeling in response to repeated stress (see Chapter 2). Although stress fractures are a relatively uncommon etiology of hip pain, if not diagnosed in a timely fashion, progression to serious complications can occur.[418] It is estimated that 1.0–7.2% of all stress fractures involve the femoral neck, with another 5% involving the femoral head.[419] The fracture typically occurs on the superior side (tension-side fractures—high risk) or the inferior side (compression-side fractures—low risk) of the femoral neck.[420] The tension-side fracture may develop into a complete and displaced fracture if left untreated.

The most frequent symptom is the onset of sudden hip pain, usually associated with a recent change in training (particularly an increase in distance or intensity) or a change in training surface. The earliest and most frequent symptom is a pain in the deep thigh, inguinal, or anterior groin area.[420] Pain can also occur in the lateral aspect or anteromedial aspect of the thigh. The pain usually occurs with weight bearing or at the extremes of hip motion and can radiate to the knee. Less severe cases may only have pain following a long run. Night pain may occur if the fracture progresses. Stress fractures are generally classified as fatigue or insufficiency fractures[225]:

- Fatigue stress fractures are caused by repetitive and abnormally high forces from muscle action and/or weight-bearing torques and are often found in persons with normal bone densities. This type of stress fracture at the hip is most common in athletes involved in intense training, including military personnel.
- Insufficiency stress fractures are associated with individuals who have compromised bone densities. Since insufficiency stress fractures are associated with decreased bone mineral density, they tend to be most common in the elderly, especially postmenopausal women. Other predisposing factors for poor bone density include radiation treatments, rheumatoid arthritis due at least in part to the associated disuse and either corticosteroid or methotrexate treatment, renal failure, coxa vara, metabolic disorders, and Paget's disease.

The physical examination is often negative, although there may be a noncapsular pattern of the hip,[225] an empty end-feel, or pain at the extremes of hip internal or external rotation or pain with resisted hip external rotation.[421] In addition, the auscultatory patellar-pubic percussion test may be positive (see "Special Tests").

Differential diagnosis includes OA of the hip, referred symptoms from the spine, trochanteric bursitis, or septic arthritis.

Radiographs taken soon after the symptoms begin have been reported to be positive in only 20% of cases.[420] Diagnosis is best confirmed with bone scintigraphy (scan), although these have been shown to be prone to false negatives.[422] The intervention varies according to the bone scintigraphy findings.[420]

- If there is a positive scan only, or sclerosis and no fracture line on the radiographs, the intervention ranges from modified bed rest to non–weight-bearing with crutches until symptoms subside. Once pain-free, weight bearing is progressed. When significant PWB is pain free, cycling and swimming may be permitted. Weekly radiographs are obtained until the athlete is full weight bearing without pain. Water running and water walking are progressed. If these remain pain free, running on land is commenced, with the initial run being no further than one-quarter mile.
- If there is an overt fracture line on the radiographs with no displacement and provided that only the cortex is involved, an initial period of either bed rest or complete non–weight-bearing is necessary. The patient is progressed to partial and then full weight bearing on crutches as symptoms permit. Roentgenograms every 2–3 days during the first week are necessary to detect any widening of the fracture line. If healing does not occur, internal fixation with some form of hip pin is indicated.

An overt fracture with radiographic evidence of opening or displacement is significant and requires surgical intervention, usually in the form of a hip screw and plate. Displaced fractures must be treated as an orthopaedic emergency.

HIP FRACTURE

Hip fracture, defined as a fracture of the proximal third of the femur, is the orthopaedic problem with the highest incidence, cost, and risk.[423] The morbidity rates after the fracture are 32–80%.[424] Hip fractures are associated with substantial morbidity and mortality in the elderly. Approximately 90% of hip fractures result from a simple low-energy fall.[425] The most common risk factors for falls (and thus hip fractures) are age, gender, race, institutionalization/hospitalization, medical comorbidities (cardiac disease, stroke, dementia, poor hip fracture, osteoporosis), hip geometry, medication, bone density, diet, smoking, alcohol consumption, fluorinated water, urban versus rural residents, and climate.[426] A number of hip fractures exist:

- Intertrochanteric: occur on the proximal, upper part of the femur or thigh bone between the greater trochanter, where the gluteus medius and minimus muscles attach, and the lesser trochanter, where the iliopsoas muscle attaches.
- Femoral neck: Fractures of the femoral neck are proximal to intertrochanteric fractures, whereas subtrochanteric fractures are distal or below to the trochanters.

Intertrochanteric

The intertrochanteric area of the femur, the area of the lesser and the greater trochanters and where the femur changes from an essentially vertical bone to a bone angling at a 45-degree angle from the near-vertical to the acetabulum or pelvis, is proximal to the femoral shaft and distal to the femoral neck. The etiology of intertrochanteric fractures is typically a combination of increased bone fragility of the intertrochanteric area of the femur associated with decreased muscle tone of the muscles in the area secondary to the aging process.

The current approach for intertrochanteric fractures is surgical intervention. With few exceptions, open reduction with internal fixation (ORIF) is used to treat essentially all intertrochanteric fractures. Following the procedure, a preventive protocol of antiembolism stockings and anticoagulants is followed. Physical therapy involves functional and gait training according to the weight-bearing status, and a progressive exercise program of ROM and strengthening.

CLINICAL PEARL

Hip fractures are associated with a high risk of deep vein thrombosis (DVT) (see Chapter 1). Routine thromboprophylaxis remains critical and is the standard of care.

Subtrochanteric

The subtrochanteric region of the femur is exposed to high stresses during ADL; during normal ADL, up to six times the body weight is transmitted across the subtrochanteric region of the femur.[116] These fractures are most frequently seen in two patient populations; older osteopenic patients after a low-energy fall and younger patients involved in high-energy trauma. This region of the femur consists primarily of cortical bone, so healing in this region is predominantly through a primary cortical healing, which makes fracture consolidation quite slow to occur. Surgical treatment can be divided into three main techniques:

- External fixation: rarely used but is indicated in severe open fractures. External fixation is usually temporary, and the conversion to internal fixation can be made if and when the soft tissues have healed sufficiently.
- Open reduction with plates and screws. Following ORIF and plate fixation, minimally protected weight bearing can begin immediately but is advanced slowly beginning approximately 4 weeks after surgery, with full weight bearing anticipated at 8–12 weeks.
- Intramedullary fixation. Following intramedullary nailing, if the bone quality and cortical contact is adequate, 50% PWB can be allowed immediately. With less stability, patients can perform touchdown weight bearing.

As most elderly patients may have difficulty complying with the weight-bearing restrictions, they are often permitted to progress to full postoperative weight-bearing status.

Femoral Neck Fracture

Femoral neck fractures are often associated with multiple injuries and high rates of avascular necrosis and nonunion. Hip fractures are common in the geriatric population and can have devastating consequences. A number of factors predispose the elderly population to fractures, including decreased physical activity, osteoporosis, impaired vision, neurologic disease, and poor balance. The decision for operative or nonoperative treatment and the type of surgical intervention, are based on many factors. Tension-type fractures are less stable than compression fractures, the latter of which can be treated nonoperatively. Tension fractures may require operative stabilization with multiple screws or pins as they are potentially unstable. Nondisplaced fractures are often treated conservatively with bed rest and/or the use of crutches until x-ray films show evidence of callus formation and passive hip movement is pain free. In the elderly population, premorbid cognitive function, walking ability, and independence in ADL are considered when determining the optimal method of surgical repair.

CLINICAL PEARL

Femoral neck fractures are frequently treated using a prosthesis or replacement device (i.e., total hip arthroplasty or hemiarthroplasty).

The prognosis for femoral neck fractures depends on the extent of injury (i.e., whether circulation has been disturbed, amount of comminution, and the amount of displacement), the adequacy of the reduction, and the adequacy of fixation. Maintaining aerobic conditioning throughout the rehabilitation process is important.

The weight-bearing status following the surgical procedure depends on the stability of reduction, bone, and method of fixation. The exercises performed initially include quadriceps sets, gluteal sets, heel slides, active-assisted hip abduction and adduction, and supine internal and external hip rotation. Once PWB ambulation is allowed, aquatic training such as swimming or deep-water running may be used if available. Once full weight bearing is achieved, exercises begin to address functional strengthening of the gluteus medius, the iliopsoas, gluteus maximus, adductors (magnus, longus, and brevis), quadriceps, and hamstrings.

If protected or non–weight-bearing ambulation is necessary, then upper body exercise, such as an upper body ergometer, can be used.

THERAPEUTIC TECHNIQUES

More recently, the minimally invasive anterior approach, using one or two small incisions, has become more popular.

The rationale for minimally invasive procedures is that the use of small incisions potentially lessens soft tissue trauma during surgery and, therefore, should improve and accelerate a patient's postoperative recovery. Other benefits include reduced blood loss, reduce postoperative pain, shorter length of hospital stay and lower cost of hospitalization, a more rapid recovery of functional mobility and a better cosmetic appearance of the surgical scar.

A review of the literature reveals inconsistent practice patterns in the physical therapy management of THA patients. Most surgeons have designed their own postsurgical protocols, which should be strictly adhered to. Standard precautions are observed with patients who underwent a lateral or posterolateral approach to prevent posterior hip dislocation. These include the following:

- Avoidance of hip adduction. Typically an abduction wedge or pillow is prescribed. A pillow is placed between the legs if the patient wants to lie on the side.
- Avoidance of hip internal rotation. Combinations of hip flexion, internal rotation, and adduction must be avoided for up to 4 months after surgery or until physician clearance.
- Avoidance of hip flexion greater than 90 degrees (bending forward at the hip, reaching for objects or tying shoes). Elevated chairs or toilet seats can be used to increase compliance, as can an assistive device or reacher.

Precautions for a patient who underwent an anterior/anterior lateral or direct lateral approach, with or without trochanteric osteotomy include:

- Avoidance of hip flexion greater than 90 degrees.
- Avoidance of hip extension, adduction, and external rotation past neutral.
- Avoidance of the combined motions of flexion, abduction, and external rotation.

If a trochanteric osteotomy was performed, or the gluteus medius was incised and repaired, the patient should not perform active, antigravity hip abduction for at least 6–8 weeks or until approved by the surgeon.

Techniques to Increase Joint Mobility

Passive Articular Mobilization Techniques

In a single-blind randomized study[287] investigating interventions for hip OA, 109 subjects were randomly assigned to receive mobilization and manipulation to the hip joint or active exercises designed to improve strength and ROM for nine visits over a period of 5 weeks. Success rates after 5 weeks were 81% in the manual therapy group and 50% in the exercise group. Furthermore, patients in the manual therapy group had significantly better outcomes on pain, stiffness, hip function, and ROM. The effects of manual therapy on the improvement of pain, hip function, and ROM remained after 29 weeks.

Mobilizations of this joint are typically performed using a sustained stretch to decrease a hip joint capsular restriction, with the stretch being governed by the direction of the restriction, rather than by the concave–convex rule. For example, if hip joint extension is restricted, the distal femur is moved into the direction of hip extension.[427]

The joint is initially positioned in its neutral position and is progressively moved closer to the end of the range. A belt can also be used for this technique. Rotations can be combined with any sustained stretch performed in a cardinal plane. Distraction or compression techniques can be used alone or combined with rotations.

Distraction. Joint distraction mobilizations are indicated for pain and any hypomobility at the hip joint, as in the case when the pain is reported by the patient before tissue resistance is felt by the clinician. The lateral distraction technique (Fig. 19-30) can be used to increase hip joint ROM into adduction and internal rotation.

Leg Traction (Inferior Glide). An inferior distraction (Fig. 19-31) can be used for temporary relief of joint pain, to increase ROM into hip joint abduction and for stretching capsular adhesion that is pronounced in the inferior portion of the joint capsule. [107,114]

Quadrant (Scouring) Mobilizations. Quadrant mobilizations involve flexion and adduction of the hip, combined with simultaneous joint compression through the femur.[114,427–429] The flexed and adducted thigh is swept through a 90- to 140-degree arc of flexion while maintaining joint compression. This arc of motion should feel smooth and should be pain free. In an abnormal joint, pain or an obstruction to the arc occurs during the movement. In selected nonacute cases, the procedure may be used as an effective mobilizing procedure, where grade II to III mobilizations are applied perpendicular to the arc throughout.[114,428]

Posterior Glide. The posterior glide mobilization (Fig. 19-32) is used to increase flexion and to increase internal rotation of the hip.

Anterior Glide. The anterior glide (Fig. 19-33) is used to increase extension and to increase external rotation of the hip.

Inferior Glide. The inferior glide is used to increase abduction of the hip.

Mobilizations with Movement

To Restore Internal Rotation of the Hip. This technique is employed when the patient presents with early signs of hip joint degeneration, as indicated by minor capsular signs and slight degenerative changes on radiographs.[430,431] A belt that can be altered in length is required for the technique.

The patient is positioned in supine with the involved hip and knee flexed and the foot just off the edge of the bed, with the clinician standing on the involved side, facing the patient's head. A belt is placed around the back of the clinician, just below the hip joints, and around the patient's thigh as proximal as possible, so that the belt is approximately horizontal. Using the hand closest to the patient's head, the clinician grasps the lateral iliac crest of the involved side, with the elbow in the crease of the clinician's groin to stabilize the pelvis during the maneuver. The clinician wraps the other

hand around the patient's midthigh. From this position, the clinician slowly extends their own hips to apply a distraction force to the patient's hip joint, while maintaining the fixation of the ilium.

If the maneuver produces any pain, it should be discontinued. This should be differentiated from discomfort, which might be caused by inappropriate placement of the belt.

To Restore Flexion of the Hip. The technique to restore flexion of the hip is identical to the one described above, except that during the distraction, the clinician passively flexes the patient's hip into flexion by side bending at the waist.[432]

Techniques to Increase Soft Tissue Extensibility

The efficacy of manual techniques for improving hip ROM has been reported in the literature. Crosman et al.[433] studied the effects of hamstring massage (effleurage, petrissage, and friction) on hip flexion range in normal individuals and noted significant range improvements after the soft tissue massage.[114] Godges et al.[434] reported improved hip flexion and hip extension ranges in normal individuals after the application of manual stretches to muscle groups opposing each respective motion, combined with exercises for the agonistic muscles.

Iliotibial Band. Stretching of the IT band is commonly prescribed in standing where the patient crosses one leg in front of the other so that the back leg is positioned in internal rotation. The patient then either places both hands on the hips or uses one hand for balance before swaying laterally toward the side of the back leg to impart a stretch on the lateral hip structures on that side. However, this particular maneuver applies more of the stretch to the gluteus medius and lateral capsule than the ITB. However, if the patient performs this sway with both arms held extended overhead, more the stretch is imparted on the ITB.[435] An alternative maneuver can be used where the patient is positioned in the half kneeling position so that one hip is flexed to 90 degrees and the other knee is on the floor. The patient is asked to maximally drop the pelvis on the side of the flexed hip to adduct that hip. The patient also is asked to extend the hip by means of a posterior pelvic tilt.

Iliopsoas. The patient is positioned in side lying (Fig. 19-91). The patient can be instructed to flex the uninvolved hip and maintain its position by using their arms to help stabilize the lumbopelvic region. While monitoring the lumbopelvic motion with one hand, the clinician passively extends the thigh with the other arm/hand. The advantage of this technique is that varying degrees of hip adduction/abduction and knee flexion/extension can be controlled. The disadvantage is that the technique is more physically demanding for the clinician.

Iliopsoas and Rectus Femoris. Although a number of exercises have been advocated to stretch these muscle groups, because of their potential to increase the anterior shear of the lumbar vertebrae either directly or indirectly, the standing/kneeling position is preferred.

A pillow is placed on the floor, and the patient kneels down on the pillow with the other leg placed out in front in the typical lunge position (Fig. 19-92). The patient is asked to perform a posterior pelvic tilt and to maintain an erect position with respect to the trunk. From this starting position, the patient glides the trunk anteriorly, maintaining the trunk in a near-vertical position. A stretch on the upper aspect of

FIGURE 19-91 Side-lying hip flexor stretch.

FIGURE 19-92 Iliopsoas and rectus femoris stretch.

FIGURE 19-93 Tensor fascia latae stretch.

the anterior thigh of the kneeling leg should be felt. T e rectus femoris can be stretched further from this position by grasping the ankle of the kneeling leg and raising the foot toward the buttock (Fig. 19-92).

Tensor Fascia Latae. The patient is positioned supine with the legs straight. The foot of the leg to be stretched is placed on the table on the outside of the uninvolved straight leg. The patient reaches and grasps the knee of the involved leg and pulls the knee across and over the straight leg (Fig. 19-93). Both shoulders should be kept flat on the table. At the point the stretch is felt, the position is maintained for approximately 30 seconds. The stretch is repeated 10 times.

HISTORY

General Demographics

A 62-year-old male

History of Current Condition

A patient presents with complaints of aching pain in the right groin that varies in severity and extends down the anterior thigh to the knee. The pain began gradually about 3 months before. Initially, the patient felt stiffness whenever he sat for prolonged periods of time or after a night's sleep. The patient reports that he can no longer walk as far as he once did and that negotiating stairs was especially painful.

Past History of Current Condition

A long history of OA of the spine and occasional twinges of pain in the right groin. The patient also has a history of right-sided sciatica.

Past Medical/Surgical History

The patient had a total joint replacement of the right knee approximately 4 months ago.

Medications

Celecoxib

Other Tests and Measuresc

Radiographs of right hip are negative for loose bodies, tumors, and fracture. Advanced OA of right hip was noted.

Social Habits (past and present)

Nonsmoker. Drinks occasionally. Active life style.

Social History

Married. Two children, both live close by.

Family History

No relevant history of hip problems in family.

Growth and Development

Normal development; left-handed.

Living Environment

Lives in an apartment. One flight of stairs to negotiate.

Occupational/Employment/School

Retired railroad laborer. High school education.

Functional Status/Activity Level

The patient demonstrates difficulty rising from a chair and transferring from bed to chair.

Health Status (self-report)

In general good health, but pain interferes with tasks at home and with helping his sick wife.

Systems Seview

Unremarkable

Questions

1. List the possible structure(s) that can produce groin pain.
2. What might the history of pain with early morning stiffness and pain with stair negotiation tell the clinician?
3. What other activities might increase the patient's symptoms? Why?

4. To help rule out the various causes of groin pain, what other questions can you ask?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms and the tests you would use to rule out each one.
6. Does this presentation/history warrant a Cyriax lower quarter scanning examination? Why or why not?

CASE STu DY

t Hig H pa in

HISTORY

History of Current Condition

A 22-year-old male sustained a kick to the right thigh approximately 2 weeks ago while playing college soccer. He complains of a dull ache on the anterior aspect of his thigh. The pain is worse with activities that involve attempting to squat or kick. The patient also reports feeling a lump on the front of his thigh. The patient saw his physician who diagnosed the condition as a deep quadriceps contusion and prescribed 8 weeks of physical therapy.

Past History of Current Condition

No previous history of thigh pain.

Past Medical/Surgical History

- No history of previous knee or hip injury.
- No back pain/surgery reported.
- No knee surgeries reported.
- History of chronic ankle sprains.

Medications

None.

Other Tests and Measures

Radiograph results pending.

Occupational/Employment/School

Full-time student at local college for the past 2 years.

Functional Status/Activity Level

Very active. In addition to soccer, the patient also plays tennis and racquetball.

Health Status (self-report)

In general, good health.

Questions

1. Given the specific mechanism of injury, list all of the structures you suspect could be injured and will require a specific examination.
2. What condition could be present with the history of pain in a muscle belly following a contusion?
3. What other activities do you suspect would increase the patient's symptoms? Why?
4. In a patient with an insidious onset of pain, what questions would you ask to help rule out the various causes of anterior thigh pain?
5. What is your working hypothesis at this stage?
6. Does this presentation/history warrant a lower quarter scan? Why or why not?

CHAPTER 20

The Knee

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joint, ligaments, muscles, and blood and nerve supply that comprise the knee joint complex.
2. Describe the biomechanics of the tibiofemoral and patellofemoral joints (PFJs), including the forces involved with closed-chain and open-chain activities, the open- and close-packed positions, normal and abnormal joint barriers, force couples, and joint stabilizers.
3. Describe the purpose and components of an examination for the knee joint complex.
4. Perform a detailed examination of the knee joint complex, including palpation of the articular and soft-tissue structures, specific passive and active mobility tests, stability tests, and special tests.
5. Understand the purpose of muscle function testing and extrapolate information from the findings.
6. Describe the significance of muscle imbalance in terms of functional muscle performance.
7. Outline the significance of the key findings from the history, the tests and measures of the knee complex, and establish a diagnosis.
8. Describe the common pathologies of the knee joint complex and their relationship to impairment.
9. Develop self-reliant intervention strategies based on clinical findings and established goals.
10. Apply active and passive techniques to the knee joint complex and its surrounding structures, using the correct intensity and duration.
11. Evaluate intervention effectiveness to progress or modify the intervention.
12. Plan an effective home program, and instruct the patient in this program.
13. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

The knee joint complex is extremely elaborate and includes three articulating surfaces, which form two distinct joints contained within a single-joint capsule: the patellofemoral and tibiofemoral joints. Anatomically and biomechanically the tibiofemoral joint and the patellofemoral joint (PFJ) can be considered as separate entities, in much the same way as the craniovertebral joints are when compared with the rest of the cervical spine. In 15–20% of the population, an accessory sesamoid bone occurring in the gastrocnemius, the fabella, is present as part of the knee joint complex.[1,2] The fabella, when present, articulates with the lateral femoral condyle and is hence an articular sesamoid.

The knee is one of the most commonly injured joints in the body. The types of knee injuries seen clinically can be generalized into the following categories:

- Unspecified sprains or strains, and other minor injuries, including overuse injuries
- Contusions
- Meniscal or ligamentous injuries

It is important that the clinician be familiar with the diagnostic and therapeutic procedures appropriate for all of the categories of injury. It is also important that the clinician have a good understanding of differential diagnosis as pain in the thigh, knee, and calf can result from a broad spectrum of conditions.

ANATOMY

TIBIOFEMORAL JOINT

The tibiofemoral joint consists of the distal end of the femur and the proximal end of the tibia (Fig. 20-1). The tibiofemoral joint has great demands placed on it in terms of both stability and mobility. The femur is the largest bone in the body and

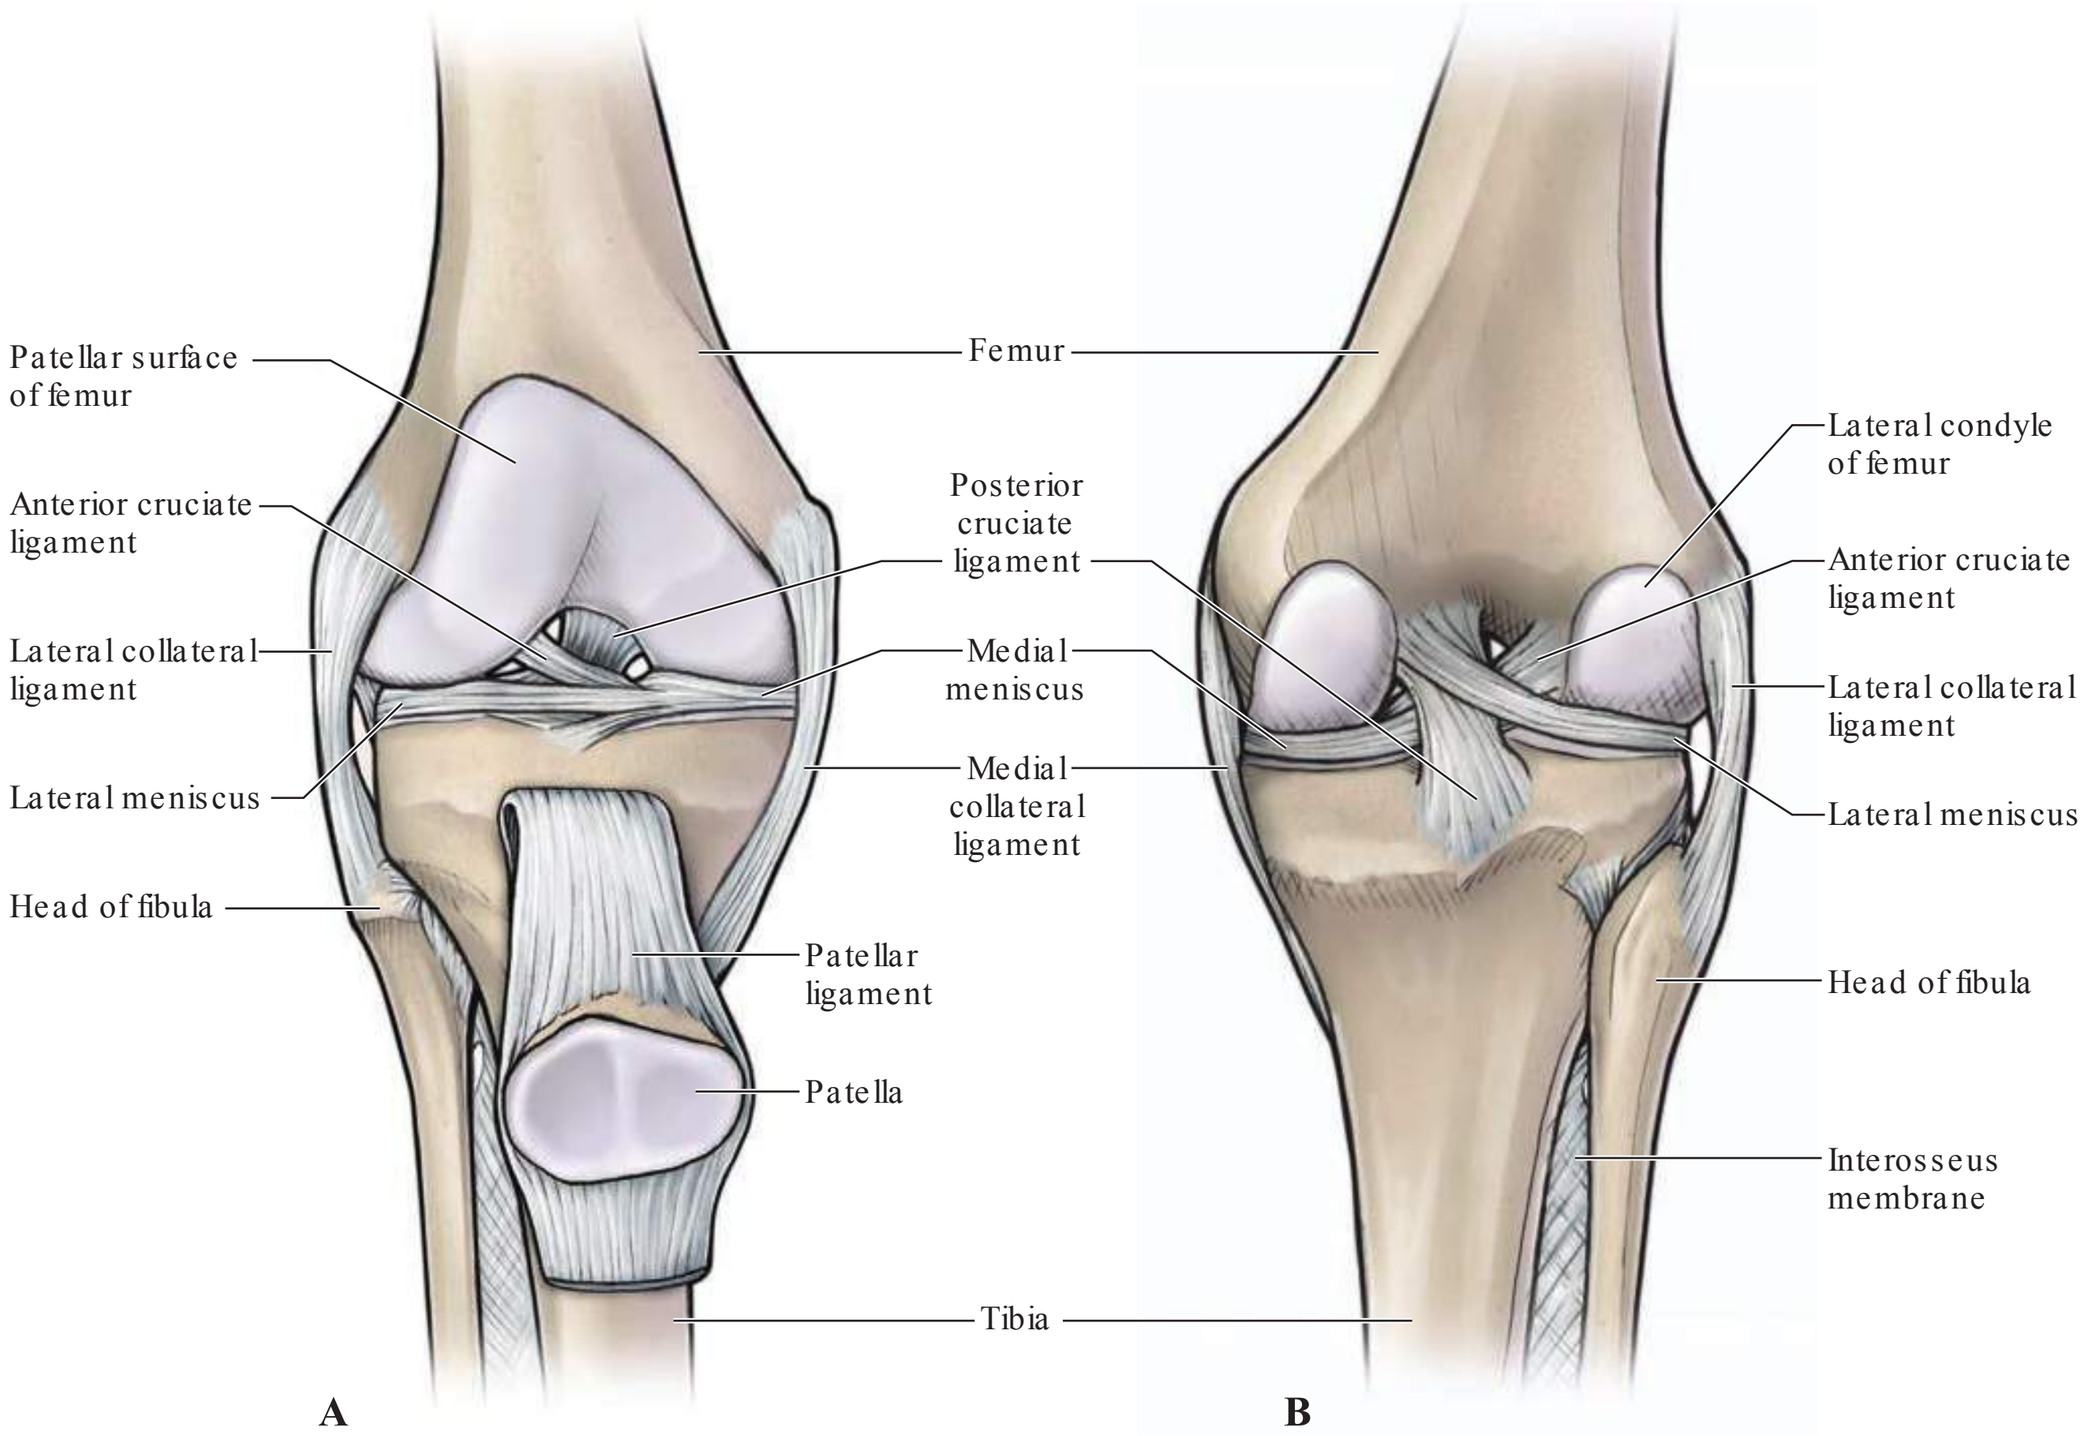

FIGURE 20-1 Anterior and posterior views of the bones of the tibiofemoral joint. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

represents approximately 25% of a person's height. [3] Its distal aspect (Fig. 20-1) is composed of two femoral condyles that are separated by an intercondylar notch or fossa. The intercondylar notch serves to accept the anterior cruciate ligament (ACL) and the posterior cruciate ligament (PCL).

CLINICAL PEARL

A narrow intercondylar notch has been associated with an increase in injuries to the ACL.[4]

The femoral condyles (Fig. 20-1) project posteriorly from the femoral shaft. The smaller lateral femoral condyle is ball-shaped and faces outward, whereas the elliptical-shaped medial femoral condyle faces inward. The lateral condyle serves as the origin of the popliteus, whereas the lateral epicondyle serves as the origin of the lateral head of the gastrocnemius and the lateral collateral ligament (LCL). The medial epicondyle (Fig. 20-1) serves as the insertion site for the adductor magnus, the medial head of the gastrocnemius, and the medial collateral ligament (MCL).

The anteroposterior length of the adult medial femoral condyle is on average 1.7 cm greater than that of its lateral counterpart, resulting in an increased length of the articular surface on the medial femoral condyle as compared with that of the lateral femoral condyle.[5] Thus, the articulating surfaces are asymmetric, yet work in unison.[2] The distal and the posterior portion of the femoral condyles articulate with the tibia.

The proximal tibia (Fig. 20-2) is composed of two plateaus separated by the intercondylar eminence, including the medial and lateral tibial spines.[6] The tibial plateaus are concave in a mediolateral direction. In the anteroposterior direction, the medial tibial plateau is also concave, whereas the lateral is convex, producing more asymmetry and an increase in lateral mobility. The medial plateau has a surface area that is approximately 50% greater than that of the lateral plateau, and its articular surface is three times thicker.[7] The concavity of the tibial plateaus is accentuated by the presence of the menisci (see later).

PATELLOFEMORAL JOINT

The PFJ is a complex articulation, dependent on both dynamic and static restraints for its function and stability.

The patella (Fig. 20-1), a ubiquitous sesamoid bone found in birds and mammals, plays an important role in the biomechanics of the knee. Its articular anatomy is uncomplicated: it is a very hard, triangular-shaped bone, situated in the intercondylar notch and embedded in the

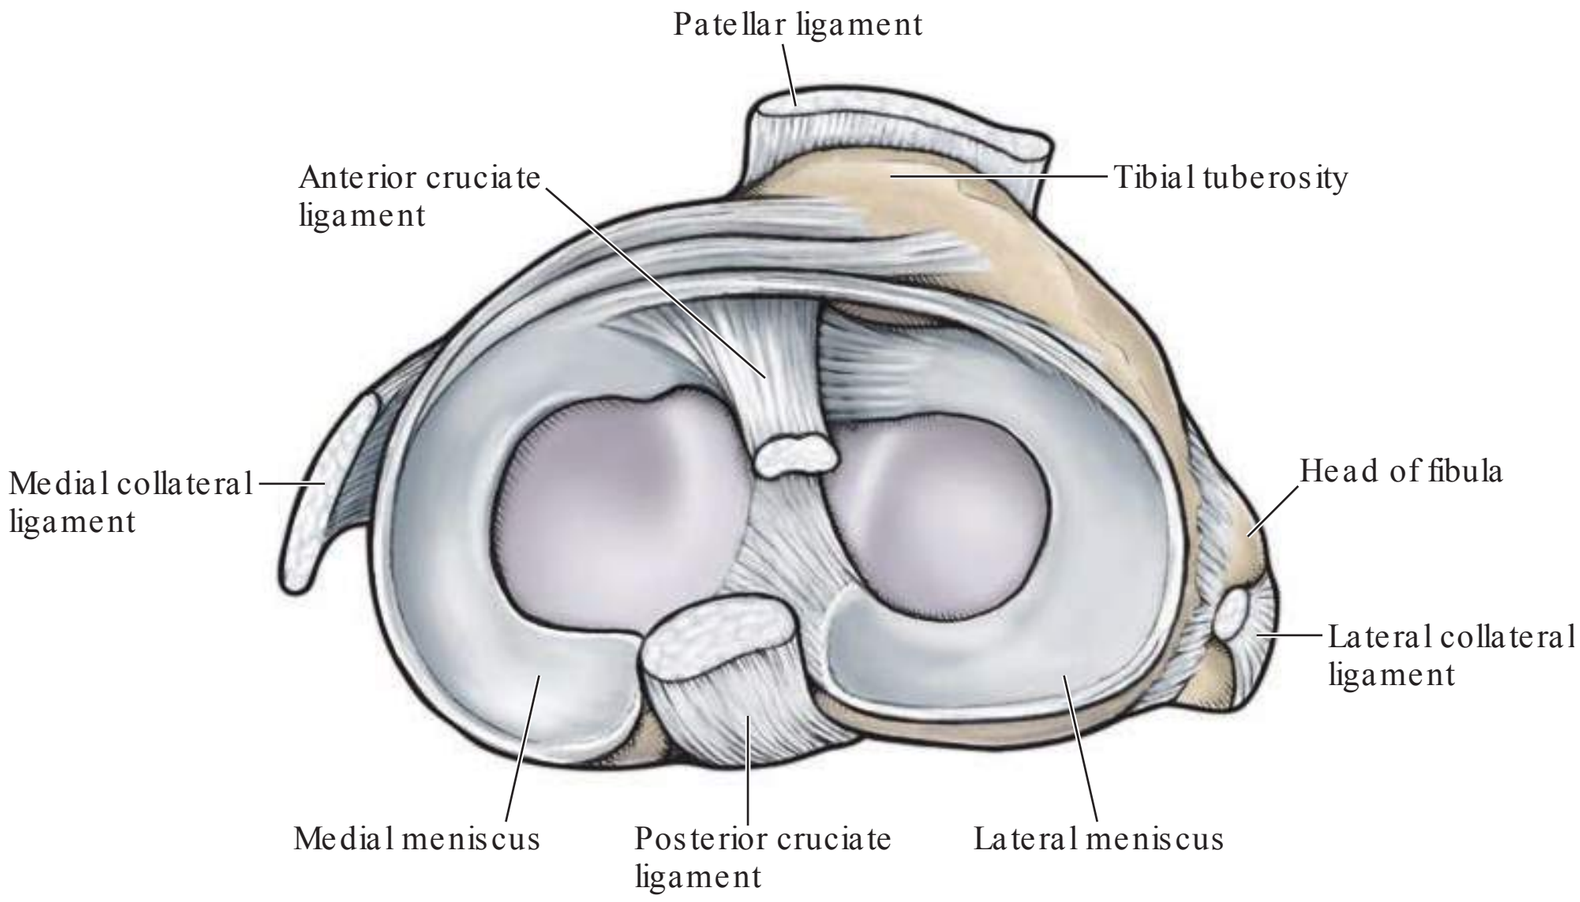

FIGURE 20-2 Articulating surfaces of the tibia. (Reproduced, with permission, from Chapter 36. Thigh. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

tendon of the quadriceps femoris muscle above and the patellar tendon below. The groove has a complex architecture with increasing height of the groove's lateral facet at the proximal aspect, providing a deeper "patella track" in knee extension.[8] The thickness of the patella varies considerably, attaining a maximum height of 2–2.5 cm (0.77–1 in) at its central portion.[9] The posterior surface of the patella can include up to seven facets. A smaller facet, known as the odd facet, exists medially and is delineated by a second vertical ridge. These concave medial and lateral facets are separated by a vertical ridge and are covered with aneural hyaline cartilage, the thickest cartilage in the body (up to 7-mm thick).[9] The articular cartilage of the patella is unique because it lacks conformity with the underlying bone.[10] The hyaline cartilage, here as elsewhere, functions to minimize the friction that occurs at the functional contact areas of the joint surfaces.

Radiographic and cadaver studies have classified the patella into three Wiberg classifications (type A–C) based on the size and shape of these lateral and medial facets.

The patellar surface of the femur is divided into medial and lateral facets that closely correspond to those on the posterior surface of the patella.[11] The PFJ functions to[12]

- provide the articulation with low friction;
- protect the distal aspect of the femur from trauma and the quadriceps from attritional wear;
- improve the cosmetic appearance of the knee;
- improve the moment arm (distance from the center of gravity and the center of rotation) of the quadriceps. This is achieved by elevating the quadriceps femoris muscle from the center of knee rotation. This increases the efficiency of the quadriceps muscle and provides it with leverage for extending the leg. The patellar contribution to the knee extensor moment arm increases with increasing amounts of knee extension;
- decrease the amount of anteroposterior tibiofemoral shear stress placed on the joint.

JOINT CAPSULE AND SYNOVIUM

The capsule of the knee joint complex is composed of a thin, strong fibrous membrane and is the largest synovial capsule in the body. The capsule ascends anteriorly approximately 2 finger breadths above the patella to form the suprapatellar pouch. Posteriorly, it ascends to the origins of the gastrocnemius. Inferiorly, the capsule attaches to the edges of the articulating surfaces of the tibial plateaus, with the exception of the intercondylar eminence, and a small portion of the anterior intercondylar region.[13] A synovial membrane lines the inner portion of the knee joint capsule. By lining the joint capsule, the synovial membrane excludes the cruciate ligaments from the interior portion of the knee joint, making them extrasynovial yet intraarticular.

The articularis genu, located superior to the patella, is thought to function to retract the knee capsule during knee extension. Thus, it serves a similar function as the anconeus in the elbow.

PROXIMAL TIBIOFIBULAR JOINT

The proximal, or superior, tibiofibular joint (Fig. 20-1) is an almost plane joint with a slight convexity on the oval tibial facet and a slight concavity of the fibular head. The joint is located below the tibial plateau on the lateral condyle of the tibia. The tibial articulating facet faces laterally, posteriorly, and inferiorly. Although the joint is often described as a simple, synovial, modified ovoid, it functions as a modified sellar when combined with the distal, or inferior, tibiofibular joint (see Chapter 21).

The joint capsule of the proximal tibiofibular joint complex is thicker anteriorly than posteriorly and, in 10% of the population, the synovium is continuous with that of the knee joint.[14] The joint receives support from anterior and posterior ligaments, and an interosseous membrane. The interosseous membrane attaches between the medial border of the fibula and the lateral border of the tibia, providing attachment to the deep anterior and posterior muscles of the leg. The majority of its fibers pass obliquely in an inferior and lateral direction.

T e proximal tibiofibular joint has more motion than its distal partner. T e motion occurring at the proximal joint, consists of two glides, one in a superoinferior direction, and the other in an anteroposterior direction.[7] T ese motions are possible because of the orientation of the joint line, which also facilitates an osteokinematic spin of the fibula. T e motion at this joint can be decreased by articular fibrosis or by soft-tissue restraints; the biceps femoris can pull or hold it posteriorly, whereas the tibialis anterior can pull or hold it anteriorly.

Although the capsular pattern of restriction for this joint is unclear, it is probably indicated by pain during an isometric contraction of the biceps femoris with the knee at 90 degrees of flexion. T e close-packed position for this joint, equally debatable, is probably weight-bearing (WB) ankle dorsiflexion.

Both the tibia and fibula are vulnerable to fracture at the lower third of their shaft. Anterior joint subluxations occur at this joint as a result of medial knee joint strain or an inversion sprain of the ankle. Posterior joint subluxation can occur as a result of a lateral knee joint strain, but is often missed because of the more serious ligament damage to the knee.

T e nerve supply to this joint is provided by the common fibular (peroneal) and recurrent articular nerves. T e joint receives its blood supply from a perforating branch of the fibular (peroneal) artery, and the anterior tibial artery.

LIGAMENTS

T e static stability of the knee joint complex depends on four major knee ligaments, which provide a primary restraint to abnormal knee motion:

- Anterior cruciate (Fig. 20-1). Provides the primary restraint to anterior translation and medial rotation of the tibia on the femur and is a secondary restraint to valgus and varus rotation of the tibia.
- Posterior cruciate (Fig. 20-1). Provides the primary restraint to posterior translation and medial rotation of the tibia on the femur and is a secondary restraint to valgus and varus rotation of the tibia.
- Medial (tibial) collateral (Fig. 20-1). Provides the primary restraint to valgus and lateral rotation of the tibia, and is a secondary restraint to the anterior and posterior translation of the tibia on the femur.
- Lateral (fibular) collateral (Fig. 20-1). Provides the primary restraint to varus and lateral rotation of the tibia, and is a secondary restraint to the anterior and posterior translation of the tibia on the femur.

Cruciate Ligaments

T e two central intraarticular cruciate ligaments derive their name from the Latin word crucere (cross) because they cross each other (Fig. 20-1). Both the ACL and PCL lie in the center of the joint, and each is named according to their attachment sites on the tibia.[14] T e cruciate ligaments, which differ from those of other joints in that they restrict normal, rather than abnormal, motion, are the main stabilizing ligaments of the knee and restrain against anterior (ACL) and posterior (PCL) translations of the tibia on the femur. T ey also restrain against excessive internal and external rotation and varus movement of the tibia.

CLINICAL PEARL

One study[15] analyzed the coupled internal–external rotation of the tibia, finding that when an anterior force was applied to the tibia of a knee with intact ligaments, internal rotation occurred, whereas a posterior force produced external rotation of the tibia. These movements, rotations with coupled anterior and posterior translation, were found to be greater in flexion than near extension.[16] Another study[17] found this increase to be more marked at an angle of 20 degrees of flexion than at full extension or at 90 degrees of flexion.

T e blood supply to the cruciate ligaments is largely provided from the middle and inferior geniculate branches of the popliteal artery. T e cruciate ligaments are innervated by the posterior articular nerve, a branch of the posterior tibial nerve.[18] T e function of this nerve supply is questionable although it may serve as proprioceptive in nature.[19] In addition, the cruciate ligaments contain mechanoreceptors, suggesting that disruption of the ligament structure can produce partial deafferentation of the joint.[20] Evidence of a proprioceptive function of the ACL comes from extensive histologic observations demonstrating that the ACL appears to contain proprioceptive nerve endings.[21,22] Indeed, Krauspe et al.,[18] in single-fiber studies, identified a total of 26 mechanoreceptors of the cruciate ligament among 13 animals.

Although these cruciate ligaments function together, they are described separately.

Anterior Cruciate Ligament

T e ACL is a unique structure and one of the most important ligaments to knee stability, serving as a primary restraint to anterior translation of the tibia relative to the femur, and a secondary restraint to both internal and external rotation in the non–weight-bearing (NWB) knee.[23–26] An injury to this ligament has terminated many a promising sports career.[27,28]

T e ACL (Fig. 20-1) is composed of a vast array of individual fascicles. T ese, in turn, are composed of numerous interlacing networks of collagen fibrils. T e fascicles originate on the inner aspect of the lateral femoral condyle in the intercondylar notch (resident's ridge), which serves as the anterior limit of the ACL in the anatomical position, and travel obliquely and distally through the knee joint. T ey enter the anterior intercondylar surface of the tibial plateau, where they partially blend with the lateral meniscus. As the fascicles of the ACL course through the knee joint and attach to their insertion sites, they fan out and give a slight spiral appearance to the ligament, a phenomenon that is more pronounced during knee flexion.[29,30]

T e synovial tissue that enfolds the ACL consists of an intimal layer, facing the joint cavity, and a subsynovial layer. T e subsynovial layer is in direct contact with the ACL and contains neurovascular structures. T e ACL is considered intraarticular yet extrasynovial because of the posterior invagination of the synovial membrane.

Although the posterior articular nerve is the major nerve for the ACL, afferent fibers have also been demonstrated in the medial and lateral articular nerves.[31]

Like all ligaments, the ACL behaves as a viscoelastic structure, allowing it to dissipate energy and to adjust its length and internal load distribution as a function of load history.[32,33] T is means that the normal ACL is capable of microscopic adjustments to internal stresses over time, thus influencing the laxity, stresses, and kinematics of the joint in subtle but potentially important ways.[34] One anatomic factor that contributes to selective fiber recruitment during tensile loading is the specific location of the insertions of the ACL on the femur and the tibia. T ese differing insertion sites allow different fibers of the ACL to be recruited with every subtle three-dimensional (3D) change in the position of the joint.[29,34–36]

T e ACL consists of two functional bundles—the anteromedial (AM) and posterolateral (PL) bundles—named for their position on the tibia. Butler et al.[37] have shown that whatever the angle of knee flexion, the ACL absorbs nearly 90% of the force causing anterior translation.[26,38,39] T e femoral footprints of the AM and PL bundles are vertically aligned when the knee is in full extension, and the femoral origin of the AM bundle is located superior to the PL insertion.[40] In this configuration, the two bundles are parallel to each other, whereas with the knee in 90 degrees of flexion, the two bundles cross each other, and the femoral insertions are nearly horizontally aligned.[40,41] T e tensile strength of the ACL is equal to that of the knee collaterals, but is half that of the PCL.[42] Since its fibers are unyielding, forcing the ACL more than 5% beyond its resting length may result in rupture.[26] Several factors can influence the amount of tension on the ACL[41,43]:

- When the knee is in full extension, the AM and PL bundles are under tension.
- When the knee is at 60 to 90 degrees of flexion, the PL bundle is lax and allows rotation of the tibia on the femur.
- T e PL bundle limits anterior translation of the tibia at low angles of knee flexion (0–30 degrees).
- T e AM bundle primarily resists anterior translation of the tibia and undergoes less change in length than the PL bundle throughout the range of knee motion.
- T e PL bundle is maximally lengthened when the knee is in full extension, and the AM bundle is under maximum tension when the knee is flexed between 45 degrees and 60 degrees.
- Compressive loading of the tibiofemoral joint, such as that occurs during WB, has been shown to reduce anteroposterior laxity and stiffen the joint when compared with the NWB.[44] T ese changes appear to reflect the increased strain borne by the ACL during the transition from NWB to WB.[45] T us, the popular belief in the beneficial effects of early WB and closed-kinetic chain exercises (CKCEs) following anterior cruciate reconstruction may be open to question (Table 20-1).[45]

TABLE 20-1 Rank Comparison of Peak ACL Strain Values During Commonly Prescribed Rehabilitation Activities

Rehabilitation Activity	Peak Strain (Mean ± ISD)	No. of Subjects
Isometric quads contraction at 15 degrees (30 Newton meters [Nm] of extension torque)	4.4 (0.6)%	8
Squatting with sport cord	4.0 (1.7)%	8
Active flexion–extension of the knee with 45-N weight boot	3.8 (0.5)%	9
Lachman test (150 N of anterior shear load: 30 degrees of flexion)	3.7 (0.8)%	10
Squatting	3.6 (1.3)%	8
Active flexion–extension (no weight boot) of the knee	2.8 (0.8)%	18
Simultaneous quadriceps and hamstring contraction at 15 degrees	2.8 (0.9)%	8
Isometric quadriceps contraction at 30 degrees (30 Nm of extension torque)	2.7 (0.5)%	18
Stair climbing	2.7 (2.9)%	5
Anterior drawer (150 N of anterior shear load: 90 degrees of flexion)	1.8 (0.9)%	10
Stationary bicycling	1.7 (1.9)%	8
Isometric hamstring contraction at 15 degrees (10 Nm of flexion torque)	0.6 (0.9)%	8
Simultaneous quadriceps and hamstring contraction at 30 degrees	0.4 (0.5)%	8
Passive flexion–extension of the knee	0.1 (0.9)%	10
Isometric quads contraction at 60 degrees (30 Nm of extension torque)	0.0%	8
Isometric quadriceps contraction at 90 degrees (30 Nm of extension torque)	0.0%	18
Simultaneous quadriceps and hamstring contraction at 60 degrees	0.0%	8
Simultaneous quadriceps and hamstring contraction at 90 degrees	0.0%	8
Isometric hamstring contraction at 30 degrees, 60 degrees, and 90 degrees to −10 Nm of flexion torque	0.0%	8

ACL, anterior cruciate ligament; ISD, implied standard deviation.
Data from Beynnon BD, Fleming BC. Anterior cruciate ligament strain in-vivo: A review of previous work. J Biomech. 1998;31:519–525.

- Stair-climbing exercises using exercise equipment such as the Stairmaster 4000PT (Randall Sports Medicine, Kirkland, WA) have been shown to produce moderate strain on the ACL compared with other rehabilitation activities.[46]

The circumstances that cause the highest loads and strains on the ACL during daily function are[34] quadriceps-powered extensions of the knee, moving it from approximately 40 degrees of flexion to full extension; hyperextension of the knee; excessive internal tibial rotation; or excessive varus or valgus stress on the tibia if a collateral ligament is torn.

Both estimates[47,48] and measurements[23,24] have shown that the maximum measured strain differential in the ACL is approximately 5% during any rehabilitation exercise.[34,49] This strain represents only approximately one-quarter of the failure strain of the normal ACL, suggesting that these exercises load the normal ACL to only a small fraction of its failure capacity.[32,34,36]

Posterior Cruciate Ligament

The PCL attaches posteriorly to the insertion of the posterior horns of the lateral and medial menisci on the posterior part of the posterior intercondylar fossa of the tibia.[50] From here, the PCL extends obliquely medially, anteriorly, and superiorly to attach to the lateral surface of the medial femoral condyle (Fig. 20-1). Overall, the ligament is wider at its femoral origin and narrowest near the tibial insertion.[51] The PCL is covered by synovial lining and is therefore considered to be extrasynovial yet intraarticular.

Information regarding the biomechanical function of the PCL is scant compared with that of the ACL. It is known that the PCL is 50% thicker and has twice the tensile strength of the ACL.[52] The PCL is more vertical in extension and horizontal in flexion.[53] Like the ACL, the PCL consists of two bundles: anterior lateral and posterior medial. Overall, the ligament is most taut with further flexion of the knee.[54] Specifically, the anterior lateral bundle is taut in flexion, while the posterior medial bundle is taut in extension. According to Butler et al.,[37] the PCL provides 90–95% of the total restraint to posterior translation of the tibia on the femur, with the remainder being provided by the collateral ligaments, posterior portion of the medial and lateral capsules, and the popliteus tendon. The contribution percentage resisting posterior translation decreases as the knee extends. The PCL is significantly loaded if a posteriorly directed force is applied to the tibia when the knee is flexed to 90 degrees or greater while in neutral rotation.[55] If the same force is applied to the tibia when the knee is in terminal extension, the load on the PCL is not increased.[55] This is contrary to the popular belief that hyperextension of the knee is the mechanism of injury of the PCL. The PCL also restrains internal rotation of the tibia on the femur and helps prevent posteromedial instability at the knee.[56]

Other functions of the PCL include acting as a secondary restraint to external rotation of the tibia on the femur at 90 degrees of flexion,[57] assisting with a rolling/gliding mechanism of the tibiofemoral joint, and resisting varus/valgus forces at the knee after the collateral ligaments have failed.

A significant force is needed to tear the PCL. Thus, tears of the PCL are usually the result of severe contact injuries that often occur in traumatic situations, such as a dashboard injury during a motor vehicle accident.

In concert with the PCL are the anterior and posterior meniscofemoral ligaments, which comprise approximately 22–50% of the cross-sectional area of the PCL.[51,58] Although these ligaments arise from the common PCL origin they are distinct structures having different insertion sites.[59] Both are named with respect to the orientation to the PCL (see "Lateral Meniscus"). Since the insertion site of the meniscofemoral ligaments is different from that of the PCL, if a midsubstance tear of the PCL occurs, it is possible that one or both of the meniscofemoral ligaments may remain intact.[60]

Medial Collateral Ligament

Both the MCL and the LCL are considered to be extra-articular ligaments.

The MCL, or tibial collateral ligament (Fig. 20-1), develops as a thickening of the medial joint capsule.[61] It can be subdivided into a superficial band and a deep band.

- The superficial band is a thick, flat band, and has a fan-like attachment proximally on the medial femoral condyle, just distal to the adductor tubercle, from which it extends to the medial surface of the tibia approximately 6 cm below the joint line, covering the medial inferior genicular artery and nerve.[62] The superficial band blends with the posteromedial corner of the capsule and, when combined, is referred to as the posterior oblique ligament.[63] The superficial band is separated from the deep layer of the ligament by a bursa. Since the superficial band is farther from the center of the knee, it is the first ligament injured when a valgus stress is applied.[64]
- The deep band (medial capsular ligament) is a continuation of the capsule. It blends with the medial meniscus and consists of an upper meniscofemoral portion and a lower meniscotibial portion.

The anterior fibers of the MCL are taut in flexion and can be palpated easily in this position. The posterior fibers, which are taut in extension, blend intimately with the capsule and with the medial border of the medial meniscus, making them difficult to palpate.

Information regarding the biomechanical function of the collateral ligaments is quite scarce compared with that of the ACL. It would appear that the MCL is the primary stabilizer of the medial side of the knee against valgus forces, and external rotation of the tibia, especially when the knee is flexed.[65] Grood et al.[66] determined that the MCL was the primary restraint, providing 57% and 78% of the total restraining moment against valgus force at 5 and 25 degrees of flexion.[67]

CLINICAL PEARL

The MCL complex acts as the primary restraint to valgus rotation of the tibia, providing as much as 80% of the restraining force to valgus loads.[68]

The LCL provides the primary restraint to varus rotation of the knee, acts as a secondary restraint to external rotation and posterior displacement of the tibia[68] and, during normal gait, is the primary passive structure resisting the knee adduction (varus) moment.[68]

Lateral Collateral Ligament

The LCL, or fibular collateral ligament (Fig. 20-1), arises from the lateral femoral condyle and runs distally and posteriorly to insert into the head of the fibula. The LCL forms part of the so-called arcuate–ligamentous complex. This complex also comprises the biceps femoris tendon, iliotibial tract, and the popliteus.

The cord-like LCL develops independently and remains completely free from the joint capsule and the lateral meniscus. It is separated from these structures by the popliteus tendon and straddled by the split tendon of the biceps femoris. The LCL can be divided into three parts:

1. Anterior. This part consists of the joint capsule.
2. Middle. This part is considered to be part of the iliotibial band (ITB) and covers the capsular ligament.
3. Posterior. This Y-shaped portion of the ligament is part of the arcuate–ligamentous complex, which supports the posterior capsule.[69,70]

The main function of the LCL is to resist varus forces. It offers the majority of the varus restraint at 25 degrees of knee flexion,[71,72] and in full extension. Abnormal varus laxity arising subsequent to injuries of the LCL and other PL structures has been shown to increase stress on cruciate ligament grafts and has been implicated as one of the causes of crucial ligament reconstruction failure.[68]

OTHER RESTRAINTS

Some structures in the knee clearly augment the functions of the ACL and the PCL. These structures are known as secondary restraints.[34] The secondary restraints include the structures in the PL and posteromedial corners of the knee, which serve to control anterior tibial translation relative to the femur.[34,55,73,74]

Dynamic stability synergistic to the PCL is provided by unopposed contraction of the quadriceps complex, which increases anterior tibial translation. Conversely, an isolated contraction of the hamstrings results in a posterior translation of the tibia, which is synergistic to the ACL. Cocontraction of the hamstrings and the quadriceps has been theorized to minimize tibial translation in either direction.[34] The popliteus muscle–tendon complex (PMTC) contributes to both static and dynamic PL knee joint stabilization.[75] During concentric activation, the popliteus internally rotates the tibia on the femur. During eccentric activation, it serves as a secondary restraint to tibial external rotation on the femur (see "Popliteus").[76]

The knee joint is also strengthened externally by the patellar ligament, oblique popliteal ligaments, and the fabella.

1. The patellar ligament, or patellar tendon, lies in the thickened portion of the quadriceps femoris tendon between the top of the patella and the tibia (Fig. 20-1). The patellar ligament strengthens the anterior portion of the knee joint and prevents the lower leg from being flexed excessively.
2. The oblique popliteal ligament, located on the posterior surface of the knee joint, is a dense thickening in the posterior capsule made up of a continuation of the popliteal tendon and part of the insertion of the semimembranosus.[66] It arises posterior to the medial condyle of the tibia and extends superomedially to attach to the posterior fibrous capsule. The oblique popliteal ligament provides reinforcement to the lateral capsule, limits AM rotation of the tibia, and prevents hyperextension of the knee.
3. The fabella is located in the PL corner of the knee and may be osseous or cartilaginous in makeup. When the fabella is present, there is a fabellofibular ligament, which courses superiorly and obliquely from the lateral head of the gastrocnemius to the fibular styloid.[70] The fabellofibular ligament helps prevent excessive internal rotation of the tibia and adds further ligamentous support on the lateral and PL aspects of the knee.[77] Seebacher et al. found through dissection that the arcuate ligament was quite large in the absence of a fabella.[1]

CLINICAL PEARL

Purists classify the patellar tendon as a ligament because it serves as the connection between two bones (tibia and patella). However, because this structure attaches the quadriceps unit to the tibia, it functions as a tendon.

MENISCI

The word meniscus comes from the Greek word mēniskos, meaning "crescent,", diminutive of mēnē, meaning "moon."[78] The lateral and medial menisci (Fig. 20-2), attached on top of the tibial plateaus, lie between the articular cartilage of the femur and the tibia. The knee meniscus was once described as "a functionless embryonic remnant."[79] However, both menisci are now recognized as being vital for the normal function and long-term health of the knee joint. The characteristic crescent shape of the medial and lateral menisci is achieved between the 8th and 10th week of gestation.[80] The unique and complex structure of the menisci makes treatment and repair challenging and, if left untreated, may lead to degenerative joint changes.[80a] The blood supply of the meniscus, which is key to successful meniscal recovery or repair, comes from the perimeniscal capsular arteries, which are branches of the lateral, medial, and middle genicular arteries, which in turn are branches of the popliteal artery.[80] Although the developing menisci are highly vascular throughout, by adulthood this vascularity has significantly reduced such that only the outer 10–25% of the lateral meniscus (with the exception of the PL corner of the lateral meniscus adjacent to the popliteus tendon) and the outer 10–30% of the medial menisci are vascularized (referred to as the red zone), which allows these areas to have the potential for healing.[81] The remaining inner portions of the menisci (65–75%) are considered avascular and have less potential to heal. These inner portions receive nourishment from the synovial fluid by diffusion or mechanical pumping (i.e., joint motion).[78] However, despite the lack of vascularity to the inner portions, tears involving the avascular zone may heal. This healing capacity may be improved with the addition of a fibrin clot or with such techniques as trephination (making a burr hole).[82,83]

Medial Meniscus

The crescent-shaped, or U-shaped, medial meniscus (Fig. 20-2), with the wider separation of its anterior and posterior horns, is larger and thicker than its lateral counterpart and sits in the concave medial tibial plateau.[84] The medial meniscus is significantly wider posteriorly than anteriorly. It is attached to the anterior and posterior tibial plateau by coronary ligaments. These ligaments connect the outer meniscal borders with the tibial edge and restrict movement of the meniscus. The medial meniscus also has an attachment to the deeper portion of the MCL and the knee joint capsule. The horns of the lateral meniscus are closer together than those of the medial, which makes the former almost circular and the latter nearly semilunar (Fig. 20-2). The anterior horn is attached to the tibial plateau near the intercondylar fossa anterior to the ACL.[80] There is significant variability in the attachment location of the anterior horn of the medial meniscus.[78] The posterior horn of the medial meniscus, which is attached to the posterior intercondylar fossa of the tibia between the lateral meniscus and the PCL, receives a piece of the semimembranosus tendon.[78]

The transverse genicular ligament serves as a link between the lateral and medial menisci.

Lateral Meniscus

The lateral meniscus, which forms a C-shaped incomplete circle,[84] sits atop the convex lateral tibial plateau (Fig. 20-2). It occupies a larger portion (approximately 80%) of the articular surface than the medial meniscus (approximately 60%) and is more mobile than its medial counterpart.[78] Both horns of the lateral meniscus are attached to the tibia.[78]

The periphery of the lateral meniscus attaches to the tibia, the capsule, and the coronary ligament, but not to the LCL. The posterior horn of the lateral meniscus attaches to the inner aspect of the medial femoral condyle via the anterior and posterior meniscofemoral ligaments of Humphrey and Wrisberg, respectively[78]:

1. The ligament of Humphrey, also known as the anterior meniscofemoral ligament, runs anteriorly to the PCL and inserts on the posterior aspect of the lateral meniscus.[59]
2. The ligament of Wrisberg, also known as the posterior meniscofemoral ligament, runs posteriorly to the PCL to insert either into the superior/lateral aspect of the tibia, the posterior aspect of the lateral meniscus, or the posterior capsule.[85]

The meniscofemoral ligaments become taut with internal rotation of the tibia and help with stabilization of the meniscus.[62]

CLINICAL PEARL

The lateral meniscus often is associated with the appearance of synovial-filled cysts, which may occur following a minor injury to the meniscus and produce a small internal tear. As fluid begins to congregate within this tear, it is pushed deeper and deeper into the meniscus. The swelling eventually produces a small bulge on the lateral aspect of the meniscus.

The lateral meniscus has an interesting relationship with the popliteus tendon, which supports it during knee extension and separates it from the joint (see later discussion).[75]

Menisci Function

The menisci assist in a number of functions, including load transmission, shock absorption, joint lubrication and nutrition, secondary mechanical stability (particularly the posterior horn of the medial meniscus that blocks anterior translation of the tibia on the femur),[84] and the guiding of movements.[86]

Load Transmission

The meniscus is viscoelastic, with greater stiffness at higher deformation rates. Many studies have confirmed the role of the menisci in load transmission by showing decreased contact area and increased peak articular stresses following partial or total meniscectomy.[86–89] WB produces axial forces across the knee, which compress the menisci, resulting in "hoop" (circumferential) stresses. By converting joint loading forces to radial-directed hoop stresses on their circumferential collagen fibers, and taking advantage of their viscoelastic nature, the menisci transmit 50–60% of the joint load when the knee is in extension, and 85–90% when the knee is in flexion.[90–92] The lateral meniscus carries 70% of the compressive load in the lateral compartment, compared with just 40% of the medial meniscus in its respective compartment.[84]

Shock Absorption

Because of their viscoelastic nature, the menisci are able to assist in shock absorption. During the normal gait pattern, the articular surface of the knee bears up to six times the body weight, with over 70% of that load borne by the medial tibial plateau.[84] The medial tibial plateau bears most of this load during stance when the knee is extended, with the lateral tibial plateau bearing more of the much smaller loads imposed during the swing phase.[93] This is compensated for by the fact that the medial tibial plateau has a surface area roughly 50% larger than the lateral plateau, and articular cartilage that is approximately three times thicker than the lateral articular cartilage.[94]

CLINICAL PEARL

A meniscectomy can reduce the shock-absorbing capacity of the knee by 20%.[95] Loss of just 20% of a meniscus can lead to a 350% increase in contact forces.[96]

Joint Lubrication

The menisci assist in joint lubrication by helping to compress synovial fluid into the articular cartilage, which reduces frictional forces during WB. A meniscectomy increases the coefficient of friction within the knee, thereby increasing the stresses on the articular surfaces.[97]

Joint Stability

The menisci deepen the articulating surfaces of tibial plateaus. This increases the stability of the knee, especially during axial rotation and valgus–varus stresses.[97,98]

If the ACL is intact, the menisci do not significantly contribute to anteroposterior stability.[99] However, in an ACL-deficient knee, the posterior horn of the medial meniscus functions as a secondary restraint to an anteroposterior translation by wedging between the femur and the tibia.[100,101] In contrast, the increased mobility of the lateral meniscus prevents it from contributing to anteroposterior stability.[102] T is difference helps to explain the higher incidence of medial meniscus tears seen in ACL-deficient knees.[102]

Proprioception

Mechanoreceptors have been identified in the anterior and posterior horns of the menisci.[103] T e presence of these mechanoreceptors would seem to suggest that the menisci are capable of detecting proprioceptive information in the knee joint, thus playing an important afferent role in the sensory feedback mechanism of the knee.[78]

Guiding Movement

During flexion and extension of the knee, the menisci move posteriorly and anteriorly, respectively. T e lateral meniscus has greater mobility because it does not attach to the LCL, and, as mentioned previously, its capsular attachment is interrupted by the passage of the popliteus tendon.[75,104] T e posterior medial corner of the medial meniscus has the least amount of motion because it is constrained by its attachment to the tibial plateau by the meniscotibial portion of the posterior oblique ligament which has been reported to be more prone to injury.[78] During knee motion, the menisci move on the tibial plateau with the femoral condyles to maintain joint congruence.[104] T e femur, accompanied by the menisci, rolls anteriorly on the tibia during extension, and posteriorly during flexion (Fig. 20-3A). T ompson et al.[105] demonstrated that the mean anteroposterior excursion of the menisci during a 120-degree arc of motion was 5.1 mm at the medial meniscus, and 11.2 mm at the lateral. T e inner sides of the menisci, which are attached by their horns to the tibial plateau, move with the tibia. As the body of each meniscus is fixed around the femoral condyle, they move with the femur. T erefore, during movements between tibia and femur, distortion of the menisci is inevitable.

- During flexion of the knee, the menisci move posteriorly. T e medial meniscus is moved about 5 mm by the pull of the semimembranosus tendon, and the lateral meniscus is pulled about 11 mm by the popliteus, resulting in an external rotation of the tibia.
- During extension, the menisci move anteriorly.
- During external rotation of the tibia, the menisci will follow the displacement of the femoral condyles, which means that the medial meniscus is pushed posteriorly, and the lateral meniscus is pulled anteriorly. During internal rotation, the opposite occurs. T ese rotations are conjunct, integral with flexion and extension, but can also be adjunct and independent, best demonstrated with the knee semiflexed. Conjunct external rotation of the tibia on the femur during the last stages of knee extension is part of a locking mechanism called the "screw home" mechanism (Fig. 20-3B), described later.

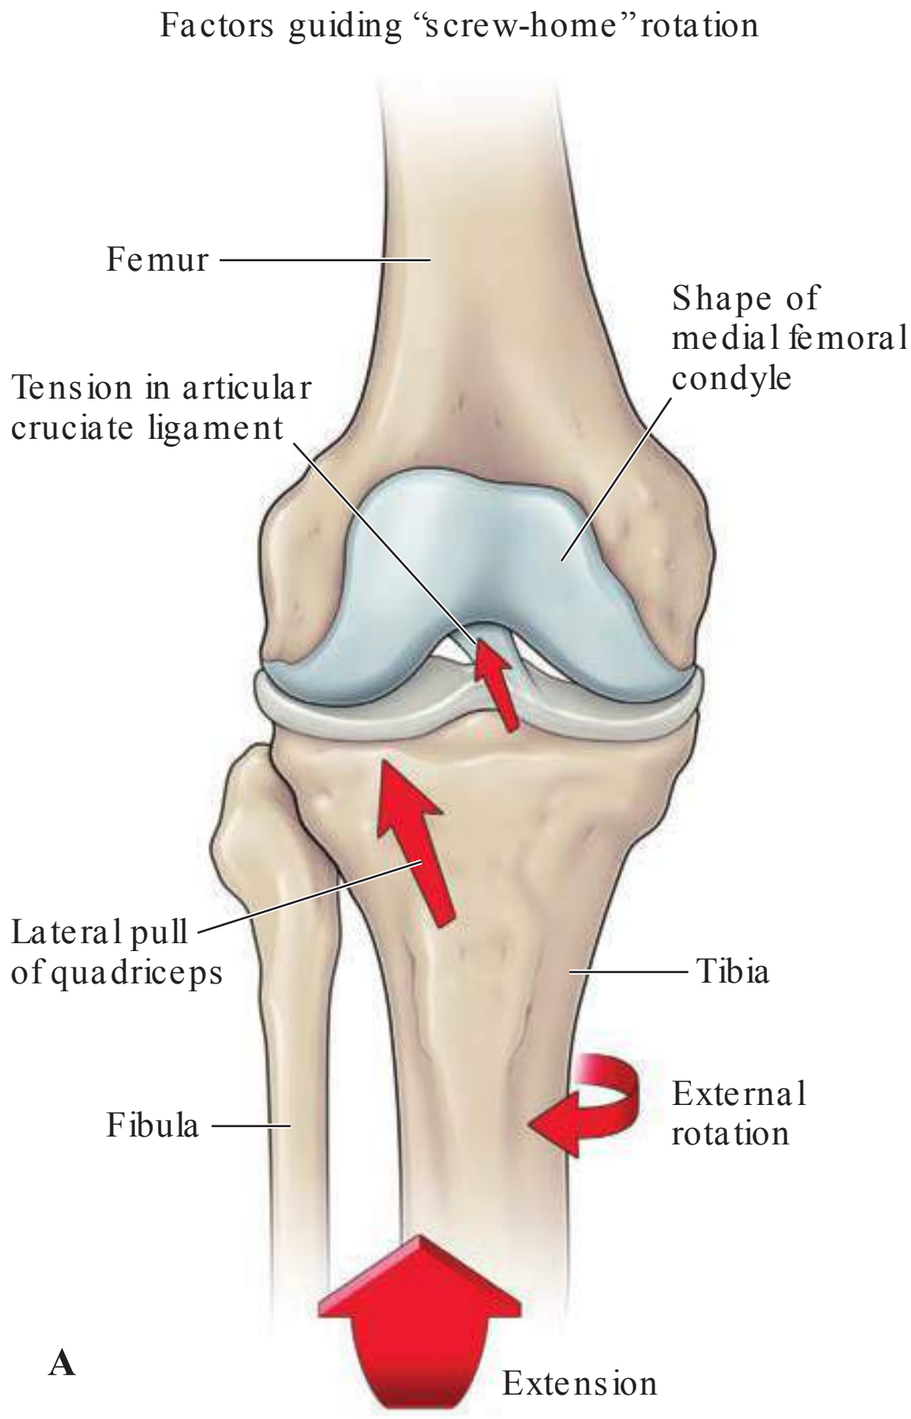

FIGURE 20-3 Tibiofemoral motions.

- T e medial coronary ligament is stretched during external rotation of the tibia, whereas the lateral coronary ligament is stretched during internal rotation of the tibia.

BURSAE

T ere are a number of bursae situated in the soft tissues around the knee joint. T e bursae serve to reduce friction and to cushion the movement of one body part over another.

Superficial and Deep Infrapatellar Bursae

The superficial infrapatellar bursa is located between the patellar tendon and the skin, whereas the deep infrapatellar bursa is located between the patellar tendon and the tibia.

Prepatellar Bursa

The prepatellar bursa is located between the skin and the anterior aspect of the patella.

Tibiofemoral Bursa

The tibiofemoral bursae consist of a bursa between the head of the gastrocnemius muscle and the joint capsule on both sides, a bursa between the LCL and both the biceps femoris and popliteus, and a bursa between the MCL and the femoral condyle. There are also a number of bursae between the various tendons of the pes anserinus and between the MCL and the superficial pes anserinus.

The bursae around the knee can have contact with each other and with the knee joint capsule.

CLINICAL PEARL

A "Baker cyst" may occur with fluid accumulation when there is a natural connection between the semimembranosus bursa and the knee joint.

Fat Pads

There are three fat pads located at the anterior knee: the quadriceps fat pad, the prefemoral fat pad, and the infrapatellar (Hoffa's) fat pad. The fat pads of the knee house neurovascular projections. The functions of the fat pads include the following:

- Synovial fluid secretion
- Joint stability
- Neurovascular supply
- Occupiers of dead space

PLICA

Synovial plicae of the knee were first described at the beginning of the last century.[106,107] Postmortem studies have shown plica to be present in 20–50% of knees,[108–110] with the highest prevalence in individuals of Japanese descent.[107,111–114]

Synovial plica represents a remnant of the three separate cavities in the synovial mesenchyme of the developing knee. These cavities are supposed to coalesce into one cavity at the 12-week stage of fetal growth.[115,116] The size and extent of this remnant depend on the degree of reabsorption.[117]

The three joints involved in the developing knee from which the remnants evolve are[113]

1. the joint between the fibular and the femur;
2. the joint between the tibia and the femur;
3. the joint between the patella and the femur.

The most common plica in the knee is called the anterior or inferior plica, or mucous ligament.[115,118] This plica is represented by a tape-like fold running from the fat pad to the intercondylar notch of the femur and overlying the ACL. The plicae to the medial and lateral sides of the patella, which run in a horizontal plane from the fat pad to the side of the patellar retinaculum, are referred to as the superomedial or superolateral plicae or the suprapatellar membrane, or the medial or lateral synovial shelf.[115]

It has been suggested that symptomatic synovial plicae are one of the causes of anterior knee pain in children and adolescents.[119–121]

RETINACULA

The wing-like retinacula of the knee are formed from structures in the first and second layers of the knee joint. The retinacula can be subdivided into the medial and the lateral retinacula for clinical examination and intervention purposes.[122,123] The retinacula serve to connect the patella to a number of structures, including the femur, menisci, and tibia, both medially and laterally.[124]

The lateral retinaculum is the stronger and thicker of the two. It consists of two distinct layers of fibrous connective tissue: the superficial and deep retinacula. These structures are oriented longitudinally with the knee extended.[123]

- The superficial retinaculum consists of fibers from the vastus lateralis (VL) and the ITB.[125]
- The deep retinaculum consists of the lateral patellofemoral ligament, the deep fibers of the ITB, and the lateral patellotibial ligament.[125] These structures connect the patella to the ITB and help prevent medial patellar excursion.[126]

Although partially located deep to the ITB, the lateral retinaculum is blended with the biceps femoris to form a so-called conjoint tendon.[1,123] This relationship may explain why adaptively shortened hamstrings can lead to patellofemoral symptoms.[124] It is also well established that adaptive shortening of the lateral retinaculum is a common finding in patellofemoral dysfunction.[127–131]

Given the fact that the medial retinaculum is thinner than the lateral retinaculum, it is not thought to be as significant to patella position and tracking as its lateral counterpart.

MUSCLES

The major muscles that act on the knee joint complex are the quadriceps, the hamstrings (semimembranosus, semitendinosus, and biceps femoris), the gastrocnemius, the popliteus, and the hip adductors (Table 20-2).

Quadriceps

The four muscles that make up the quadriceps are the rectus femoris, the vastus intermedius, the VL, and the vastus medialis (Fig. 19-7). The quadriceps tendon represents the

TABLE 20-2 Muscles of the Knee: Actions, Nerve Supply, and Nerve Root Derivation

Action	Primary Muscles	Peripheral Nerve Supply	Nerve Root Derivation
Flexion of knee	Biceps femoris	Sciatic	L5, S1–2
	Semimembranosus	Sciatic	L5, S2–2
	Semitendinosus	Sciatic	L5, S1–2
	Gracilis	Obturator	L2–3
	Sartorius	Femoral	L2–3
	Popliteus	Tibial	L4–5, S1
	Gastrocnemius	Tibial	S1–2
	Tensor fascia latae	Superior gluteal	L4–5
Extension of knee	Rectus femoris	Femoral	L2–4
	Vastus medialis	Femoral	L2–4
	Vastus intermedius	Femoral	L2–4
	Vastus lateralis	Femoral	L2–4
	Tensor fascia latae	Superior gluteal	L4–5
Internal rotation of flexed leg (non–weight bearing)	Popliteus	Tibial	L4–5
	Semimembranosus	Sciatic	L5, S1–2
	Semitendinosus	Sciatic	L5, S1–2
	Sartorius	Femoral	L2–3
	Gracilis	Obturator	L2–3
External rotation of flexed leg (non–weight bearing)	Biceps femoris	Sciatic	L5, S1–2

Data from Magee DJ. Orthopaedic Physical Assessment. 2nd ed. Philadelphia, PA: WB Saunders; 1992.

convergence of all four muscle–tendon units, and it inserts into the anterior aspect of the superior pole of the patella. The quadriceps muscle group is innervated by the femoral nerve. The quadriceps muscles can act to extend the knee when the foot is off the ground, although more commonly, they work as decelerators, preventing the knee from buckling when the foot strikes the ground.[132,133]

Rectus Femoris

The rectus femoris (see Fig. 19-7), which originates at the anterior inferior iliac spine (AIIS) is the only quadriceps muscle that crosses the hip joint. The other quadriceps muscles originate on the femoral shaft. This gives the hip joint substantial significance with respect to the knee extensor mechanism in the examination and intervention.[133] The line of pull of the rectus femoris, with respect to the patella, is at an angle of about 5 degrees with the femoral shaft.[133]

Vastus Intermedius

The vastus intermedius (see Fig. 19-7) has its origin in the proximal part of the femur, and its line of action is directly in line with the femur.

Vastus Lateralis

The VL (Fig. 19-7) is composed of two functional parts: the VL and the vastus lateralis oblique (VLO).[132] The VL has a line of pull of about 12–15 degrees to the long axis of the femur in the frontal plane, whereas the VLO has a pull of 38–48 degrees.[133]

Vastus Medialis

The vastus medialis (Fig. 19-7) is composed of two parts that are anatomically distinct[132]: the vastus medialis obliquus (VMO) and the vastus medialis proper, or longus (VML).[134] The VML appears to have little biomechanical significance unlike its counterpart, the VMO.

Vastus Medialis Obliquus. The VMO arises from the adductor magnus tendon.[135] The insertion site of the normal VMO is the medial border of the patella, approximately one-third to one-half of the way down from the proximal pole. If the VMO remains proximal to the proximal pole of the patella and does not reach the patella, there is an increased potential for malalignment.[10]

The vector of the VMO is medially directed, and it forms an angle of 50–55 degrees with the mechanical axis of the leg.[132,135–137] The VMO is least active in the fully extended position[138–140] and plays little role in extending the knee, acting instead to realign the patella medially during the extension maneuver. It is active in this function throughout the whole range of extension.

According to Fox,[141] the vastus medialis is the weakest of the quadriceps group and appears to be the first muscle of the quadriceps group to atrophy and the last to rehabilitate.[142] The normal VMO/VL ratio of electromyographic (EMG) activity in standing knee extension from 30 to 0 degrees is 1:1,[143] but in patients who have patellofemoral pain, the activity in the VMO decreases significantly; instead of being tonically active, it becomes phasic in action.[144] The presence of swelling also inhibits the VMO, and it requires almost half of the

volume of effusion to inhibit the VMO as it does to inhibit the rectus femoris and VL muscles.[145]

The VMO is frequently innervated independently from the rest of the quadriceps by a separate branch of the femoral nerve.[132]

Vastus Medialis Longus. The VML originates from the medial aspect of the upper femur and inserts anteriorly into the quadriceps tendon, giving it a line of action of approximately 15–17 degrees off the long axis of the femur in the frontal plane.[133]

Since the quadriceps group is aligned anatomically with the shaft of the femur and not with the mechanical axis of the lower extremity, any quadriceps muscle contraction (regardless of knee-flexion angle) results in compressive forces acting on the PFJ.[146]

Hamstrings

As a group, the hamstrings primarily function to extend the hip and to flex the knee. The hamstrings are innervated by branches of the sciatic nerve.

Semimembranosus Muscle

The semimembranosus muscle (Fig. 19-8) arises from the lateral facet of the ischial tuberosity and the ischial ramus. This muscle inserts into the posteromedial aspect of the medial tibial condyle and has a key expansion that reinforces the posteromedial corner of the knee capsule. The semimembranosus pulls the meniscus posteriorly, and internally rotates the tibia on the femur, during knee flexion, although its primary function is to extend the hip and flex the knee.

Semitendinosus Muscle

The semitendinosus muscle (see Fig. 19-8) arises from the upper portion of the ischial tuberosity via a shared tendon with the long head of the biceps femoris. From there, it travels distally, becoming cord-like about two-thirds of the way down the posteromedial thigh. Passing over the MCL, it inserts into the medial surface of the tibia and deep fascia of the lower leg, distal to the gracilis attachment, and posterior to the sartorius attachment. These three structures are collectively called the pes anserinus ("goose foot") at this point. Like the semimembranosus, the semitendinosus functions to extend the hip, flex the knee, and internally rotate the tibia.

Biceps Femoris

The biceps femoris (see Fig. 19-8) muscle is a two-headed muscle. The longer of the two heads arises from the inferomedial facet of the ischial tuberosity, whereas the shorter head originates from the lateral lip of the linea aspera of the femur. The muscle inserts on the lateral tibial condyle and the fibular head. The biceps femoris functions to extend the hip, flex the knee, and externally rotate the tibia. The superficial layer of the common tendon has been identified as the main force creating external tibial rotation and controlling the internal rotation of the femur.[147] The pull of the biceps on the tibia retracts the joint capsule and pulls the iliotibial tract posteriorly, keeping it tight throughout flexion.

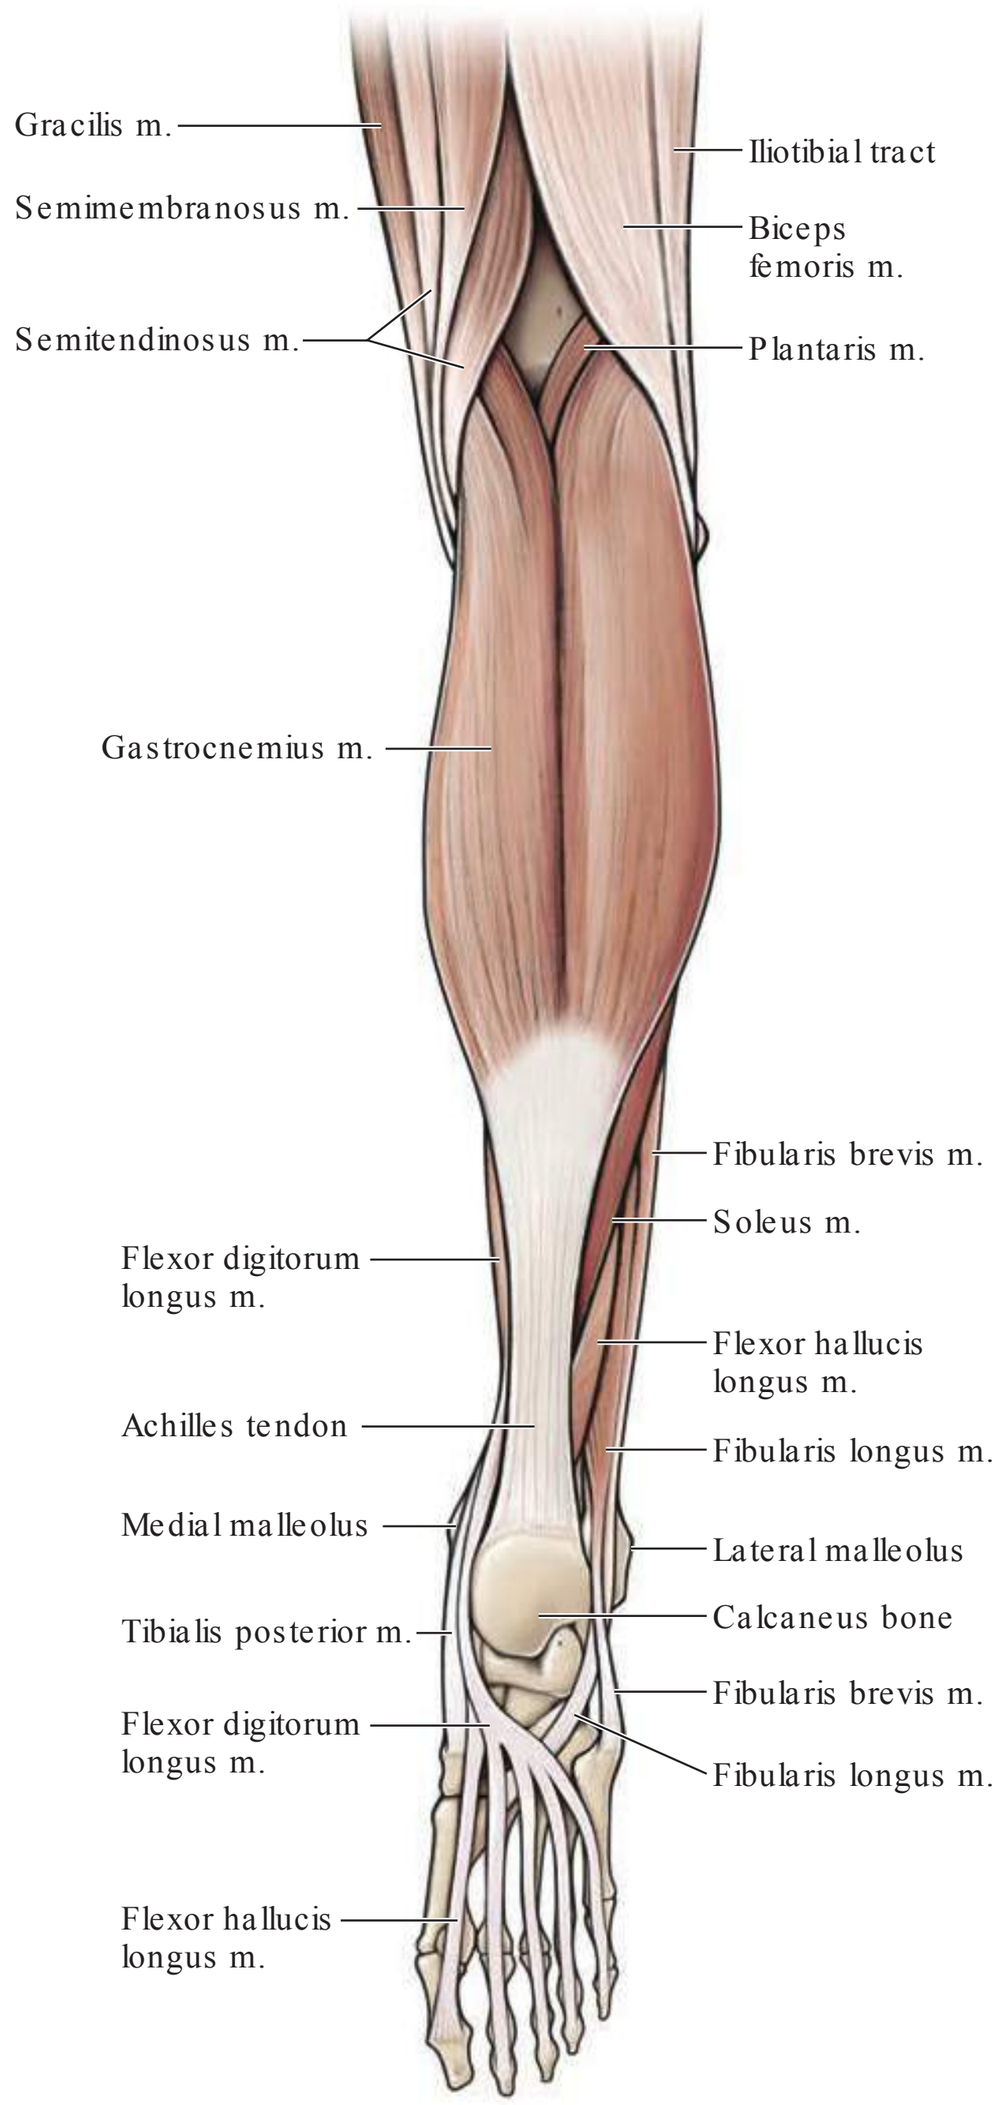

FIGURE 20-4 Gastrocnemius muscle.

Gastrocnemius

The gastrocnemius originates from above the knee by two heads, each head connected to a femoral condyle and to the joint capsule (Fig. 20-4). Approximately halfway down the leg, the gastrocnemius muscles merge to form an aponeurosis. As the aponeurosis gradually contracts, it accepts the tendon of the soleus, a flat, broad muscle deep to the gastrocnemius. The aponeurosis and the soleus tendon end in a flat tendon called the Achilles tendon, which attaches to the posterior aspect of the calcaneus. The two heads of the gastrocnemius and the soleus are collectively known as the triceps surae (see Chapter 21).

Although the primary function of the gastrocnemius–soleus complex is to plantar flex the ankle and to supinate the subtalar joint, the gastrocnemius also functions to flex or

extend the knee, depending on whether the lower extremity is WB or not. It has been proposed that weakness of the gastrocnemius may cause knee hyperextension.[148]

In addition, it has been theorized that the gastrocnemius acts as an antagonist to the ACL, exerting an anteriorly directed pull on the tibia throughout the range of knee flexion–extension motion, particularly when the knee is near full extension.[149,150]

Popliteus

The popliteus originates from the lateral femoral condyle near the LCL. The muscle has several attachments, including the lateral aspect of the lateral femoral condyle, the posteriormedial aspect of the head of the fibula and the posterior horn of the lateral meniscus.[151] The larger base of this triangular muscle inserts obliquely into the posterosuperior part of the tibia above the soleal line. The muscle has several important functions, including the reinforcement of the posterior third of the lateral capsular ligament[69] and the unlocking of the knee during flexion from terminal knee extension. It performs this latter task by internally rotating the tibia on the femur (a good example of an arcuvial muscle), preventing impingement of the posterior horn of the lateral meniscus by drawing it posteriorly, and, with the PCL, preventing a posterior glide of the tibia.[69,152–154] Since knee joint injury frequently involves some component of transverse-plane rotation and the popliteus muscle has been described as an important, primary, dynamic, transverse-plane, rotatory knee joint stabilizer, an understanding of its function in relation to other PL knee joint structures is important.[155] Attached to the popliteus tendon is the popliteofibular ligament, which forms a strong attachment to the popliteal tendon and the fibula. This ligament adds to PL stability.[156–159] A medial portion of the popliteus penetrates the joint, becoming intracapsular with the lateral meniscus. This part of the popliteus tendon is pain sensitive, and an injury here can often mimic a meniscal injury on the lateral aspect of the joint line.[75] Differentiation between these two lesions can be elucidated with the reproduction of pain with resisted flexion in an extended and externally rotated position of the tibia if the popliteus is involved.

Hip Adductors

The hip adductors, which play an indirect role in the medial stability of the knee (Table 20-3), are described in Chapter 19. The exception to this is the two-joint gracilis muscle, the third member of the pes anserinus group, which in addition to adducting and flexing the hip, assists in flexion of the knee and internal rotation of the lower leg.

Tensor Fascia Latae

The tensor fascia latae (TFL) arises from the outer lip of the iliac crest and the lateral surface of the anterior superior iliac spine (ASIS) (Fig. 19-5). Over the flattened lateral surface of the thigh, the fascia latae thickens to form a strong band, the iliotibial tract. When the hip is flexed, the TFL is anterior to the greater trochanter and helps maintain the hip in flexion. As the hip extends, the TFL moves posteriorly over the greater trochanter to assist with hip extension. The TFL is also a weak extensor of the knee, but only when the knee is already extended. The muscle is innervated by the superior gluteal nerve, L4–L5.

Iliotibial Band (Tract)

The ITB or tract begins as a wide covering of the superior and lateral aspects of the pelvis and thigh in continuity with the fascia latae (Fig. 20-4 and Fig. 19-5). It inserts distal and lateral to the patella at the tubercle of Gerdy on the lateral condyle of the tibia. Anteriorly, it attaches to the lateral border of the patellar. Posteriorly, it is attached to the tendon of the biceps femoris. Laterally, it blends with an aponeurotic expansion from the VL.[160] (see Chapter 19).

Like the patella tendon, the ITB can be viewed as a ligament or a tendon. Its location adjacent to the center of rotation of the knee allows it to function as an anterolateral stabilizer of the knee in the frontal plane[161] and to both flex and extend the knee.[133,162] During stationary standing, the primary function of the ITB is to maintain knee and hip extension, providing the thigh muscles an opportunity to rest. While walking or running, the ITB helps maintain flexion of the hip and is a major support of the knee in squatting from full extension until 30 degrees of flexion. In knee flexion greater than 30 degrees, the iliotibial tract becomes a weak knee flexor, as well as an external rotator of the tibia.

MAJOR NERVES AND BLOOD VESSELS

The posterior structure of the knee joint is a complex of nerves and blood vessels.

TABLE 20-3 Hip Adductors Involved in Knee Stability

Muscle	Proximal Attachment	Distal Attachment	Innervation
Adductor longus	Pubic crest and symphysis	By an aponeurosis to middle third of linea aspera of femur	Obturator nerve, L3
Adductor magnus	Inferior ramus of pubis, ramus of ischium, and inferolateral aspect of ischial tuberosity	By an aponeurosis to linea aspera and adductor tubercle of femur	Obturator nerve and tibial portion of sciatic nerve, L2–4
Gracilis	Thin aponeurosis from medial margins of lower half of body of pubis, whole of inferior ramus, and joining part of ramus of ischium	Upper part of medial surface of tibia, below tibial condyle and just proximal to tendon of semitendinosus	Obturator nerve, L2

The knee joint is innervated by the posterior articular branch of the posterior tibial nerve, which is formed from all five anterior divisions (L4, L5, and S1–S3) of the sacral plexus (see below), and the terminal branches of the obturator and femoral nerves.[78] The course and distribution of the femoral nerve are described in Chapter 3. The lateral portion of the capsule is innervated by the recurrent peroneal branch of the common fibular (peroneal) nerve, which is formed by the upper four posterior divisions (L4, L5, and S1, S2) of the sacral plexus (see below). The saphenous nerve is the largest cutaneous branch of the femoral nerve (L2–L4). It leaves the subsartorial canal approximately 8–10 cm above the medial condyle of the knee and gives off branches to the medial aspect of the knee. Entrapment of the saphenous nerve during its course here can occur because of direct trauma, genu valgus, or knee instability, resulting in saphenous neuritis. The sciatic nerve (see Chapter 3) provides motor branches to the hamstrings and all muscles below the knee.[163] It also provides the sensory innervation to the posterior thigh and entire leg and foot below the knee (except the medial aspect, which is innervated by the saphenous nerve).[163]

The major blood supply to this area comes from the femoral (see Chapter 19), popliteal, and genicular arteries.

- Popliteal. Before bifurcating into the anterior and posterior tibial arteries, the popliteal artery normally courses beneath and between the medial and lateral heads of the gastrocnemius, adjacent to the plantaris and popliteus muscles, and through the tendinous arch of the soleus.[164,165] Alteration of these normal structural relationships can cause compression of the popliteal artery—popliteal artery entrapment syndrome (see Chapter 5).
- Genicular. The descending genicular artery arises from the femoral artery, just before it passes through the adductor hiatus and immediately divides into the saphenous branch of descending genicular artery and the articular branches of descending genicular artery. The superior medial genicular artery and the superior lateral genicular artery both arise from the popliteal artery. The middle genicular artery is a small branch of the popliteal artery that originates inferior or distal to both of the superior genicular arteries. Arising from the middle genicular artery are the inferior medial and inferior lateral genicular arteries.

Common Fibular (Peroneal) Nerve

The common fibular (peroneal) nerve is a component of the sciatic nerve as far as the upper part of the popliteal space. At the apex of the popliteal fossa, the common fibular (peroneal) nerve begins its independent course, descending along the posterior border of the biceps femoris, before traveling diagonally across the posterior aspect of the knee joint to the upper external portion of the leg near the head of the fibula. Sensory branches are given off in the popliteal space. These include the superior and inferior articular branches to the knee joint and the lateral sural cutaneous nerve. The latter nerve joins the medial calcaneal nerve (from the tibial nerve) to form the sural nerve, supplying the skin of the lower posterior aspect of the leg, the external malleolus, and the lateral side of the foot and fifth toe.[16]

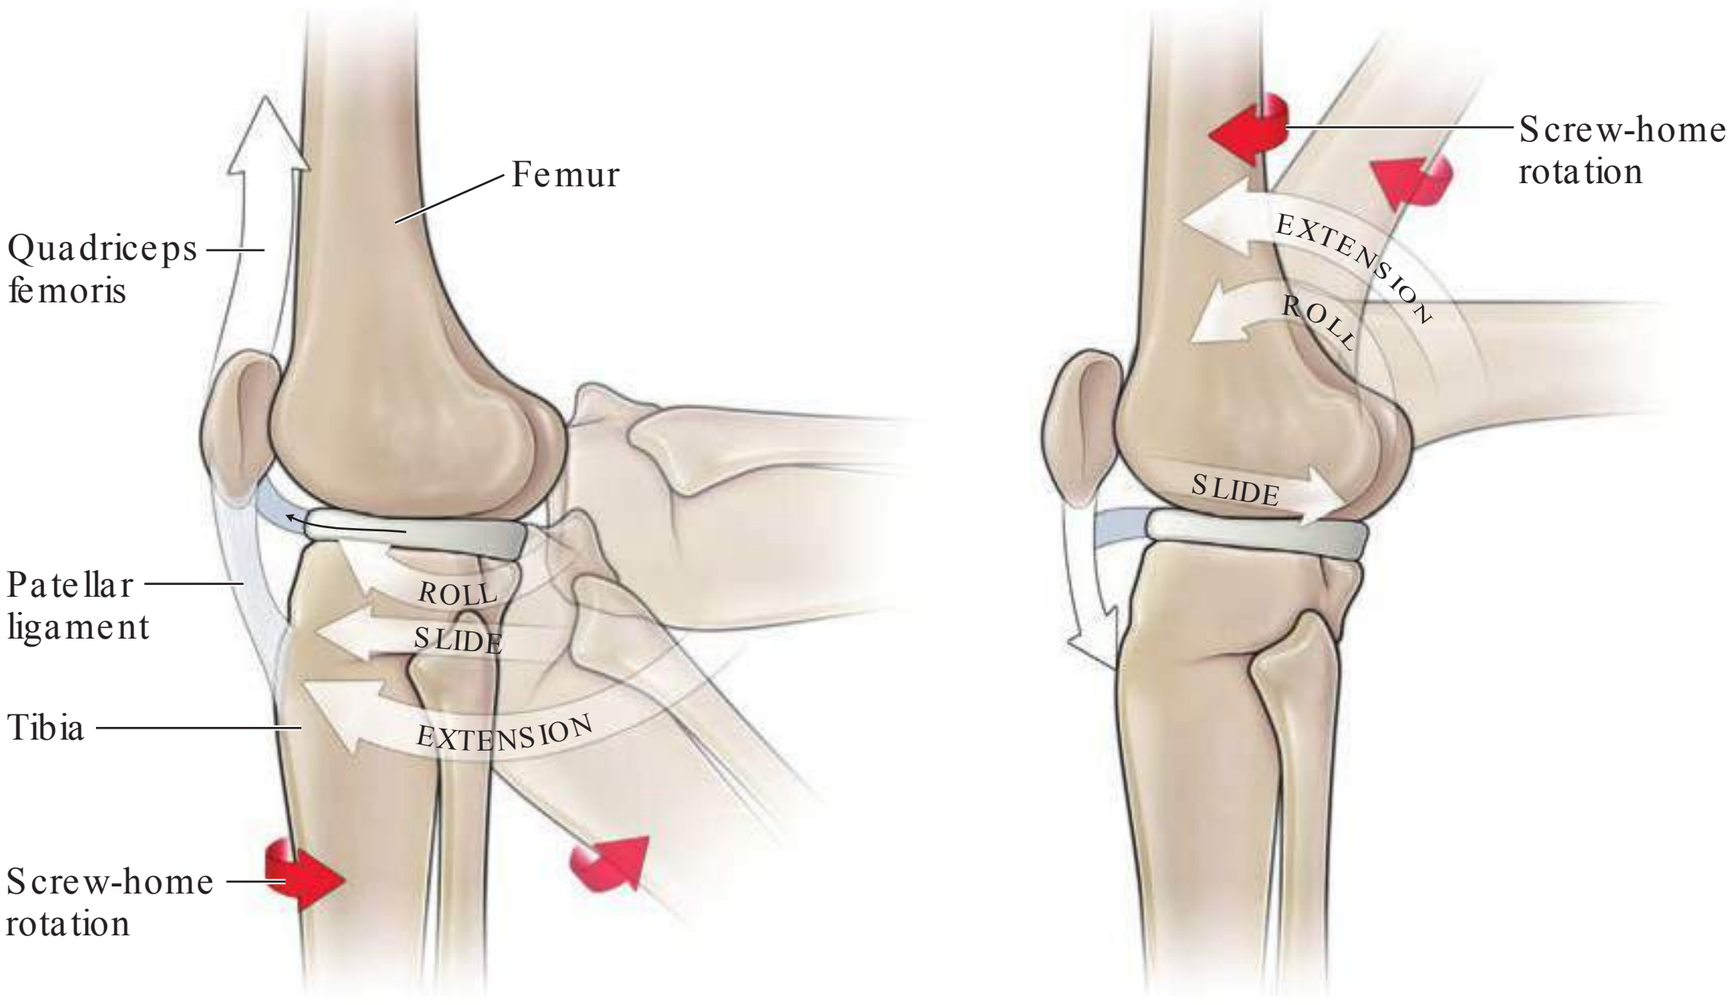
The common fibular (peroneal) nerve curves around the lateral aspect of the fibula toward the anterior aspect of the bone, before passing deep to the two heads of the fibularis (peroneus) longus muscle, where it divides into three terminal branches: the recurrent articular, and the superficial and deep fibular (peroneal) nerves. The recurrent articular nerve accompanies the anterior tibial recurrent artery, supplying branches to the proximal tibiofibular and knee joints, and a twig to the tibialis anterior muscle.

Tibial Nerve

The tibial nerve, the larger of the two branches of the sciatic nerve, begins its own course in the upper part of the popliteal space. It descends vertically through this space, passing between the heads of the gastrocnemius muscle to the posterior aspect of the leg, and to the posteromedial aspect of the ankle, where its terminal branches serve the foot and ankle (see Chapter 21).

The tibial nerve supplies the gastrocnemius, plantaris, soleus, popliteus, tibialis posterior, flexor digitorum longus pedis, and flexor hallucis longus muscles. Articular branches pass to the knee and ankle joints.

BIOMECHANICS



As intermediate joints, the tibiofemoral joint and the PFJ depend on the appropriate mechanical behavior of the hip and ankle to maintain their proper dynamic alignment.[166]

Tibiofemoral Joint

The tibiofemoral joint, or knee joint, is a ginglymoid, or modified hinge joint, which has six degrees of freedom. For example, during gait it rotates about the sagittal, transverse, and coronal axes (i.e., osteokinematics), and translates in the sagittal, transverse, and coronal planes (i.e., arthrokinematics). The bony configuration of the knee joint complex is geometrically inappropriate and lends little inherent stability to the joint. Joint stability is, therefore, reliant on the static restraints of the joint capsule, ligaments, and menisci, and the dynamic restraints of the quadriceps, hamstrings, and gastrocnemius.[34,167] Since the ligaments share tensile load-carrying functions with the musculotendinous units, these structures can be considered to complement each other's functions directly.[34] The PCL is located very near the long axis of tibial rotation and has been described as the main stabilizer of the knee.[168]

The most common knee motions consist of flexion and extension in the sagittal plane, coupled with other motions such as varus and valgus motions, and external and internal rotation. This is because the longitudinal axis of the knee is not perpendicular to the sagittal plane but lies along a line that connects the origins of the collateral ligaments on the medial and lateral femoral epicondyles.[11,169]

All the motions about the tibiofemoral joint consist of a rolling, gliding, and rotation of the femoral condyles and the

A Tibial-on-femoral extension **B** Femoral-on-tibial extension

FIGURE 20-5 The arthrokinematics of knee motions.

tibial plateaus (Fig. 20-5). T is rolling, gliding, and rotation occurs almost simultaneously, albeit in different directions, and serves to maintain joint congruency.[5,170]

- Flexion and extension occur with a mediolateral translation around a mediolateral axis. In the relaxed standing position, with the knee straight or slightly flexed, the vector force is behind the knee; therefore there is a tendency for further knee flexion unless the quadriceps contracts.[104]
- A varus–valgus angulation occurs with anteroposterior translation around an anteroposterior axis.
- External and internal rotation of the joint occurs with superior–inferior translation around a superoinferior axis and transverse plane. T e available range of motion (ROM) in rotation is dependent on the flexion–extension position of the knee.[171] T e amount of rotation progressively increases from no rotation at the terminal extension to 70 degrees of rotation (40 degrees of external rotation and 30 degrees of internal rotation) available at 90 degrees of flexion. T e amount of available rotation decreases as further flexion occurs.

During the initial 30 degrees of knee flexion, the LCL provides a greater contribution to resisting tibial varus, and the PMTC provides a greater contribution to resisting tibial external rotation and posterior translation.[155,172] For flexion to be initiated from a position of full extension, the knee joint must first be "unlocked." As mentioned previously, the service of locksmith is provided by the popliteus muscle, which acts to internally rotate the tibia with respect to the femur, enabling flexion to occur.[94]

During flexion of the knee, the femur rolls posteriorly and glides anteriorly, with the opposite motion occurring during extension of the knee. T is arrangement resembles a twin wheel, rolling on a central rail. Available knee flexion can vary between 120 and 160 degrees, depending on the position of the hip and the girth of the soft tissues around the leg and the thigh.

From 30 to 5 degrees of WB knee extension (moving toward full knee extension), the lateral condyle of the femur, together with the lateral meniscus, become congruent, moving the axis of movement more laterally. T e tibial glide now becomes much greater on the medial side, which produces internal rotation of the femur, and the ligaments, both extrinsic and intrinsic, start to tighten near terminal extension. At this point, the cruciates become crossed and are tightened.

In the last 5 degrees of extension, rotation is the only movement accompanying extension. T is rotation is referred to as the "screw home" mechanism and is a characteristic motion in the normal knee, in which during terminal knee extension the tibia externally rotates relative to the femur (Fig. 20-3). T is motion is known to be a complex function of surface geometry of the menisci, tension in the ligamentous structures, and the action of muscles,[173,174] and has been described both in vivo[175–178] and in vitro.[179,180] T is external rotation of the tibia through swing into stance allows for the tibia and foot to be in the correct alignment at initial contact.[181] Interestingly, the screw home mechanism is reduced in ACL deficient knees, which could be attributed to a reduction in passive tension developed during terminal stance, thereby influencing the sensation of knee instability in these individuals.[182]

Knee hyperextension is usually available from 0 to 15 degrees.[183] During knee hyperextension, the femur does not continue to roll anteriorly but instead tilts forward. T is creates anterior compression between the femur and the tibia.[148] In the normal knee, bony contact does not limit hyperextension as it does at the elbow. Rather, hyperextension is checked by the soft-tissue structures. When the knee hyperextends,

the axis of the thigh runs obliquely inferiorly and posteriorly, which tends to place the ground reaction force anterior to the knee. In this position, the posterior structures are placed under tension, which helps to stabilize the knee joint, negating the need for quadriceps muscle activity.[152]

CLINICAL PEARL

The transition from NWB to WB has been found to produce a threefold increase of anterior translation of the tibia relative to the femur in the ACL-deficient knee compared with the contralateral normal knees.[184]

The normal capsular pattern of the knee joint is a gross limitation of flexion and slight limitation of extension. The ratio of flexion to extension is roughly 1:10; thus, 5 degrees of limited extension corresponds to a 45–60-degree limitation of flexion. The causes of a capsular pattern in the knee are the same as for any other joint. These include traumatic arthritis, rheumatoid and reactive arthritis, osteoarthrosis, monarticular and steroid-sensitive arthritis, crystal synovitis or gout, hemarthrosis, and septic arthritis.

Open-kinetic chain (OKC) and closed-kinetic chain (CKC) exercises have different effects on tibial translation and ligamentous strain and load:

- During active OKC knee extension, the shear component produced by unopposed contraction of the quadriceps depends on the angle of knee flexion, increasing as the knee-flexion angle increases.
- During CKC exercises for the lower extremity, the flexion moment arms of the knee and hip increase as a squat is performed.

Patellofemoral Joint

The PFJ is susceptible to orthopedic injury because it is the least stable joint in the lower limb and forces that are multiple times body weight are applied rapidly through a wide ROM during activities of daily living.[185] The patella is an inactive component of the knee extensor mechanism. In view of the frequent problems associated with the PFJ, it is remarkable that, for much of the time, the articulating surfaces of this joint are not even in contact.[186] Indeed, there is no bone-to-bone contact with the femur in full knee extension, or during standing or walking on level ground[10,187,188] (Table 20-4). As the knee flexes, a number of forces act upon this joint. To assist in the control of the forces around the PFJ, there are a number of static and dynamic restraints:

1. Static restraints. There is evidence to support the relationship between femoral and tibial alignment and PFJ mechanics under static conditions. For example, increased knee abduction has been linked to increased PFJ stress,[189] and increased internal femoral rotation with respect to the tibia has been shown to be related to decreased patellofemoral contact area[190] and increased PFJ stress.[191] The primary static restraints for this joint are the medial patellofemoral ligament, medial and lateral retinacula, and the contact of the patella with the lateral edge of the patellar groove.

TABLE 20-4 Patella–Femur Contact During Range of Knee Flexion

Knee Range of Flexion (Degrees)	Facet Contact
0	No contact
15–20	Inferior pole
45	Middle pole
90	All facets
Full flexion (135 degrees)	Odd facet and lateral aspect

Data from Goodfellow JW, Hungerford DS, Woods C. Patellofemoral joint mechanics and pathology: I and II. J Bone Joint Surg Br. 1976;58:287–299; Aglietti P, Insall JN, Walker PS, et al. A new patella prosthesis. Clin Orthop Relat Res. 1975;107:175–187.

Although originally described as part of the medial patellofemoral ligament, the medial quadriceps tendon-femoral ligament has also been identified as a soft-tissue constraint against patellar lateralization and instability.

a. The appropriate tension on the medial patellofemoral ligament and lateral retinaculum assures patellar tracking through the groove. Inappropriate tensioning may result in excessive pressure on the lateral PFJ surfaces (lateral patellofemoral pressure syndrome) or medial subluxation of the patella from the groove.

b. The PFJ is intrinsically unstable because the tibial tubercle lies lateral to the long axis of the femur, and the quadriceps muscle and the patella is, therefore, subject to a laterally directed force.[192] The causes of insufficient engagement include
   - an abnormally high patella,
   - patellar dysplasia,
   - a poorly developed patellar groove (trochlea).

   The trochlea acts as a lateral buffer to the patella. If the patella fails to engage securely in the patellar groove at the start of flexion, it slips laterally, and as flexion continues, it can dislocate completely or slip back medially to its correct position.[192] Sometimes the patella engages correctly at the start of the flexion but subluxes or dislocates as flexion proceeds.[192] This disengagement may be the result of a defective lateral trochlear margin, an unusually shallow groove, or malalignment (if excessive genu valgus is present, the laterally directed force applied to the patella is greater).

c. The passive restraints to the translation of the patella are provided by the structures that form the superficial and deep lateral retinaculum.

d. Medial retinaculum. Although not as robust as its lateral counterpart, the medial retinaculum is the primary static restraint to lateral patellar displacement at 20 degrees of knee flexion, contributing 60% of the total restraining force.[193]

2. Dynamic restraints.
   a. The primary dynamic restraints of the PFJ are the quadriceps muscle, particularly the VMO, and the

extensor mechanism in general. T e activity of the VMO increases as the torque around the knee increases, and it provides the only dynamic medial stability for the patella.[140,145] However, the muscle vector of the VMO is more vertical than normal when a patellar malalignment is present, making it less effective as a dynamic stabilizer.[194,195] T e timing of the VMO contractions relative to those of other muscles, especially the VL, also appears to be critical and has been found to be abnormal with patellar malalignment.[132,196–199]

CLINICAL PEARL

The tension provided by the dynamic restraints of the PFJ can prevent the patella from slipping laterally. However, excessively tight lateral structures or deficient medial structures may increase the laterally directed forces. This may result in maltracking of the patella or possible subluxation.[141] The lateral structures (VL, lateral retinaculum, and ITB) may be tight from fibrosis of the VL[200] or adaptively shortened for no obvious reason.[192] The medial structures (medial retinaculum) may be loose after injury to the medial retinaculum, from stretching after repeated dislocations, or from severe wasting of the vastus medialis.[192]

b. Neuromuscular control. Deficits in the timing of muscle activity have been identified in a number of musculoskeletal conditions.[198] A study by Cowan et al.,[198] which found that on average the onset of EMG activity of the VL occurred before that of VMO in subjects with patellofemoral pain syndrome (PFPS), appears to lend support to this theory. T us, specific retraining of the VMO is believed to improve patellar tracking.[198]
c. T e integrity of the links of the kinematic chain. Hip muscle weakness[201] and excessive foot pronation[202] have been proposed to result in PFP.

In addition to the static and dynamic restraints, there are two anatomical factors that can negatively impact the PFJ, the quadriceps angle, and the alignment angle.

Quadriceps Angle

T e quadriceps (Q) angle can be described as the angle formed by the bisection of two lines, one line drawn from the ASIS to the center of the patella, and the other line drawn from the center of the patella to the tibial tubercle[203] (Fig. 20-6). T e angle is a measure of the tendency of the patella to move laterally when the quadriceps muscles are contracted.[204,205] T e Q-angle increases with knee extension.

T e Q-angle was originally described by Brattström,[206] although many authors had previously described the importance of genu valgus and its relationship to patellofemoral instability. Brattström described the Q-angle as the angle formed by the resultant vector of the quadriceps force and the patellar tendon with the knee in an "extended, end-rotated" position.

Various normal values for the Q-angle have been reported.[120,203,207–210] T e most frequent ranges cited are 8–14 degrees for males and 15–17 degrees for females. T e discrepancy between males and females allegedly results from the wider pelvis of the female, although this has yet to be proven. Indeed, it is not even clear that, on average, women have a significantly greater Q-angle.[208,211] Angles of greater than 20 degrees are considered abnormal and may be indicative of potential displacement of the patella.[212–214]

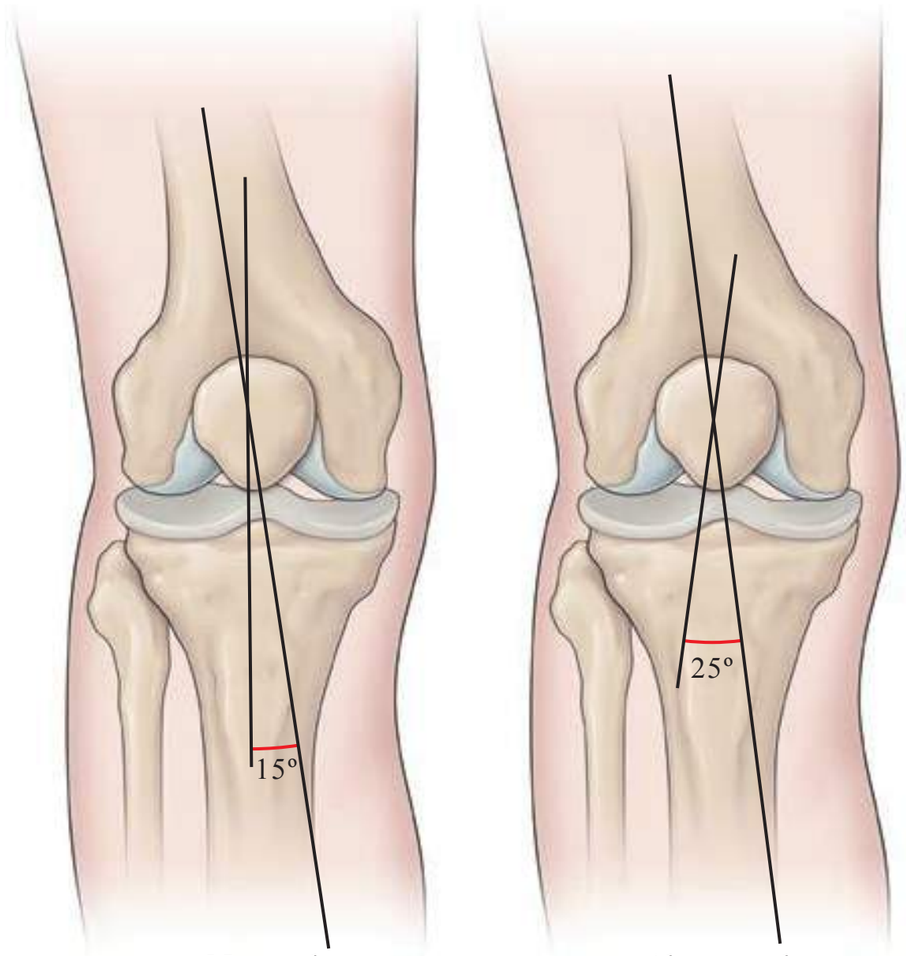


FIGURE 20-6 The Q-angle.

T e Q-angle can vary significantly with the degree of foot pronation and supination, and when compared with measurements made in the supine position.[210,215] Confusing this issue is that the Q-angle is increased in patients with a lateralized tibial tuberosity, but it can be falsely normal when the patella is laterally displaced.[10]

T e significance of a normal Q-angle was highlighted in a study by Huberti and Hayes[216] who concluded that, with a normal physiologic Q-angle, the pressure distributions on the patella were remarkably uniform at each of the angles of knee flexion tested (20, 30, 60, 90, and 120 degrees) between the medial and lateral facets. In contrast, when the physiologic Q-angle was decreased by 10 degrees, the patellar contact pressure increased by 53% at 20 degrees of knee flexion. However, when the knee-flexion angle increased beyond 20 degrees, the contact pressure actually decreased, with the lowest value at 90 degrees.[216]

CLINICAL PEARL

It has been theorized that increased frontal plane hip motion may affect the lateral forces acting on the patella by increasing the "dynamic" quadriceps angle.[217]

Although this measurement has been used to evaluate and treat PFJ pathology, few studies have examined its reliability. Greene et al.[218] evaluated the interobserver and intraobserver reliability of the Q-angle measurement comparing clinically derived Q-angle measurements with radiographically derived measurements. A reliability analysis was performed using intraclass correlation coefficients (ICCs). For interobserver

measurements, the ICCs ranged from 0.17 to 0.29 for the four variables evaluated (right and left, extension and flexion). For intraobserver measurements, the ICCs ranged from 0.14 to 0.37. The average ICC between the clinically and radiographically derived measurements ranged from 0.13 to 0.32, which demonstrates poor interobserver and intraobserver reliability of Q-angle measurement and poor correlation between clinically and radiographically derived Q-angles.

One imaging process somewhat analogous to the Q-angle is the tibial tubercle trochlear groove (TT-TG) distance, which may be measured with advanced 3D imaging (CT or MRI).[8] Nine to 11 mm distance is generally considered normal for adults, while a distance of > 20 mm or > 15 mm is pathological depending on the population studied.[219–221]

CLINICAL PEARL

Although an increased Q-angle is traditionally associated with valgus knees, some of the highest Q-angles are found in patients with a combination of genu varus and proximal tibial torsion.[205,222]

Alignment Angle

The A-angle, an assessment of the relationship between the patella and the tibial tuberosity, is another measurement that has been used to evaluate and treat PFJ pathology and as a quantitative measurement of patellar alignment. The A-angle is defined as the relationship between the longitudinal axis of the patellar and the patella tendon or the patella's orientation to the tibial tubercle. The angle is created by drawing imaginary lines through the patella longitudinally and from the tibial tuberosity to the apex of the inferior pole of the patella. An A-angle greater than 35 degrees is often cited as a cause of patellar pathomechanics. However, there has been little research on the reliability of this quantitative technique, and there is also a lack of research in determining if this angle differs significantly between individuals with patellofemoral dysfunction and those without. Ehrat et al.[223] performed a study to determine intrarater and interrater reliability for the A-angle. The results of the study indicated that the A-angle was not reproducible.

Patella–Femur Contact and Loading

The amount of contact between the patella and the femur appears to vary according to a number of factors, including (1) the angle of knee flexion, (2) the location of contact, (3) the surface area of contact, and (4) the PFJ reaction force (PJRF).[186] This is knowledge is particularly important when prescribing OKC and CKC exercises (see "Intervention Strategies"). Each of these factors is discussed separately.

Angle of Knee Flexion

As knee flexion proceeds, the quadriceps vector becomes more perpendicular, and the force on the patella gradually increases (Fig. 20-7).[224] This increasing force is somewhat dissipated by the increased patellofemoral contact with increasing flexion (see later discussion).[142] However, because the force increases more rapidly than the surface area, the

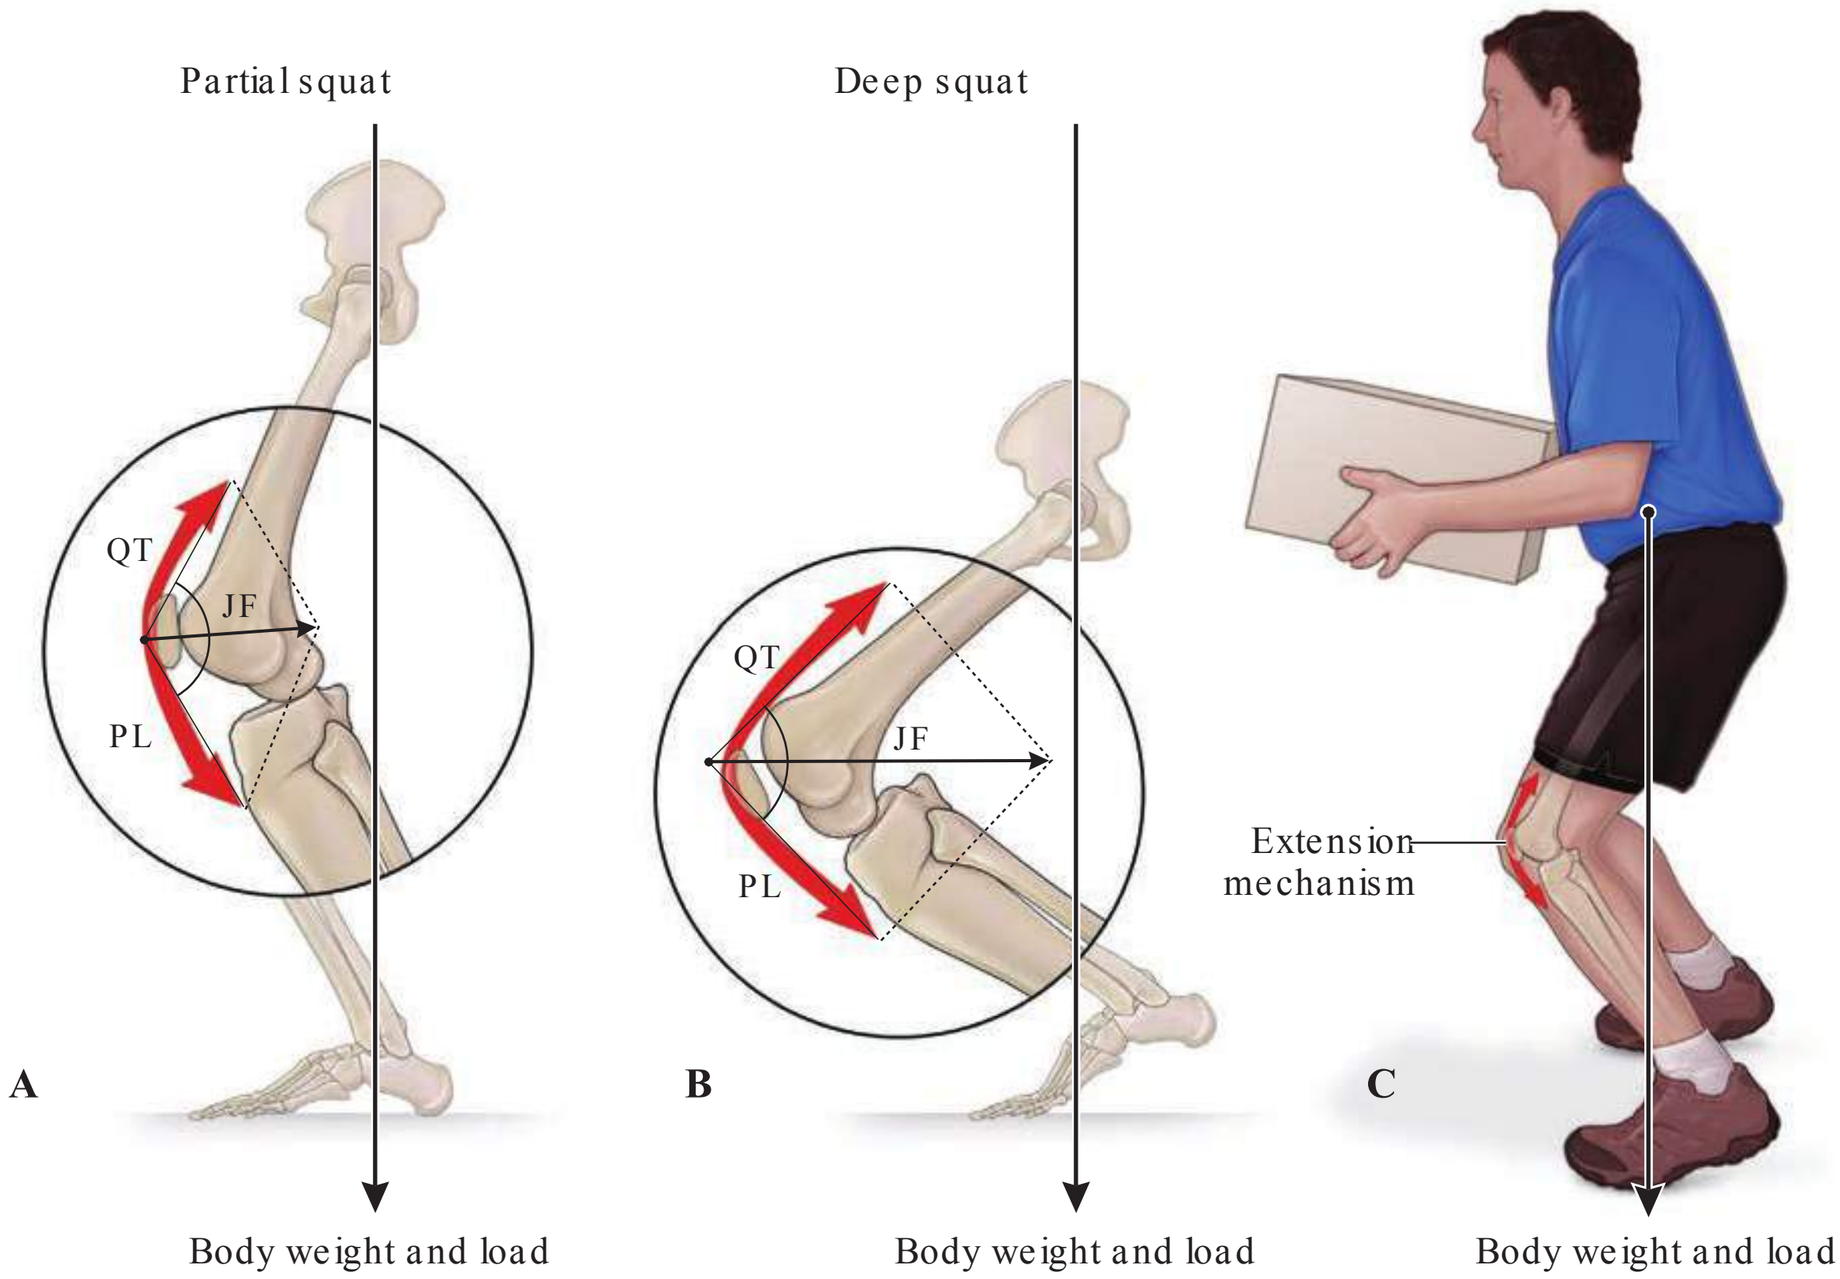

FIGURE 20-7 The relationship between the depth of the squat position and the compression force within the patellofemoral joint.

stress on the patella increases significantly with flexion.[187] At 20- to 30-degree flexion, the patella articular surface is most constrained by the walls of the trochlea groove. Any muscle imbalance between the lateral and medial quadriceps muscles can affect the patellar alignment and distribution of pressure in the lower flexion angles of less than 60 degrees.[186] T is can produce a rotation of the patella in the coronal plane.[225] At higher flexion angles, imbalances are likely to produce a tilt of the patella in the sagittal plane.[225]

Location of Contact

In the normal knee, as the knee flexes from 10 to 90 degrees, the contact area shifts gradually from the distal to the proximal pole of the patella.[188,216,226,227] At full extension, the patella is not in contact with the femur but rests on the supratrochlear fat pad.[225] From full extension to 10 degrees of flexion, the tibia internally rotates, allowing the patella to move into the trochlea.[186] T is brings the distal third of the patellar into contact with the femur. From 10 to 20 degrees of flexion, the patella contacts the lateral surface of the femur on the inferior patellar surface.[188,228] T e middle surfaces of the inferior aspect of the patellar come into contact with the femur at around 30–60 degrees of flexion, at which point the patella is well-seated in the groove.[188,228] As the knee continues to flex to 90 degrees; the patella moves laterally, and the area of patella contact moves proximally.[186] At 90 degrees of knee flexion, the entire articular surface of the patella (except the odd facet) is in contact with the femur.[188,228] Beyond 90 degrees, the patella rides down into the intercondylar notch. At this point, the medial and lateral surfaces of the patella are in contact with the femur, and the quadriceps tendon articulates with the patellar groove of the femur.[186] At approximately 120 degrees of knee flexion, there is no contact between the patella and the medial femoral condyle.[195,229] At 135 degrees of knee flexion, the odd facet of the patella makes contact with the medial femoral condyle.[188,228]

Surface Area of Contact

Knowledge of the patellofemoral contact pattern is useful for determining the limits of motion when patients with patellofemoral symptoms perform OKC and CKC exercises.[226] Some authors have proposed that the contact area quadruples as the knee flexes from 20 to 90 degrees.[199,230]

Patellofemoral Joint Reaction Force

The PJRF is a function of quadriceps and patellar tendon tension and of the angle formed between the quadriceps and patellar tendon. These forces are caused by the increase in patellar and quadriceps tendon tension and the increase in the acuity of the Q-angle that occurs during knee flexion.[199,227,231,232]

CLINICAL PEARL

A recently proposed theory[233] describes a collection of altered kinematics—increased hip adduction and internal rotation, increased knee valgus and increased external tibial rotation—collectively referred to as the dynamic knee valgus. These altered kinematics theoretically increase the Q-angle and subsequent lateral forces on the patella and joint contact pressure.[217] The findings from a controlled laboratory study by Salsich et al.[234] recommend avoiding dynamic knee valgus during the rehabilitation programs with patellofemoral pain, as this movement pattern is associated with increased pain.

Patellar Tracking

Patellar tracking, specifically patella maltracking and its relation to dysfunction, continues to be the subject of many studies.[235] In the normal knee, the patella glides in a sinuous path inferiorly and superiorly during flexion and extension, respectively, covering a distance of 5–7 cm with respect to the femur.[235] A concave, lateral, C-shaped curve is produced by the patella as it moves from approximately 120 degrees of knee flexion toward approximately 30 degrees of knee extension. T e lateral curve produces a gradual medial glide of the patella from 45 to 15 degrees of knee flexion in the frontal plane and a medial tilt (from 45 to 0 degrees of knee extension) in the sagittal plane.[199,236] Further extension of the knee (between 15 and 0 degrees) produces a lateral glide of the patella in the frontal plane and a lateral tilt in the sagittal plane.[199,236]

One proposed mechanism for abnormal patellar tracking is an imbalance in the activity or tension of the medial and lateral restraints.[197,198,237]

T e cause of the imbalance tends to be hypertonus of the VL, or an excessively tight TFL or ITB.[186] Other joints within the lower kinetic chain can also influence the tracking of the patella.

Jumping and Landing

Jumping and landing involve a number of recognized kinematic phases, which include the following[238]:

- Preparatory phase. During this phase, which places the muscles on a stretch to provide a more explosive contraction, the individual flexes at the hips, knees, and ankles. T is is accomplished by an eccentric contraction of the gastroc-soleus and quadriceps, as well as control of the back extensors to maintain trunk position.
- Takeoff phase. T e power necessary for this is generated through the plantar flexors, knee extensors, hip extensors, and back extensors. Forward and upward movement of the upper body increases the momentum.
- Landing phase. During this phase, the generated forces must be dissipated which is usually accomplished by returning to a flexed position. Abductor strength has been correlated with landing kinematics, more so in females than males.[239]

Kicking

T e popularity of the game of soccer has grown exponentially over the past two decades and, as kicking is the defining action of the game, a knowledge of kicking mechanics has become a really important. T e components of the soccer kick can be broken down into the following phases[238,240,241]:

- T e angle of approach. T e angle of approach can alter peak ball velocity.
- Plant limb position. T e position of the plant limb not only affects the direction of the kick, but also the velocity and trajectory of the kick. T ere is a strong correlation between single-leg balance and kicking accuracy, but not with velocity of the kick.[242]
- Swing limb loading. T is phase is analogous to the cocking phase of throwing, and it is here that the hip flexors and knee extensors are on a stretch to store elastic energy. T is phase may be affected by foot placement of the stance leg due to the hips being allowed to adopt a more open or closed position.
- Hip flexion/knee extension. During this phase, the individual attempts to release the stored elastic energy from the previous phase in a controlled manner depending on the intent. T e speed created in this phase may be achieved by rotational hip speed combined with both hip flexor and knee extensor muscular strength. In a 2006 study of kicking a football, magnetic resonance imaging (MRI) signal changes of 30% in the adductor longus and 49% in the gracilis were found in the kicking leg following 100 kicks.[243]
- Foot contact. During this phase, the foot and ankle of the kicking leg are placed in a plantar flexed position and the hip and knee of the kicking leg rapidly flex and extend respectively.
- Follow-through. During this phase, the kicking leg continues to move forward, relying on the hamstrings and trunk for deceleration.

CLINICAL SIGNIFICANCE OF OKC AND CKC ACTIVITIES

As previously discussed, in relation to the lower kinetic chain, which includes the lumbar spine, pelvic joints, hip, knee, foot, and ankle joints, the motions that occur during activities can be described as CKC or OKC motions.

CLINICAL PEARL

A closed-chain motion at the knee joint complex occurs when the knee bends or straightens while the lower extremity is WB, or when the foot is in contact with any firm surface. An open-chain motion occurs when the knee bends or straightens when the foot is not in contact with any surface.

Since the knee joint complex is an integral part of the lower kinetic chain, movement at any portion of the kinetic chain will influence knee joint mechanics, necessitating an examination of the entire chain as part of a comprehensive assessment. Kinetic chain exercises need to be monitored carefully to detect the influence of any abnormal motion that occurs in one portion of the segment on the remaining portions of the kinetic chain.[244] For example, normal biomechanics dictates that the tibiofemoral joint extends during midstance as the body traverses the fixed foot. Excessive pronation in either magnitude or duration prevents the knee joint from acquiring the necessary external rotation of the tibia for this extension, which in turn may affect patella tracking.[145,245]

Another example occurs during the descending phase of a squat, which requires simultaneous flexion at the hip and knee, and dorsiflexion at the ankle. If ankle dorsiflexion motion is limited, subtalar joint pronation will increase to compensate for the lack of dorsiflexion.[244,245] T is increased pronation, which is coupled with internal rotation of the lower extremity, results in an increase in the functional Q-angle and may contribute to persistent patellofemoral pain.[244]

Whether the motion occurring at the knee joint complex occurs as a CKC or OKC has implications on the biomechanics and the joint compressive forces induced. A significant number of studies[42,246–258] have examined the biomechanics of the knee during OKC and CKC activities and have attempted to quantify and compare cruciate ligament tensile forces, tibiofemoral compressive forces, and muscle activity about the knee during these activities.

Closed-Kinetic Chain Motion

Tibiofemoral Joint

During CKC knee flexion, the femoral condyles roll backward and glide forward on the tibia. During CKC knee extension, the femoral condyles roll forward and slide backward. During CKC knee flexion, as the femur rolls posteriorly, the distance between the tibial and femoral insertions of the ACL increases. Since the ACL cannot lengthen, it guides the femoral condyles anteriorly.[183] In contrast, during CKC extension of the knee, the distance between the femoral and tibial insertions of the PCL increases. Since the PCL cannot lengthen, the ligament pulls the femoral condyles posteriorly as the knee extends.[183]

It has been suggested by some studies that the CKCE, with its axial loading of the joint, and resultant joint compressive forces and minimization of shear forces exerted on the knee, may protect the anterior cruciate graft during quadriceps exercises through use of the contours of the joint, thereby providing greater stabilization to the knee.[259,260] Other studies have shown that CKCEs such as squatting do not necessarily protect the ACL any more than OKC flexion and extension exercises[261] (Table 20-4). However, increasing the resistance during the CKCEs does not produce a significant increase in ACL strain values, unlike increasing the resistance during OKC flexion–extension exercises.[261]

It would appear that CKCEs are only beneficial if performed in a restricted range, with some studies demonstrating that CKCEs at greater than 30 degrees of knee flexion can exacerbate patellofemoral problems.[248,250]

T us, a "paradox of exercise"[249] is encountered for the patient recovering after an ACL reconstruction, whereby the patient risks excessive ACL strain if these exercises are performed at less than 30 degrees of knee flexion, but PFJ complications if the exercises are performed at greater than 30 degrees of knee flexion.[251] Consequently, patients undergoing ACL rehabilitation who are susceptible to patellofemoral pain should be forewarned about potential PFJ complications when performing these exercises. T ese patients should also

be advised to inform the clinician of any anterior knee pain that develops during their rehabilitative process.

Patellofemoral Joint

During CKCEs, the flexion moment of the arm increases as the angle of knee flexion increases. In addition, the joint reaction force increases proportionately more during knee flexion than the magnitude of the contact area.[195] T us, the articular pressure gradually increases as the knee flexes from 0 to 90 degrees,[195] with maximum values occurring at 90 degrees of flexion.[216] However, because this increasing force is distributed over a larger patellofemoral contact area, the contact stress per unit area is minimized. Changes in the Q-angle of 10 degrees can increase patellofemoral contact pressures by 45% at 20 degrees of flexion.[216] As the Q-angle increases, the patella tends to track more laterally.[142] A 50% decrease in tension in the VMO can displace the patella laterally by up to 5 mm.[225]

From 90 to 120 degrees of flexion, the articular pressure remains essentially unchanged because the quadriceps tendon is in contact with the trochlea, which effectively increases the contact area.[262]

T us, for the PFJ, CKCEs are performed in the 0–45-degree range of flexion, with caution used when exercising between 90 and 50 degrees of knee flexion, where the PJRFs can be significantly greater.[262]

Open-Chain Motion

Tibiofemoral Joint

During OKC flexion, the tibia rolls and glides posteriorly on the femur, while during extension the opposite occurs. OKC knee extension involves a conjunct external rotation of the tibia while OKC knee flexion involves a conjunct internal rotation of the tibia.

OKC activities produce shear forces at the tibiofemoral joint in the direction of tibial movement. For example, OKC knee extension produces anterior shear stresses.[263] As the ACL provides 85% of the restraining force to this tibial shear,[37] OKC knee extension may compromise a repaired or reconstructed ACL,[264] especially in the last 45 degrees of knee extension,[263,265,266] although at full extension, the ACL is under no tension.[24,247,264,267–269] However, if resistance is applied to the lower leg during OKCEs, an increase in strain on the ACL is demonstrated,[24] particularly in the last few degrees of extension.[34] OKCE is preferred over CKCE if minimal PCL tensile force is desired. Since PCL tension generally increases with knee flexion, knee ROMs that are less than 60 degrees will minimize PCL tensile force.[251] T e higher compressive forces that occur during the beginning and end ranges of knee flexion in OKCE may serve to unload some of the tensile force in these respective cruciate ligaments.[251]

Both OKCEs and CKCEs appear equally effective in minimizing ACL tensile force, except during the final 25 degrees of knee extension in OKCEs.

OKC flexion, resulting from an isolated contraction of the hamstrings, reduces ACL strain throughout the ROM,[24] but increases the strain on the PCL as flexion increases from 30 to 90 degrees.[267]

CLINICAL PEARL

It may be prudent to exclude the final 25 degrees of knee extension range for the patient using OKCE for rehabilitation immediately following an ACL injury.[251]

Patellofemoral Joint

In an OKC activity, the forces across the patella are their lowest at 90 degrees of flexion. As the knee extends from this position, the flexion moment arm (contact stress/ unit) for the knee increases, peaking between 35 and 40 degrees of flexion, while the patella contact area decreases.[248,270] T is produces an increase in the PJRF at a point when the contact area is very small. At 0 degrees of flexion (full knee extension), the quadriceps force is high, but the contact stress/ unit is low.

T us OKCEs for the PFJ should be performed from 25 to 90 degrees of flexion (60–90 degrees if there are distal patellar lesions), or at 0 degree of extension (or hyperextension) from a point of view of cartilage stress.[262] OKCEs are not recommended for the PFJ between 0 and 45 degrees of knee flexion, especially if there are proximal patellar lesions, as the PJRFs are significantly greater.[262]

CLINICAL PEARL

Increased tension in the PCL occurs at greater than 65 degrees of knee flexion in CKCE, and at greater than 30 degrees with OKCEs.[251] Therefore, it may be prudent to limit knee flexion during both OKCE and CKCE to knee angles of less than 30 degrees following a PCL injury.[251]

EXAMINATION

T e common pathologies for the knee joint complex are detailed after this section. An understanding of both is obviously necessary. Since the mention of the various pathologies occurs with reference to the examination, and vice versa, the reader is encouraged to switch between the two discussions.

History

With the vast number of specific tests available for the knee joint complex, it is tempting to overlook the important role of the history, which can detail both the chronology and mechanism of events. T e diagnosis of most tibiofemoral and PFJ disorders often can be made on the basis of a thorough history and physical examination alone. T e patient's family history, medical history, and history of the present knee problem are necessary for a complete diagnosis. A medical screening questionnaire for the knee, leg, ankle, and foot region is provided in Table 20-5. In addition to those questions outlined in "History" section in Chapter 4, the clinician should determine the following:

Chief Complaint

It is important to elucidate the exact nature and location of the patient's chief complaint. Does the complaint relate to

TABLE 20-5 Medical-Screening Questionnaire for the Knee, Leg, Ankle, and Foot Region

	Yes	No
Have you recently had a fever?		
Have you recently taken antibiotics or other medicines for an infection?		
Have you had a recent surgery?		
Have you had a recent injection to one or more of your joints?		
Have you recently had a cut, scrape, or open wound?		
Have you been diagnosed as having an immunosuppressive disorder?		
Do you have a history of heart trouble?		
Do you have a history of cancer?		
Have you recently taken a long car ride, bus trip, or plane flight or been bedridden for any reason?		
Have you recently begun a vigorous physical training program?		
Do you have growing, hip, thigh, or calf aching or pain that increases with physical activity, such as walking or running?		
Have you recently sustained a blow to your shins or any other trauma to either of your legs?		

Data from DuVall RE, Godges J. Introduction to physical therapy differential diagnosis: The clinical utility of subjective examination. In: Wilmarth MA, ed. Medical Screening for the Physical Therapist. Orthopaedic Section Independent Study Course 14.1.1 La Crosse, WI: Orthopaedic Section, APTA; 2003:1–44.

pain or instability, or both? If the chief complaint is pain, is there a history of recent trauma?

Onset of Symptoms

Questions about the onset of symptoms (traumatic versus insidious) are, as with any joint, important. Acute injuries are often traumatic and can be associated with both pain and instability. Reports of immediate pain associated with an inability to weight bear can indicate a muscle, ligament, or fracture injury and should be related to the patient's current complaints to identify the likely cause. As always, an insidious onset of pain should alert the clinician to the possibility of a serious condition. Pain in the knee can be referred from the hip, the back, and the sacroiliac joint. Complaints of shooting pain, burning pain, and pain that travels down the thigh should be carefully investigated using a lumbar screen to rule out radicular symptom production. A gradual, nontraumatic onset of knee pain could also indicate PFJ dysfunction or symptomatic degenerative joint disease (DJD) of the knee joint complex. The characteristic clinical features in an uncomplicated osteoarthritis (OA) of the knee joint are a dull and aching pain that occurs at the end of the day or after prolonged periods of standing or walking.[271] As the disease progresses, there is pain and stiffness on rising in the morning, which eases with activity or rest, and a limitation of movement in the capsular pattern.

Mechanism of Injury

The clinician should determine how exactly the injury happened—was it a traumatic blow, a contact injury, a noncontact injury, or did the patient fall? The position of the joint at the time of the traumatic force dictates which anatomic structures are at risk for injury; hence, an important aspect of obtaining the patient's history for acute injuries is to allow him or her to describe the position of the knee and direction of forces at the time it was injured.[272] The direction the patient was turning to and the direction of the blow help to determine the structures likely affected.[273] Twisting injuries can result in injuries to the ligaments or meniscus. Contact injuries can result in deep bone bruising, muscle contusions, and ligamentous or meniscal injury when combined with twisting or hyperextension.

The primary mechanisms of injury in the knee are direct trauma, a varus or valgus force (with or without rotation), hyperextension, flexion with posterior translation, a twisting force, and overuse.[65]

- **Direct trauma.** A direct blow to the anterior aspect of the knee may cause a patellar injury. Repetitive microtrauma to the patella may also be a factor. For example, Bloom[274] describes a condition called airplane knee, in which the frequent flyer in coach class gets repetitive knee bumps from the passenger in front when the seat is dropped back suddenly.
- **Valgus force.** A history of a valgus force to the knee without rotation could indicate damage to the medial meniscus, collateral ligament, epiphyseal plate, or patellar dislocation–subluxation.[272] A history of a valgus force with rotation could indicate damage to the ACL, or the posteromedial capsule (the so-called unholy triad).
- **Varus force.** A history of a varus force with rotation can involve the LCL, the PL capsule, and the PCL.[272]
- **Hyperextension.** A hyperextension force can result in ACL injuries and associated medial meniscal tears. Complaints of buckling or giving way after the injury can reinforce a suspicion of ligamentous involvement.
- **Flexion.** During flexion, as the tibia internally rotates, the posterior horn of the medial meniscus is pulled toward the center of the joint. If excessive, this movement can produce a traction injury of the medial meniscus, tearing it from its peripheral attachment and producing a longitudinal tear of the substance of the meniscus.[273]
- **Flexion with a posterior translation.** This mechanism can result in a PCL injury.
- **Twisting force.** Meniscal injuries are usually associated with a torsional force that combines compression and rotation, often in activities that require cutting maneuvers.[274] In addition, the ACL often is injured during traumatic twisting injuries in which the tibia moves

forward with respect to the femur, often accompanied by valgus stress.[273] No direct blow to the knee or leg is required, but the foot is usually planted, and the patient may remember a "popping" sensation at the time of the injury. Similar to the ACL, PCL injuries often occur during twisting with a planted foot in which the force of the injury is directed posteriorly against the tibia with the knee flexed.[273]

- Overuse. A patellar injury is most often a result of overuse.[274] Typically, there is an associated 4–6-week training program change. T ese changes can include (1) increasing a training load more than 10% per week; (2) not allowing a 15% decrease for a week off; (3) not using an alternate-day or hard-easy pattern; (4) changing quickly from flat to hill training; (5) running in one direction on a canted road; (6) running in worn-out shoes; or (7) biking in cleated shoes that fix the tibial rotation relative to the pedal.[274]

Location of Symptoms

T e location of the symptoms may afford the clinician clues as to the cause. Initially, the clinician should consider the anatomical structures underlying the area of pain to ascertain the cause. Medial knee pain can be caused by a spectrum of possibilities ranging from localized musculoskeletal to nonmusculoskeletal pathology (Table 20-6).[275] For example, medial meniscal lesions frequently result in posterior medial joint line pain and mild medial joint line pain.[272] Medial knee pain also may suggest an MCL injury. MCL injury can produce pain at the medial femoral condyle, medial joint line, or proximal tibia.[272] Lateral joint line pain may be caused by an LCL injury. Localized swelling over specific knee structures, such as the MCL or LCL, also may accompany the pain. Midlateral joint line pain often is caused by a lateral meniscal lesion. PFJ pain usually is anterior, radiating medially and laterally, but primarily in, around, or under the patella.[274] Posterior knee pain may be secondary to joint effusion producing distention of the posterior capsule, a mild strain of one of the gastrocnemius muscles or a PCL tear.[272] Posterior knee pain accompanied by snapping could indicate a Baker cyst.

Behavior of Symptoms

Symptoms that are not alleviated with rest could indicate a nonmechanical source, or a chemically induced source, such as an inflammatory reaction. A hot and swollen joint without a history of trauma should provoke suspicions about hemophilia, rheumatoid arthritis, an infection, or gout.

Quality of the Symptoms

Deep knee pain may indicate damage to one of the cruciate ligaments. Generalized pain in the knee region is characteristic of referred pain, or pain from a contusion or partial tear of a muscle or ligament.[276] Often a patient with a chronic condition has several complaints, and a historical investigation can help identify the original cause. Patients do not always recognize the significance that an old injury may play in their current condition, but these options must be considered if the clinician is unable to make a diagnosis with the information available.

TABLE 20-6 Differential Diagnosis of Medial Knee Pain

Cause	Condition
Local musculoskeletal	Patellofemoral syndrome
	Medial meniscus tear
	Patellar tendinitis
	Lateral patellar subluxation
	Pes anserine tendinitis
	Pes anserine bursitis
	Vastus medialis strain
	Saphenous neuropathy
	Medial collateral ligament sprain
	Medial tibial plateau fracture
	Medial tibial plateau stress fracture
	Proximal tibia stress fracture
Tumors	Osteochondroma
	Chondroblastoma
	Giant cell tumor
	Osteoid osteoma
	Osteosarcoma
	Ewing sarcoma
	Chondrosarcoma
	Fibrosarcoma
	Pigmented villonodular synovitis (PVNS)
	Localized nodular synovitis (LNS)
Systemic disease	Thyroid disorder (Grave disease)
	Lymphoma
	Leukemia
	Myeloma
Vascular/inflammatory	Rheumatoid arthritis
	Reiter syndrome
	Saphenous thrombophlebitis
	Deep vein thrombosis
Remote neuromusculoskeletal	Hip dysplasia
	Lumbosacral pathology
	Obturator neuropathy

Data from Rosenthal MD, Moore JH, DeBerardino TM. Diagnosis of medial knee pain: Atypical stress fracture about the knee joint. J Orthop Sports Phys Ther. 2006;36:526–534.

Reports of Swelling

In the presence of trauma, the main thrust of the history should be to establish whether the patient experienced an effusion or hemarthrosis (the assessment of swelling is described in "Observation".) An effusion is a method by which the joint reacts to stress and usually takes several hours to accumulate. T e effusion can result from blood filling the joint or from an increased production of synovial fluid. T e time frame of onset provides the clinician with clues as to the nature of the effusion. Synovial effusion usually takes 6–12 hours to develop and produces a dull, aching pain as the joint capsule is distended. By contrast, an acute hemarthrosis is usually well formed after 1–2 hours, leaving a very tense and inflamed knee. T e two diagnoses that represent over 80%

of the causes of an acute tense hemarthrosis are an ACL tear and patellar dislocation.[277] Other causes of an intraarticular effusion include MCL rupture and intraarticular fracture. Patients with a meniscal lesion often report repetitive episodes of effusion.[274]

Reports of Joint Noise

Reports of grinding, popping, and clicking in the knee with a particular maneuver are common but may not be related to a pathologic process.[162] However, reports of a "pop" involving sudden rotation of the femur or tibia may indicate damage to the ACL, MCL, coronary ligament, or meniscus, or an osteochondral fracture.[162] Sprains to the ligaments of the knee are often more painful than complete ruptures because the latter have no intact fibers from which pain of a mechanical origin can occur. Instability of the knee often is described as a sensation of "giving way," sliding, or buckling. Sharp, catching pain usually indicates a mechanical problem.

Aggravating Positions or Activities

Questions should be asked to determine whether certain kinds of activities bring on the symptoms. For example, the pain may be noticed after resting or after certain activities. Morning pain and stiffness that lessens with activity or movement may indicate a degenerative joint complaint. Complaints of locking or pseudolocking during active or passive flexion and extension can highlight a dysfunctional structure. True locking of the knee is rare; however, loose bodies can cause recurrent locking or the sensation of something catching or getting in the way of movement. "Locking" that occurs with extension could indicate a lesion of the meniscus, a hamstring muscle spasm or an entrapment of the cruciate ligament. "Locking" that occurs with flexion could indicate a lesion to the posterior horn of the medial meniscus. With patellar irritability, there is no true mechanical blocking, although there may be stiffness, grating, or rapid movement inhibition.[274]

Impact on Function

The clinician should determine which functional activities reproduce the pain or exacerbate the symptoms. The following statements should be viewed as generalizations, as there are always exceptions.

- WB activities involving a twisting WB load (e.g., getting in and out of a car with low seats) tend to aggravate a meniscal lesion.
- PFJ pain often develops as a result of extended activity, such as in the middle of a long run or bike ride, continues into the evening or night, and can disturb sleep.[274]
- Walking upstairs or downstairs is usually difficult for patients with knee pathology. Usually, patients with a meniscal lesion complain of increased pain with stair climbing, whereas patients with a PFJ lesion complain of increased pain when descending stairs.
- Patients with a meniscal lesion or patellofemoral pain rarely can do a full squat without pain.
- Complaints of pain with kneeling activities are more likely to indicate a patellofemoral lesion than a meniscal lesion.
- Sitting tends to provoke more symptoms in patients with patellofemoral dysfunction than it does in those with meniscal or ligamentous lesions.

Anterior Knee Pain

Due to the prevalence of patellofemoral related disorders, there is a significant temptation to cut corners with a patient who presents with anterior knee pain, and to proceed directly to the diagnosis of patellofemoral pain.[142] However, this should be avoided, especially in light of the fact that the literature is replete with descriptions of physical examination techniques for the evaluation of the PFJ. Much of the confusion arises from the fact that patellofemoral disorders often lack any objective and identifiable structural failure.[128,278–284]

CLINICAL PEARL

The differential diagnosis of anterior knee pain (see Chapter 5) should include tears of the menisci, medial synovial plica syndrome, inflammatory or degenerative arthritis, tumors of the joint, ligament injuries that mimic patellar instability, osteochondritis dissecans of the medial femoral condyle (see Chapter 30), prepatellar bursitis, patellar tendinopathy, inflammation of the patellar fat pad, and Sindig–Larsen–Johansson syndrome.[9,142,285–287]

Classically, the pain from PFJ dysfunction is anterior, but it also can be medial,[205,288] lateral,[205,288] or popliteal (posterior).[203] Particular activities can help with differential diagnosis. Pain from rotational malalignment of the patella is typically exacerbated by activity and relieved by rest. Complaints of pain that occur when a patient arises from a seated position, negotiates stairs, or squats are associated with patellofemoral dysfunction. The so-called movie-theater—sign[205]—pain with prolonged sitting—traditionally has been associated with patellar pain from any source. Venous congestion and stretching of painful tissues are potential explanations for this symptom.[262] Activities that involve eccentric loading of the knee, and increased hill work with running, tend to provoke patellar tendinopathy, whereas inferior patellar pain following vigorous kicking, flip turns in swimming, or delivery of a fast ball in cricket would tend to implicate the fat pad.[289] The fat pad also may be irritated with the straight leg raise exercise.[282]

If a patellofemoral disorder is suspected, the clinician should look for evidence of an anatomical variant and/or a biomechanical dysfunction involving the lower quadrant. These anatomical variants can occur in any of the following joints: hip, patellofemoral, tibiofemoral, subtalar, intertarsal, or any combination of these joints. Examples of biomechanical dysfunctions that can cause patellofemoral disorders include excessive femoral anteversion, excessive genu valgum, excessive tibial external rotation, excessive pronation, and VMO dysplasia.

Edema rarely is reported with insidious onset overuse injuries, except in the case of plical irritation, ITB friction syndrome (ITBFS), irritation of the pes anserine or Osgood–Schlatter disease.[162] Following the history, a hypothesis is made, and this hypothesis is then tested with the physical

examination. Ideally, the clinician is able to process and identify responsible structures for the patient's complaints and the history of injury to aid in the differential diagnosis.

Systems Review

Knee pain and dysfunction can arise from multiple sources. Knee pain that has gradually worsened over time should lead to an evaluation of systemic illness and overuse complications such as tendinopathy. A subjective complaint of stiffness may imply swelling, and the joint mobility and effusion should be assessed. Complaints of weakness should be followed by an examination of the patient's strength and gait pattern.

The clinician needs to consider the likelihood of a specific diagnosis based on age. For example, a slipped capital femoral epiphysis (SCFE) is less likely to be the cause of a recent onset of pain in a 40-year-old fully developed man that it would be in an adolescent. Knee pain can be referred to the knee from the lumbosacral region (L3–S2 segments) or from the hip. For example, AM pain can be referred from the L2 and L3 spinal levels, whereas PL knee pain can be referred from the L4, L5, and S1 to S2 levels. The peripheral nerves are also capable of referring pain to this area. Medial knee pain having a burning quality could indicate saphenous nerve neuritis. A family history of knee problems, rheumatoid arthritis, or OA may need further investigation with a laboratory work-up or x-ray films. Pain that is constant and burning in nature should alert the clinician to the possibility of complex regional pain syndrome (CRPS), gout, or radicular pain. Intermittent pain usually indicates a mechanical problem (meniscus). The health intake questionnaire should be designed to provide evidence of undiagnosed systemic problems that relate to the knee dysfunction (e.g., Lyme disease). Chapter 5 describes some of the more common causes of referred knee pain and causes of a more serious nature.

TESTS AND MEASURES

Observation

The observation component of the examination begins as the clinician meets the patient and ends as the patient is leaving. This informal observation should occur at every visit.

Swelling or Effusion

The amount of swelling present may provide the clinician with valuable information regarding the internal damage that may have resulted. Diffuse swelling indicates fluid in the joint or synovial swelling or both. An effusion can be detected by noticing the loss of the peripatellar groove and by palpation of the fluid. A perceptible bulge on the medial aspect suggests a small effusion; this sign may not be present with larger effusions. The swelling can be examined with the patient positioned in supine, in the following ways[290]:

- Patellar ballottement/Tap Test.[290] Using one hand, the clinician grasps the patient's thigh at the anterior aspect about 10 cm above the patella, placing the fingers medial and the thumb lateral. The patient's knee is extended. With the other hand, the clinician grasps the patient's lower leg about 5 cm distal to the patella, placing the fingers medial and the thumb lateral. The proximal hand exerts compression against the anterior, lateral, and medial aspects of the thigh and, while maintaining this pressure, slides distally. The distal hand exerts compression in a similar way and slides proximally (Fig. 20-8). Using the index finger of the distal hand, the clinician now taps the patella against the femur. In the normal knee joint with minimal free fluid, the patella moves directly into the femoral condyle, and there is no tapping sensation underneath the clinician's fingertips. However, in the knee with excess fluid, the patella is "floating"; thus, ballottement causes the patella to tap directly against the femoral condyle. This sensation is transmitted to the clinician's fingertips. A positive test is indicative of a significant synovial effusion or hemarthrosis in the knee joint. However, sometimes, this test can produce false-positive results. When this is the case, the uninvolved side usually tests positive as well.

FIGURE 20-8 Patellar ballottement test.

- Stroke test. The patient is positioned in supine, with the knee extended. Using the web space between the forefinger and thumb, the clinician strokes the medial aspect of the knee in an attempt to milk the fluid into the lateral compartment. The test can be graded as follows[291]:
  - 0—No wave produced on downstroke
  - Trace—small wave on medial side with downstroke
  - 1+—Large bulge on medial side with downstroke
  - 2+—Effusion spontaneously returns to the medial side after upstroke (no downstroke necessary).
  - 3+—So much fluid that it is not possible to move the effusion out of the medial aspect of the knee

Fluid Wave Test

This test is used when there is minimal effusion (less than 30–50 cc). The patient is positioned in supine, and the clinician presses his or her fingers in both parapatellar gutters. Since the pressure is applied from below upward, the gutters are emptied. The patient is asked to stand while the clinician keeps the fingers in the parapatellar gutters. If the clinician then releases the fingers and the fluid returns to the parapatellar gutters, it is a positive sign.

If there is no swelling, but there is evidence of bruising or bleeding into the tibial area, disruption of the joint capsule may be present, or a SCFE, if the patient is an adolescent.

Popliteal swelling, which can compress the tibial or common fibular (peroneal) nerves, or both, can produce complaints of paresthesia and anesthesia.

Anthropometric measurements can be used to assess the severity of swelling in an acute knee problem (capsular effusion, extracapsular swelling). T ese measurements should include at least the following:

1. Joint line
2. 5 cm superior to the joint line to assess the suprapatellar pouch for effusion or vastus medialis atrophy
3. 15–20 cm superior to the joint line
4. 15 cm distal to the joint line.

Girth measurements have been used to assess muscle atrophy in this region but, while such measurements made with MRI and ultrasound have demonstrated strong validity, manual measurements using measuring tape are not sensitive enough unless the atrophy is severe.[292]

T e formal observation of the patient is divided into three sections: standing and walking, seated, and lying examinations.

Patient Standing

T e patient is asked to stand with the feet slightly apart and aligned straight ahead. T is position can be used to assess overall limb alignment as well as to identify possible foot abnormalities. A careful physical examination of the hip, knee, and ankle is performed, observing for both static restraints, and, to a great degree, dynamic restraints.[121] Following this position, the patient is asked to stand with the feet shoulder-width apart. T e entire trunk and lower extremities are observed. Areas of atrophy should be noted and correlated with other findings. Common areas include the medial aspect of the quadriceps following trauma, nerve injury, or knee surgery.

Degree of Femoral Retroversion or Anteversion

Femoral retroversion–anteversion is indicated by whether the feet are rotated outward or inward, respectively, in the relaxed standing position. T e position of the patella is examined to see whether it looks inward (the so-called squinting patella), which could indicate femoral anteversion. Femoral anteversion results in internal rotation of the femoral sulcus, and an increase in the Q-angle. Femoral anteversion has been associated with abnormal patellofemoral mechanics.[142,293] Even if the patella looks straight in the presence of femoral anteversion, it may be held there by tight lateral structures.[282]

Leg-Length Discrepancy

Compensations for leg-length discrepancies include excessive foot pronation, toeing-out (forefoot abduction), and a flexed knee gait or stance.[294,295]

Degree of Genu Varum/Genu Valgum

Genu varus ("bow legs") can be the result of bowing of the tibia or varus at the knee joint. An increased varus moment can contribute to early degeneration of the knee and, when exaggerated, is most often an indication of advanced DJD.[296] On the basis of the relationship between the proximal and distal aspects of the femur, a change in the orientation of the shaft and the neck will change the orientation of the tibiofemoral joint, thereby altering the WB forces through the knee joint. For example, an increase in the normal angle of inclination at the hip (coxa valga) will redirect the femoral shaft more laterally than normal, resulting in a decrease in the normal physiologic valgus angle of the knee (genu varus). T is results in a shifting of the mechanical axis to the medial compartment of the knee, increasing the compression forces medially.[67]

Genu valgus ("knock knees") can result from a change of angulation of the femur caused by femoral anteversion, tibial torsion, or excessive foot pronation. A valgus knee increases the Q-angle by displacing the tibial tuberosity laterally and can be associated with patellofemoral pain.[297]

To observe genu varum and genu valgum, the patient is positioned in standing so that the patellae face anteriorly, and the medial aspect of the knees and the medial malleoli of both lower extremities are as close together as possible. A distance of 9–10 cm (3.5–4 in) between the malleoli of the ankles with the knees touching is considered excessive and indicates genu valgum, whereas a distance of 4 cm (1.6 in) measured between the knees when the ankles are together, indicates genu varum.[298–300]

Degree of Knee Flexion

A flexed knee in the relaxed standing position is often indicative of arthritic changes of the knee.

Degree of Genu Recurvatum or Hyperextension

Knee recurvatum may be an expression of a generalized ligamentous laxity or may be associated with patella alta.[214] Hyperextension of knee produces stress on the posterior capsule, slackening of the ACL, and alterations in the compressive forces acting on the anterior articulating surface of the tibia.[296] T e anterior compressive forces can cause the inferior pole of the patella to be driven posteriorly into the fat pad, producing an irritation.

Q-Angle Assessment

A properly measured Q-angle can contribute significantly to the evaluation of patellofemoral malalignment. However, relying solely on the Q-angle measurement to determine patellofemoral alignment is an oversimplification. As with other clinical signs, an abnormal value does not necessarily identify the source of pain. T e Q-angle itself is not pathologic and is increased in only a small percentage of patients with patellar pain.[301]

T e Q-angle should be assessed dynamically and statically. It is important that this angle be measured in a consistent fashion. T e preferred position for this test is the one-legged standing position without shoes. Hyperpronation of the feet can be masked unless the foot and ankle are placed in a subtalar neutral position[302] (see Chapter 21). A measurement is then taken using an imaginary line drawn from the ASIS to the center of the patella, and a second line from the tibial tuberosity to the center of the patella (Fig. 20-6). T e WB position can be simulated in a supine patient by dorsiflexing

the ankles, extending the knees, and pointing the toes to the ceiling. With the knee flexed to 90 degrees, the tibial tubercle should lie less than 20 mm lateral to the midline of the femur at the upper edge of the femoral condyles; a distance of more than 20 mm indicates an abnormally lateral tubercle.[10] Both tight hamstrings and a decrease in ankle dorsiflexion can result in an increase in the dynamic Q-angle.[195]

A-Angle Assessment

The A-angle is a measurement that has been used to assess the position of the patella relative to the tibial tubercle.[303] It is the angle formed by the intersection of the line that bisects the patella longitudinally, and a line drawn from the tibial tubercle to the apex of the inferior pole of the patella. To measure the A-angle, the axis of the goniometer is placed at the inferior pole of the patella, so that the stationary arm bisects the patella and the moveable arm bisects the tibial tubercle. However, the results from a study by Ehrat et al.[223] indicated that the A-angle was not reproducible between examiners and recommended the need for further study before the A-angle could be used as a reliable assessment tool for patellar position.

Degree of Tibial Torsion

External tibial torsion increases the Q-angle, whereas internal torsion decreases it.[142] The vast majority of the studies focusing on anterior knee pain have examined the coronal relationships at the knee (Q-angle, patellar tilt, patellar subluxation).[304] Few studies have addressed the rotational relationships, specifically the rotational orientation of the tibia to the femur.[305] This is rotational relationship of the tibia to the femur in the transverse plane is referred to as knee version. Knee version often is recognized as a factor in the context of the osteoarthritic knee.[306–308] The significance of this rotational characteristic of the knee with anterior pain is that the patella is tethered to the tibia by the infrapatellar tendon and retinaculum, and if the tibia is rotated externally with respect to the femur, the patella will be pulled laterally by virtue of this attachment.[305] If the patella is not free to translate laterally, because of its soft-tissue attachments and its conformity with the patellar groove, increased pressure may be placed on the lateral facet. This is pressure may produce a condition called a lateral patellar compression syndrome (LPCS).[305,309]

Tibia-to-Floor Angle

If the tibia-to-floor angle is 10 degrees or greater, the extremity requires an excessive amount of subtalar joint pronation to produce a plantigrade foot.[214]

Patella Tendon-to-Patella Height Ratio

This measurement is best performed radiographically. The patella tendon length should be equal, or slightly longer than the height of the patella.[310] If a ratio of greater than 15–20% exists, patella alta should be suspected. If the ratio is less than 15–20%, patella baja should be suspected.

Foot Alignment

An often-neglected feature, which directly impacts the PFJ, is that of foot alignment. The normal WB foot exhibits a mild amount of pronation. If the foot pronates excessively, a compensatory internal rotation of the tibia may occur. This produces an increased amount of rotatory stress and dynamic abduction movement at the knee that has to be absorbed through the peripatellar soft tissues at the knee joint.[214,280,293,311] These stresses can force the patella to displace laterally.[312,313] In addition, a change in the position of the talus can affect the functional leg length. Subtalar supination may cause the leg to lengthen, whereas subtalar pronation shortens the leg.

Gait

Abnormal foot mechanics is manifested during ambulation, and abnormal gait patterns may suggest an underlying condition (see Chapter 6). The gait assessment relative to the knee allows the clinician to identify deviations of the foot, ankle, knee, or hip joint, such as excessive subtalar and midtarsal joint pronation, limited ankle dorsiflexion, tibial or femoral torsion abnormalities, and excessive varus or valgus at the knee, all of which could place the knee structures at risk for further microtrauma.[162]

During normal gait, the knee should be observed to flex to approximately 15–20 degrees at initial contact before extending to the neutral position at the terminal stance (see Chapter 6).[296] An increase in 5 degrees of pronation at midstance, a period where the foot should be in supination, holds more potential for producing pain than if the 5 degrees occurs during the contact phase.[245]

Since the joint reaction forces are reported to increase with the magnitude of quadriceps contraction and the knee-flexion angle,[314] patients with patellofemoral pain often adopt compensatory gait strategies to reduce the muscular demands at the knee. Evidence in support of this premise was reported by Dillon et al.,[315] who found that subjects with patellofemoral pain limited the amount of stance phase knee flexion during level and ramp walking.

An injury to the ACL produces distinct changes in lower extremity biomechanics during gait.[316] Although healthy individuals demonstrate an extensor torque at the knee for 10–45% of the stance phase,[317–319] gait analysis of individuals with recent ACL deficiency shows functional adaptations in a high proportion of patients, with an extensor torque that lasts for nearly the entire stance phase.[317] Other analysis has also shown a decrease in the flexion moment of the knee in the range of 0–40 degrees of flexion in patients who have a chronic tear of the ACL.[320,321]

When the normal limb moves into the midstance phase, gravity and inertia generate a moment that tends to flex the knee. Since the quadriceps muscles balance this moment, a decrease in the flexion moment suggests a decrease in the quadriceps muscle moment.[322] Such a decrease has been noted in both limbs of patients who had only one knee with a torn ACL.[321]

Andriacchi[322] termed this finding the quadriceps-avoidance gait, although not all patients who have a torn ACL have such a gait, and its prevalence appears to be partly related to the time since the injury.[323] In activities that involve knee-flexion angles of less than 30 degrees (i.e., those involving normal gait), the quadriceps-avoidance gait is most effective in preventing anterior tibial translation.[322,324,325] In activities that

involve knee-flexion angles of 40 degrees or more (e.g., jumping or sharp changes in running direction), increased contraction of the hamstrings is effective in preventing anterior tibial translation.[149,325–327]

Gait adaptations in individuals with ACL injury who have reconstruction surgery are less clear for two reasons[316]:

1. Very few comprehensive gait analyses have been conducted on this population.
2. T e large variations in surgical and rehabilitation procedures and patient characteristics, and in patient compliance with rehabilitation, limit the generalization of these potential results.

Gait can also be affected by genu recurvatum, because during the loading response in gait, an individual with genu recurvatum transfers body weight directly from the femur to the tibia without the usual muscle energy absorption and cushioning of a flexed knee provided. T is may lead to pain in the medial tibiofemoral joint (compression) and PL ligamentous structures (tensile). In individuals with quadriceps weakness, compensation may occur by hyperextending the knee to provide greater knee stability.

Stride length and cadence have recently been shown to be related to load rate and risk for injury at the knee.[328] By increasing step rate and proportionately decreasing step length to maintain a constant speed, there is a reduction in impact loading, with the greatest effect occurring at the knee.[329] A recent study that evaluated changes in biomechanics as runners adopted higher step rates found that energy absorption at the knee decreased, and the knee flexed more at initial contact.[328] Such biomechanical retraining may eventually prove effective in managing symptoms associated with knee pathologies related to repetitive and abnormal loading such as PFPS.[328]

Patient Sitting

Active Knee Extension

Although formally assessed as part of the active range of motion (AROM) with passive overpressure tests (see later), active knee extension may also be used during the observation phase of the examination. T e patient should fully extend the knee from a flexed position. Normally, the patella follows a straight line, or a slight and smooth, gradual, lateral concave "C" curve as the knee extends. T e presence of a "J sign," in which the patella slips off laterally as the knee approaches extension or apprehension with motion involving lateral or medial stress, is necessary to confirm patellar instability.[10]

T e patella may be compressed with the palm of the hand through the full ROM, as ulcerated lesions can be tender with this provocative test.[10] However, care should be taken with this maneuver, because it can provoke pain in otherwise asymptomatic patients.

Distal patellar lesions are often tender with this test in the early degrees of knee flexion, whereas proximal lesions are tender at approximately 90 degrees.[10] T is information can help guide the clinician with the intervention. Crepitus at the knee is a nonspecific finding and can be associated with both cartilaginous and synovial lesions.[10] Although often a concern to patients because they believe it to be indicative of arthritis, crepitus is often a result of tight, deep, lateral retinacular structures and can be improved with retinacular stretching techniques.[282]

In addition to observing the patella during active knee extension, the clinician should also note any evidence of a quadriceps lag manifested by an inability to fully extend the knee. T is lag can result from muscle atrophy, pain, effusion, reflex inhibition, or a loss of mechanical advantage. Quadriceps reflex inhibition has been well documented throughout the literature and is thought to result from pain or effusion, or both, although the exact etiology has yet to be determined.[277,330–335]

Some of the proposed causes for this reflex inhibition include

- the result of capsular stretching[334]
- the result of increased intraarticular pressure[331]

In the presence of various pain syndromes, such as CRPS,[330] additional muscle inhibition can occur. In most patients, any limitations of motion resolve when the pain and effusion dissipate. However, this quadriceps inhibition may allow scar tissue to form while the knee is held in a flexed position. Atrophy of the quadriceps muscle and flexion contracture usually results, and activities of daily living become more difficult to perform. Joint immobilization can complicate all of these factors. Disuse may induce abnormal cross-links between collagen fibers at abnormal locations,[336,337] decreasing their extensibility[338] and promoting intraarticular and extra-articular scarring.

Patient Lying Supine

Malalignment can be observed on certain supine, resting patients, whereas in other subjects a dynamic evaluation (walking, jumping, squatting, etc.) is required to detect an abnormal alignment. T e lateral pull test can be performed to assess patellar tracking.[339] T e patient lies supine with the knee extended and the clinician asks the patient to perform an isometric quadriceps contraction. T e clinician observes patellar tracking during the contraction. T e test is considered positive if the patella tracks more laterally than superiorly and negative if the superior displacement is equal to the lateral displacement.[339] However, since the lateral pull test has been found to have only fair intrarater, and poor interrater reliability, care must be taken in placing too much emphasis on this test when making clinical decisions.

Hip Screening

With the patient supine and then prone, the hip is flexed and rotated as the clinician checks for a source of referred pain.[205]

Since patellar malalignment can be associated with adaptive shortening, the following structures (in decreasing order of frequency) are assessed[194,205]:

- Lateral retinaculum (see "Special Tests"). A tight lateral retinaculum may pull the patella laterally.
- Hamstrings (see "Special Tests"). When an individual with tight hamstrings runs, there is a decrease in stride

length and a potential for the quadriceps to fatigue in an effort to overcome the passive resistance of the hamstrings.[340] Tightness of the hamstrings also produces an increase in knee flexion at heel strike. Since the knee cannot straighten, an increased dorsiflexion is required to position the body over the planted foot.[282] If the range of full dorsiflexion has already occurred at the talocrural joint, the further range is achieved by subtalar pronation. This has the effect of increasing the valgus vector force and the dynamic Q-angle.[282,341]

- ITB (see "Special Tests"). The ITB is maximally taut at 20–30 degrees of flexion. Adaptive shortening of this band can cause a lateral tracking and tilting of the patella, and often a stretching of the medial retinaculum.[245]
- TFL and rectus femoris (see Chapter 19). Adaptive shortening of these structures can increase the amount of compression of the patella on the femur.[245]
- Hip rotators. The hip rotators can accentuate anteversion or retroversion (see Chapter 19).[245]
- Achilles–soleus length. A decrease in talocrural joint dorsiflexion ROM may result in a compensatory subtalar pronation during ambulation and WB.[342] Soft-tissue tightness is particularly prevalent during the adolescent growth spurt, in which the long bones are growing faster than the surrounding soft tissues.[343]

Active Range of Motion

ROM testing for the tibiofemoral joint should include assessment of knee flexion and extension, tibial internal and external rotation. Normal knee motion (Table 20-7) has been described as 0 degrees of extension to 140 degrees of flexion, although hyperextension is frequently present to varying degrees.[344] In general, however, the best way to ascertain normal motion is to examine the contralateral knee, provided that it has no abnormal conditions.

The ROM testing can often be diagnostic and provides the clinician with some clues as to the cause of the problem. Examining the uninvolved knee first allays a patient's fears and helps to determine what the normal ROM is. In addition, observation of the uninvolved knee can afford the clinician information about the PFJ and the tracking of the patella.[345]

TABLE 20-7 Normal Ranges and End-Feels at the Knee

Motion	Range of Motion (degrees)	End-Feel
Flexion	0–140	Tissue approximation or tissue stretch
Extension	0–15	Tissue stretch
External rotation of tibia on femur	30–40	Tissue stretch
Internal rotation of tibia on femur	20–30	Tissue stretch

CLINICAL PEARL

Full range of knee motion requires

- Congruent articular surfaces
- Adequate muscle function
- An articular capsule with suitable capacity and flexibility
- Effective space in the medial and lateral articular recesses, intercondylar notch, and suprapatellar pouch
- Sufficient meniscal motion[346]

A number of studies have demonstrated that goniometric measurements of knee ROM performed in a clinical setting can be highly reliable.[347–351] Rothstein et al. showed that intratester and intratester reliability for flexion of the knee VIDEO was high (r = 0.91–0.99 and r = 0.88–0.97, respectively).[347] Watkins et al. showed that the intertester reliability of measurements of knee ROM obtained by visual estimation was 0.83 for flexion and 0.82 for extension.[351]

Flexion

The amount of knee flexion should be assessed to see if the motion is restricted by tight structures. If no restriction is suspected, tests are required for generalized ligament laxity and for abnormally loose patellar retinacula (see later discussion).

The primary flexors of the knee are the three hamstring muscles, assisted by the gracilis, sartorius, popliteus, and gastrocnemius muscles, and the TFL (in 45–145 degrees of flexion; see Table 20-2). The patient lies in the supine position. Using one hand, the clinician grasps the anterior aspect of the patient's lower leg, just proximal to the malleoli, while the other hand grasps the anterior aspect of the patient's thigh, just above the patella. The patient's hip is flexed to about 90 degrees and stabilized with one hand while the clinician flexes the knee with the other hand (Fig. 20-9). At the end of the ROM, the clinician exerts slight overpressure. The normal end-feel is usually one of soft-tissue approximation. A flexion limitation other than soft-tissue approximation is usually the result of an articular lesion, such as arthritis or arthrosis (capsular pattern), a lesion of one of the menisci, or a loose body.[290]

FIGURE 20-9 Knee flexion.

FIGURE 20-10 Knee extension

Rotation of the tibia relative to the femur is possible when the knee is flexed and NWB, with rotational capability greatest at approximately 90 degrees of flexion.[94]

Extension

The primary extensors of the knee are the quadriceps muscles, consisting of the rectus femoris, VL, vastus medialis, and vastus intermedius (Table 20-2). Also assisting with knee extension in the 0–30-degree flexion range is the ITB and TFL.

The patient extends the knee (Fig. 20-10), and the clinician applies overpressure by stabilizing the thigh and pulling the ankle up to the ceiling while allowing the conjunct external rotation of the tibia. Under normal conditions, the end-feel is usually hard.

A limitation of active knee motion can have a number of causes. The patient may have a neurologic deficit from a lumbar intervertebral disk (IVD) herniation, with the loss of knee motion as the primary symptom. Any acute injury causing pain may limit active knee motion as a result of muscle inhibition.[331]

Passive Range of Motion

Passive movements, as elsewhere, can determine the amount of available motion, the presence or absence of a capsular pattern, and the end-feel. At the tibiofemoral joint, the end-feel of flexion should be tissue approximation whereas the end-feel of extension and medial and lateral rotation of the tibia on the femur is tissue stretch. Passive hyperextension of the knee with overpressure is performed to assess (from the end-feel) whether the knee extension is limited as a result of an articular disorder. Such articular disorders include arthritis or arthrosis, a lesion of one of the menisci, or a loose-body involvement. Hayes et al.[352] found the intrarater reliability of end-feel and pain/resistance judgments at the knee to be generally good, especially after accounting for subject change and unbalanced distributions. Interrater reliability, however, was generally not acceptable, even after accounting for these factors.[352] In a separate study, Hayes et al.[353] explored the construct validity and test–retest reliability of the passive motion component of the Cyriax soft-tissue diagnosis system and compared the hypothesized and actual patterns of restriction, end-feel, and pain/resistance sequence (P/RS) of 79 subjects with OA of the knee and examined associations among these indicators of dysfunction and related constructs of joint motion, pain intensity, and chronicity. The results of the study are discussed next.

Consistent with the hypotheses based on Cyriax's assertions about patients with OA, most subjects had capsular end-feels for extension; subjects with tissue approximation end-feels for flexion had more flexion ROM than did subjects with capsular end-feels, and the P/RS was significantly correlated with pain intensity ($\rho = 0.35$, extension; $\rho = 0.30$, flexion).[353]

Contrary to the hypotheses based on Cyriax's assertions, most subjects had noncapsular patterns, tissue approximation end-feels for flexion, and what Cyriax called pain synchronous with resistance for both motions.[353]

Pain intensity did not differ depending on end-feel. The P/RS was not correlated with chronicity ($\rho = 0.03$, extension; $\rho = 0.01$, flexion).[353]

Reliability, as analyzed by ICCs (ICC[3,1]) and Cohen's κ coefficients, was acceptable (≥ 0.80) or nearly acceptable for ROM (ICC = 0.71–0.86, extension; ICC = 0.95–0.99, flexion) but not for end-feel ($\kappa = 0.17$, extension; $\kappa = 0.48$, flexion) and P/RS ($\kappa = 0.36$, extension; $\kappa = 0.34$, flexion).[353]

The study concluded that the use of a quantitative definition of the capsular pattern, end-feels, and P/RS as indicators of knee OA should be reexamined and the validity of the P/RS as representing chronicity and the reliability of end-feel and the P/RS are questionable.[353]

Others have found that a ratio of loss of extension to loss of flexion during passive range of motion (PROM) of between 0.03 and 0.50 was more likely than a noncapsular pattern in patients with an inflamed knee or osteoarthrosis (likelihood ratio = 3.2).[354]

According to the osteopathic theories of somatic dysfunction,[355] the following guidelines are used:

- If the restriction to movement is opposite to the direction that the bone seems to have traveled (e.g., the tibia has a reduced joint glide), a mobilization or a manipulation is the intervention of choice.
- If the restriction to movement is in the same direction that the bone seems to have moved, and the opposite movement seems to be excessive (a change has occurred in the overall starting position), a muscle imbalance should be suspected, and a muscle energy technique used.
- If the patient demonstrates normal range but pain with movement, the joint cannot be at fault.
- If a muscle is very hypertonic, a spinal dysfunction may be present (unless trauma is involved), producing a hypermobility.

Even minor losses of knee motion may have adverse effects. It is common to lose both flexion and extension; however, loss of extension is usually more debilitating.[356] A loss of extension of more than 5 degrees may cause patellofemoral pain and a limp during walking,[357] whereas restricted flexion does not severely affect gait as long as the knee can be flexed to at least 60 degrees.[358] Diminished running speed is associated with loss of flexion of 10 degrees or more,[359] whereas an extension

deficit of more than 10 degrees is poorly tolerated by active people.[360] A loss of more than 20 degrees of extension may cause a significant functional limb-length discrepancy.[359]

Patellar Motion Tests

Probably the most important part of the patellofemoral examination is the observation of the dynamics of patellar tracking in WB and NWB.

A unilateral squat (Waldron test) can be used to assess patellofemoral function.[361] T e patient stands on the involved leg, and the clinician sits or squats next to the patient. Using the entire surface of the palm, the clinician exerts slight pressure in an anteroposterior direction against the patient's patella (Fig. 20-11). From this position, the patient is asked to bend the knee slowly, if possible, to about 90 degrees, while the clinician palpates for crepitus and locking of the patella and assesses the course of movement of the patella. Crepitus or locking can indicate the presence of patellofemoral chondropathy or patellofemoral arthrosis. However, Nijs et al.[362] reported unimpressive positive and negative likelihood ratios for this test.

In patellar malalignment or pathologies of the corresponding femoral joint surface, movement of the patella can be disturbed. T e patella is observed while the patient initiates flexion of the knee to see if it engages smoothly at the proximal end of the trochlea or more distally than normal. Lateralization of the patella can occur during flexion, particularly when the Q-angle is excessive.

T e passive mobility tests for the patella are outlined in "Patellar Stability Tests".

Kinetic Chain Assessment

Ankle Motions

Ankle motions are tested because, as has been discussed, a number of structures share a common relationship with the foot, ankle, and knee joint complex (see Chapter 21) and can therefore have an impact on knee function. For example, adaptive shortening of the gastrocnemius, particularly in the presence of adaptively shortened hamstring muscles, may produce increased knee flexion at initial contact and during the stance phase of gait.[225]

Hip Motions

Several muscles cross both the hip and the knee. T ese include the rectus femoris, gracilis, sartorius, and hamstrings muscles. Adaptive shortening of any of these structures may cause alterations in postural mechanics and gait. T e hip rotators can also influence other aspects of the lower kinetic chain. Sahrmann advocates the testing of length–strength relationship of the hip external rotators because of their CKC function of decelerating lower extremity internal rotation.[162,363]

Passive Accessory Motion Testing

T e passive accessory motion tests, or joint glides, are performed at the end of the patient's available range to determine if the joint itself is responsible for the loss of motion.

Tibiofemoral Distraction

T e patient lies in the prone position. T e clinician is beside the patient. Using one hand to stabilize the thigh, the clinician uses the other hand to grip the distal tibia from the medial and lateral sides. T e clinician then applies a force perpendicular to the tibial joint surface (Fig. 20-12).

FIGURE 20-11 Waldron test.

FIGURE 20-12 Tibiofemoral distraction.

FIGURE 20-13 Posterior glide of the tibia on the femur.

Posterior Glide of the Tibia on the Femur

The patient lies in the supine position with the thigh supported by a towel. Standing to the side of the patient, the clinician applies a posterior glide through the tibia (Fig. 20-13).

Anterior Glide of the Tibia on the Femur

The patient lies in the supine position with the knee flexed and the foot placed on the table. The clinician stands to the side of the patient. Using both hands, the clinician applies an anterior glide of the tibia (Fig. 20-14).

Proximal Tibiofibular Joint

The proximal tibiofibular joint can be assessed with the patient in the supine position and the knee flexed to approximately 90 degrees. The clinician stabilizes the tibia using one hand and uses the other hand to grasp the fibular head and to assess the anterolateral and posteromedial glides (Fig. 20-15).

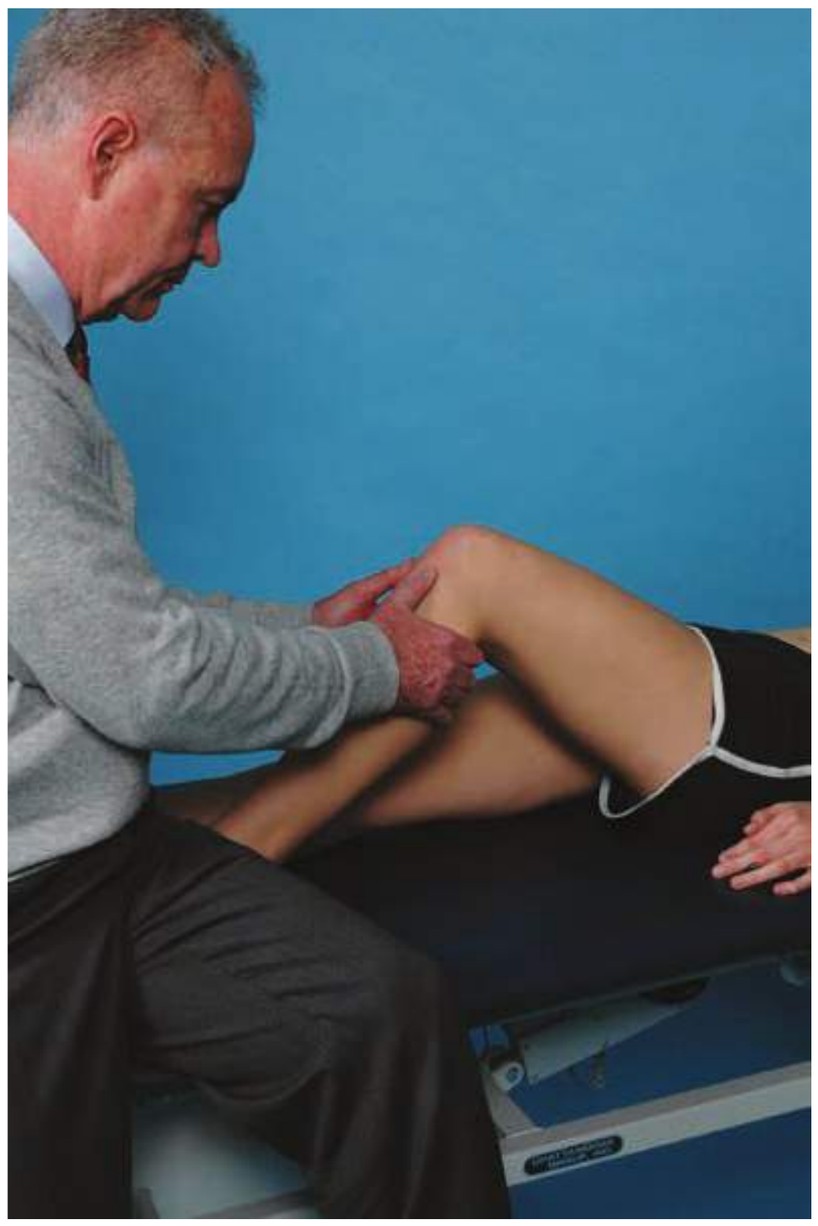

FIGURE 20-14 Anterior glide of the tibia on the femur.

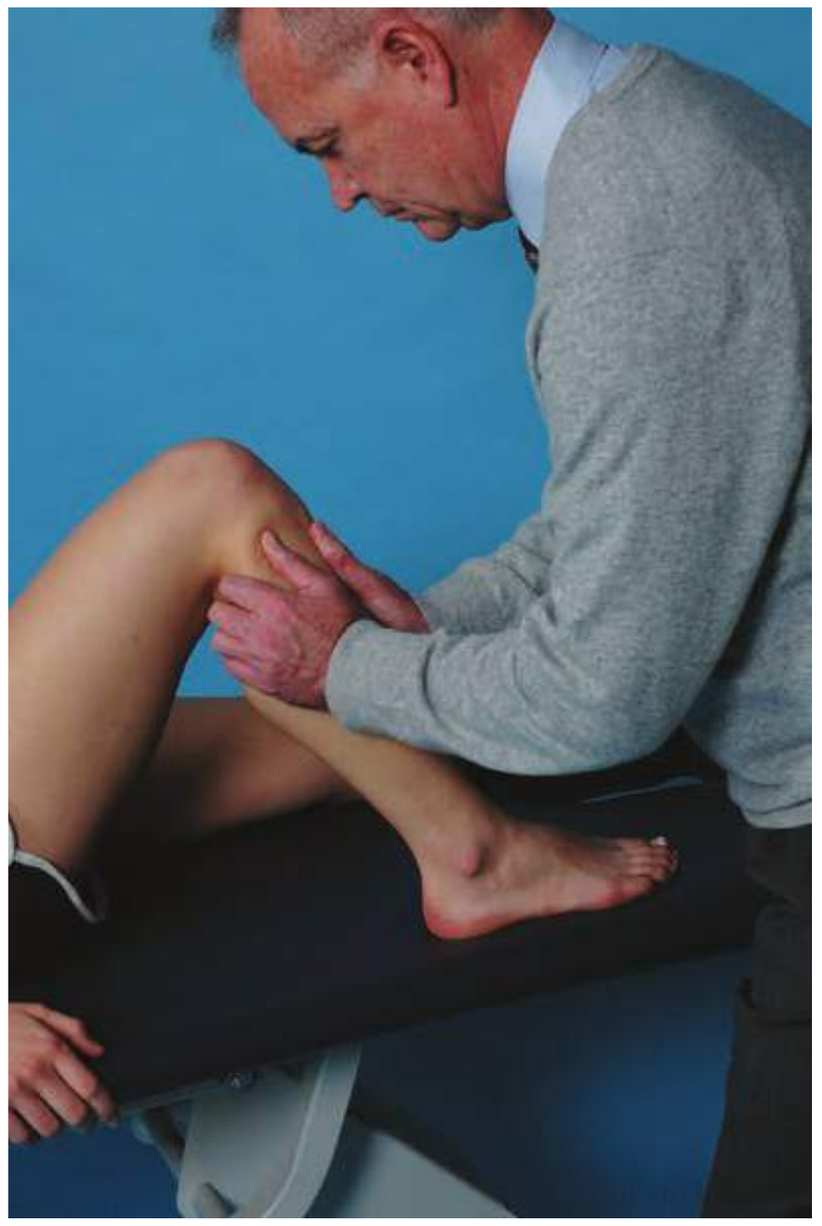

FIGURE 20-15 Mobility testing of the proximal tibiofibular joint.

Passive Tibial External Rotation

The patient lies in the supine position. Using one hand, the clinician grasps the patient's foot and brings the ankle into maximal plantar flexion. The other hand is positioned to monitor the joint space.[290] The patient's knee is flexed to 90 degrees and the hip to approximately 45 degrees. The distal hand performs an external rotation of the tibia while maintaining the ankle in maximum plantar flexion (Fig. 20-16). At the end of the ROM, the clinician exerts slight overpressure. Under normal conditions, the end-feel is firm. The clinician notes whether the pain is provoked or whether there is a hypermobility or hypomobility[290]:

- Pain with the passive external rotation of the tibia can be the result of a lesion of the medial meniscotibial ligament, medial meniscus, MCL, or the posteromedial capsuloligamentous complex.
- Hypermobility with this maneuver can be the result of a lesion of the posteromedial capsuloligamentous complex, often in combination with lesions of the MCL and the ACL. Hypermobility may also be seen in ballet dancers.
- Hypomobility of passive tibial external rotation is seen only in severe articular disorders with significant capsular limitations of motion.

Passive Tibial Internal Rotation

The patient lies in the supine position. Using one hand, the clinician grasps the patient's foot and brings the ankle into

FIGURE 20-16 Passive external rotation of tibia.

maximal plantar flexion. The other hand is positioned to monitor the joint space. The patient's knee is flexed to 90 degrees and the hip to about 45 degrees. The distal hand performs an internal rotation of the tibia while maintaining the ankle in maximum plantar flexion (Fig. 20-17). At the end of the ROM, the clinician exerts slight overpressure. Under

FIGURE 20-17 Passive tibial internal rotation.

FIGURE 20-18 Patellar mobility testing.

normal conditions, the end-feel is firm. The clinician notes whether pain is provoked or whether there is hypermobility or hypomobility[290]:

- Pain can be the result of a lesion of the lateral meniscotibial ligament, lateral meniscus or PL capsuloligamentous complex.
- Hypermobility can be the result of a lesion of the PL capsuloligamentous complex.
- Hypomobility is seen only in severe articular disorders with significant capsular limitations of motion.

Patellofemoral Joint Mobility Tests

The patient lies in the supine position with the involved knee supported in slight flexion. The clinician moves the patella superiorly, inferiorly, medially, and laterally (Fig. 20-18). Caution must be used with the lateral glide in case the joint is hypermobile, as this is the most common direction for patella dislocations. To assess the various tilts of the patella, both hands are wrapped around the patella, and the thumbs are used to tilt the patella medially and laterally (Fig. 20-19). The findings are compared with the contralateral side.

Strength Testing

Gross muscle testing is useful in checking for deficits in the lower extremities. Strength testing involves the performance

FIGURE 20-19 Patellar tilting test.

FIGURE 20-20 Strength testing the medial hamstrings.

FIGURE 20-21 Strength testing the biceps femoris.

of resisted isometric tests. The joint is placed in its resting position to minimize any joint compression forces.

Knee Flexion

The strength of the knee flexors (the hamstrings) can be assessed by positioning the patient prone with the knee flexed to approximately 80–90 degrees. By internally rotating the tibia (Fig. 20-20) and resisting knee flexion, the clinician can theoretically assess the integrity of the medial hamstrings (semimembranosus and semitendinosus). The biceps femoris is assessed similarly by externally rotating the tibia and resisting knee flexion (Fig. 20-21) VIDEO.

Knee Extension

Pain may be reproduced, and localized, with multiple angle isometric testing of the quadriceps, as described by McConnell.[196] Thus, the strength of the knee extensors (the quadriceps) is tested in 0, 30, 60 (Fig. 20-22), 90, and 120 degrees of knee flexion and held for 1 second with the femur externally rotated, to see if the pain can be reproduced or localized. The reproduction of pain with these tests suggests excessive pain from patellar compression. Any abnormal tibial movement with these tests may suggest ligamentous instability.[364] If the pain is noted during this testing, McConnell suggests returning the knee to full extension, producing and maintaining a medial glide of the patella, and then returning the knee to the painful position to retest. This action should reduce the pain if it is of a patellofemoral origin.[196]

The final 15 degrees of knee extension require a 60% increase in muscle firing.[132] An extension lag (passive knee extension that is greater than active knee extension) indicates a slight loss of quadriceps muscle function.[162,282,365]

Siegel and Jacob[364] suggest testing the quadriceps muscle at 0, 30, 60, and 90 degrees while observing for any abnormal tibial movement. Any abnormal tibial movement would suggest ligament instability or excessive pain from patellar compression.

FIGURE 20-22 Strength testing of knee extensors at 60 degrees.

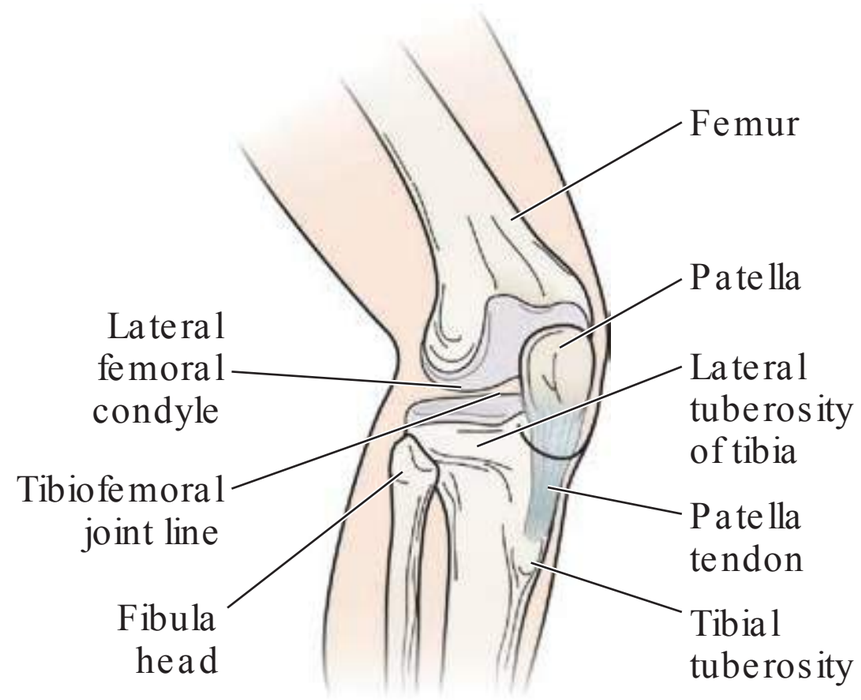

FIGURE 20-23 Palpable structures on the anterolateral surface of the knee.

Plantar Flexion

The heel raise can be used to assess the strength of the gastrocnemius. The strength of the gastrocnemius muscle is tested because of its intimate relationship to the knee and its importance in lower extremity function. The patient is positioned in standing, leaning against a wall, or supported by the clinician with the knees extended. One foot is tested at a time as the patient rises up on the toes for 10–20 repetitions (depending on age and physical ability) while standing.

- The patient everts the foot and raises up on the toes to test the lateral head.
- The patient inverts the foot and raises up on the toes to test the medial head.

The soleus muscle can be tested similarly by having the patient perform a unilateral heel raise while keeping the knee flexed.

Palpation

Palpation of the soft tissues about the knee is critical and often reveals more important information than any imaging tool. For palpation to be reliable, the clinician must have a sound knowledge of surface anatomy (Figs. 20-23 and 20-24), and the results from the palpation examination should be correlated with other findings. A logical sequence should be employed by the clinician. The skin, retinacula, quadriceps tendon, and patellar tendon are palpated to rule out any soft-tissue sources of pain. Differences in temperature between the knees suggest inflammation in the warmer of the two. The following structures should be identified and palpated.

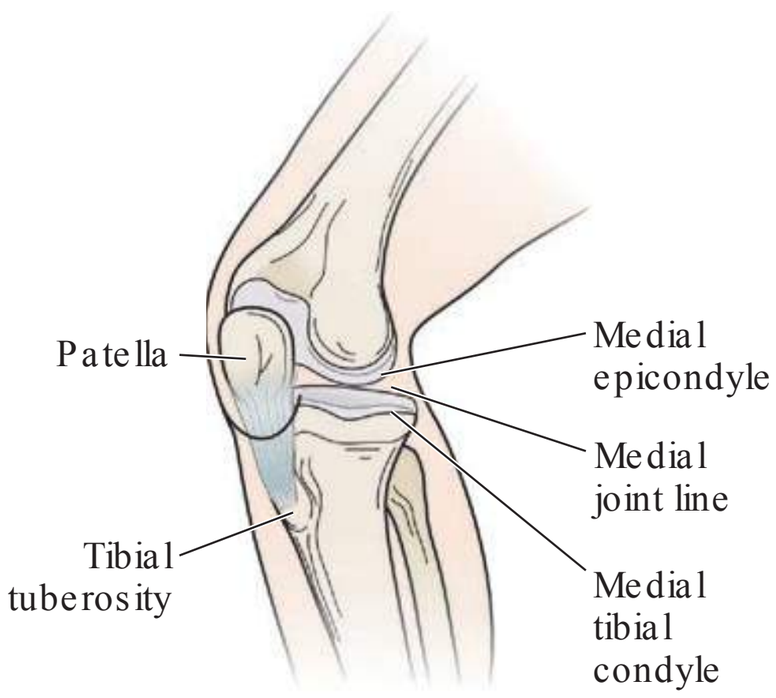

FIGURE 20-24 Palpable structures on the anteromedial surface of the knee.

Posterior Aspect

The patient lies in the prone position. The clinician locates the popliteal fossa. The semimembranosus and semitendinosus form the proximal medial border of the fossa. Deep inside this fossa, a Baker cyst can be palpated if it is present. With the knee in a slightly flexed position, the thin round tendon of the semitendinosus should be easy to palpate. Medial and lateral to this tendon are the deeper parts of the semimembranosus. The popliteal pulse can be located just below the crease of the knee, more to the lateral side than to the medial side, and posterior to the tibial plateau. Medial to the pulse is the tendon of semimembranosus. At this point, if the thumb is pushed deeper, the attachment of the PCL can be located as it arises from the back of the tibia. Even under normal circumstances, this attachment will be tender. A little lateral to this is the attachment of the meniscofemoral ligament. The PCL and meniscofemoral ligament curve inward, to attach on the inner aspect of the medial condyle of the femur.

At the proximal lateral part the fossa, the biceps femoris tendon is found. This tendon is palpable together with the common fibular (peroneal) nerve. The tendon of the gracilis is medial and anterior to the medial part of the semimembranosus. Palpation performed medially and anteriorly to this point leads to the sartorius muscle. The tendons of the sartorius, gracilis, and semitendinosus form the pes anserinus. The sartorius and gracilis muscles can be differentiated as follows: the gracilis contracts during hip adduction, while the sartorius contracts during hip abduction. Palpation more anteriorly leads to the medial femoral condyle and the adductor tubercle. Tenderness at the anterior aspect of the medial femoral condyle, associated with a snapping sensation as the knee is flexed, can indicate a symptomatic plica.[366] The adductor tubercle serves as the attachment site for the patellar retinaculum and the medial patellofemoral ligament and is a hallmark site of tenderness with lateral patellar dislocation.[290] The adductor tubercle is also the attachment site of the adductor magnus, and the origin of the MCL. The distal borders of the popliteal fossa are palpated by positioning the patient's knee in slight flexion. The medial head of the gastrocnemius can be palpated deep within and medial to the fossa while the lateral head can be found deep within and medial to the tendon of the biceps femoris muscle.

Anterior Aspect

The patient lies supine with the hip and thigh positioned in extension. The clinician palpates the medial and lateral edges of the patella. The VMO normally inserts into the upper third or half of the medial patella and is readily palpable. In patients with patella malalignment, the VMO may be dysplastic and virtually invisible inserting proximal to the superior pole of the patella.[367] Palpation of the rectus femoris insertion on the

superior aspect of the patella is only possible with the patella tipped slightly forward.[290] Complaints of pain distal to the patella during extension of the knee may indicate a patella tendon–ligament lesion at the inferior pole. In some individuals, the continuation of the tendon of the VL muscle, the lateral patellar retinaculum, can be palpated on the lateral side of the patella.[290]

Palpation of the joint space is made easier when the tibia is rotated internally and externally while in the flexed position. The anterior part of the medial meniscus is palpable in the medial joint space with the tibia externally rotated, between the patellar tendon–ligament and the anterior edge of the MCL. Under normal circumstances, the medial meniscus is not palpable beyond 30 degrees of flexion.[290] The medial meniscotibial or coronary ligament, which attaches the medial meniscus to the tibia, is palpable anteriorly with the knee positioned at 90 degrees of flexion and the tibia maximally externally rotated, proximal to the tibia (passive external rotation of the knee will provoke the patient's pain if the ligament is damaged).[290]

CLINICAL PEARL

Joint line tenderness usually is associated with a tibiofemoral injury, such as a meniscal or collateral ligament tear, but it can also be associated with patellar pathology, although the reasons are probably multifactorial.[214,285,288] Numerous studies have shown that joint line tenderness, when used in isolation, is of little value in specifically diagnosing a meniscus tear.

Other structures to palpate for tenderness on the anterior aspect of the knee include the following:

- Base (inferior pole) of the patella. Tenderness at the inferior tip of the patella indicates patellar tendinopathy.
- Infrapatellar fat pad (Hoffa's fat pad). This structure is located between the patellar tendon (anteriorly) and the anterior joint capsule (posteriorly).
- Lateral retinaculum.
- Apex of the patella.
- Accessory retinaculum from the ITB.
- Medial retinaculum.
- Medial and lateral patellar facets. These facets, which are readily palpated using the thumb and index finger, can be tested for tenderness and alignment, as can the overhang of the lateral facet over the patellar groove, by pushing the patella to one side and then the other (glide test), and then curling the fingers around and under the borders of the patella. Palpation of the facets should not elicit pain. The clinician should be able to palpate under one-third of the patella. A tilt of the patella (lateral side down) reflects a tight retinaculum, especially if the tilt cannot be passively corrected by the clinician.[367] When the patella is laterally displaced by the clinician and the patient reports sudden and considerable discomfort as the knee approaches extension, this is termed the apprehension sign (see "Special Tests").[367] The combination of tilt and lateral facet tenderness in the absence of any other positive findings on physical examination suggests clinically significant patella malalignment.[367]
- Dynamic restraints. The patient is asked to contract the quadriceps. In patients with malalignment, the VMO typically cannot be identified by sight or palpation; it inserts no farther distally than the proximal pole of the patella, and it remains soft, even with maximal quadriceps contraction.[205] In the normal knee, the VMO should be felt to contract simultaneously with the VL.

Lateral Aspect

The fibular head can be palpated by following the tendon of the biceps femoris distally. It is often more distal and posterior than imagined. On the lateral side, the highest point on the lateral femoral condyle is the lateral epicondyle, which serves as the origin of the LCL. The LCL is best palpated when the hip is maximally externally rotated, and the knee is flexed to 90 degrees in the "figure-4" cross-legged stance.[290] If the LCL is followed down to the fibular head, it will be felt to blend with the biceps femoris. On the PL aspect of the condyle is the attachment for the lateral head of the gastrocnemius. Anterior to this, there is a small circular groove, which is where the tendon of the popliteus originates from the lateral condyle. Tenderness in this location, just behind the LCL, either anterior or posterior to it, would suggest damage to the popliteus muscle.[290] On the anterolateral aspect of the knee is Gerdy tubercle, the largest bony prominence medial to the apex of the fibular head, which serves as the attachment site for the ITB.

The lateral joint space is palpated starting at a point just lateral to the patellar tendon–ligament. The anterior part of the lateral meniscus is best palpated with the knee in an extended position.

Medial Aspect

The highest point of the medial aspect of the femur is the medial epicondyle, which serves as the origin for the MCL. Superior to this point is the adductor tubercle, and superior to that is the supracondylar ridge, which is the attachment for the VMO. Very localized tenderness at the medial aspect of the knee, away from the joint line, may indicate a neuroma.[365]

Special Tests

Numerous special tests exist for the knee joint complex based on the intent and diagnostic purpose.

Stress Tests

The stress tests are used to determine the integrity of the joint, ligaments, and the menisci. A complete history and physical examination can diagnose approximately 90% of ligamentous injuries. The goal of the stress tests is to identify the degree of separation and the quality or end-feel of the separation when a stress is applied in a specific direction. Intact ligaments have an abrupt and firm end-feel, whereas sprained ligaments have a soft or indistinct end-feel depending on the degree of

injury. A comparison should always be made with the uninvolved knee before a determination is made. It is important to remember that both pain and swelling can hamper the sensitivity of these tests.[368]

Serious functional instability of the knee appears to occur unpredictably. The reasons for such discrepancies are unknown, but they may be a result of[34]

- varying definitions of instability;
- varying degrees of damage to the ACL;[369,370]
- different combinations of injuries;[73]
- different mechanisms of compensation for the loss of the ACL;
- differences in rehabilitation;
- the diverse physical demands and expectations of different populations.

Valgus Stress

The patient lies in the supine position, with the involved knee extended. The clinician applies a strong valgus force, with a counterforce applied at the lateral femoral condyle (Fig. 20-25). Normally, there is little or no valgus movement in the knee, and, if present, it should be less than the amount of varus motion. Under normal conditions, the end-feel is firm. With degeneration of the medial or lateral compartments, varus and valgus motions may be increased, while the end-feels will be normal.

With the knee tested in full extension, any demonstrable instability is usually very significant. Pain with this maneuver is caused by an increase in tension of the medial collateral structures or the connection of these structures with the medial meniscus. If pain or an excessive amount of motion is detected compared with the other extremity, a hypermobility or instability should be suspected. The following structures may be implicated:

- Superficial and deep fibers of the MCL
- Posterior oblique ligament
- Posteromedial capsule
- Medial capsular ligament
- ACL
- PCL

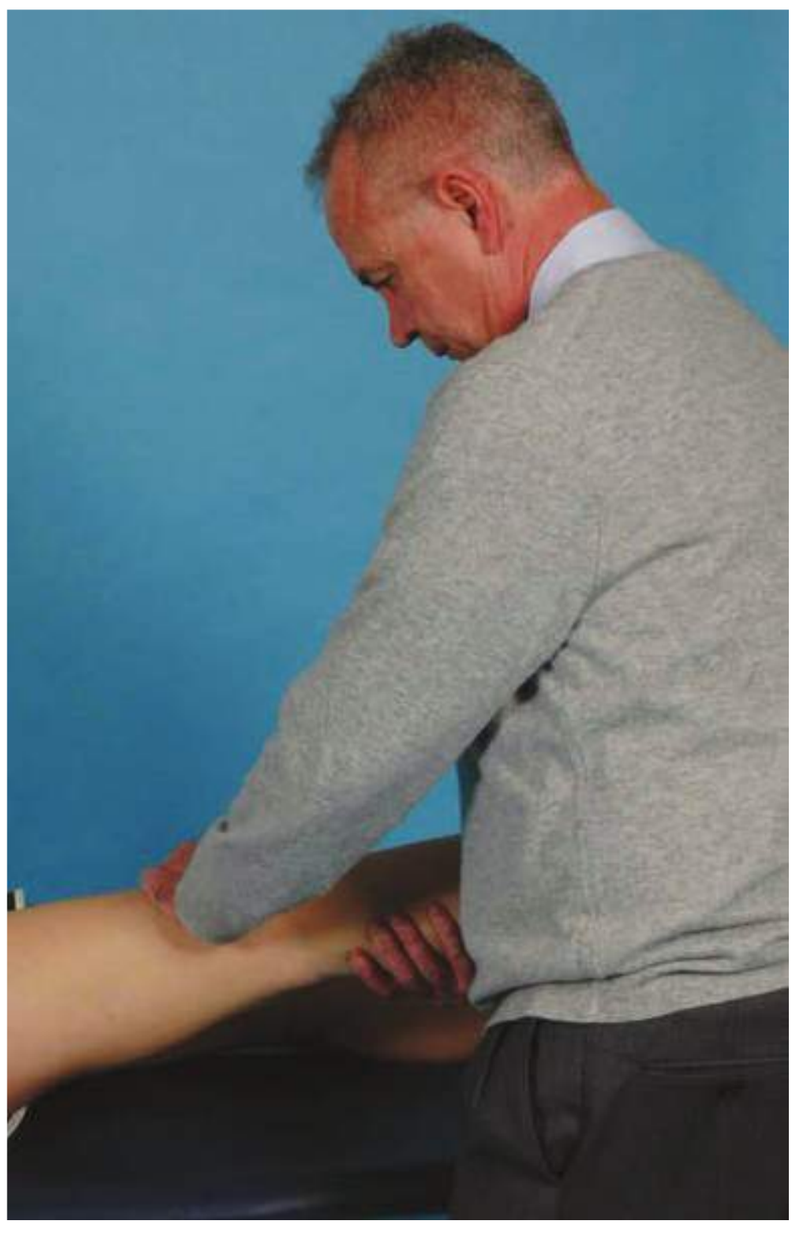

FIGURE 20-25 Valgus test.

CLINICAL PEARL

In a study by Garvin et al.[371] that looked at 23 patients with a surgically proven tear of the MCL, findings from MRI of the knee were evaluated retrospectively. MRI revealed the tear in all cases, although when the injury was severe, distinguishing high-grade partial tears from complete tears was difficult.[371] Physical examination had indicated a tear in 22 (96%) of the cases.[371] A high prevalence of associated cruciate and meniscal injuries was seen (in 23 [100%] and 12 [52%] of the cases, respectively). Tears of the LCL occurred in 13 (57%) of the patients and at least one bony infraction in 22 (96%); most of the infractions were in the lateral compartment. Infractions of the lateral femoral condyle were frequently geographic (in 14 [70%] of the 20 cases) or impacted (in 5 [25%]).[371]

To further assess the MCL, posterior oblique ligament, and PCL, the test is then repeated at 30 degrees of flexion. Hughston[56] concluded that a valgus stress test positive at 30 degrees and negative at 0 degrees indicates a tear limited to the medial compartment ligaments (posterior oblique ligament) and posterior medial capsule, whereas a valgus stress test positive at 0 degrees indicates a tear of both the PCL and the medial compartment ligaments.

The posterior fibers of the MCL can be isolated, by placing the knee in 90 degrees of flexion with the full external rotation of the tibia.[290] The femur is prevented from rotating by the clinician's shoulder. The clinician places one hand on the posterior aspect of the foot and the other on the heel, and an external rotation force is applied using the foot as a lever.

These tests can be graded by the following[64]:

- Grade I: The joint space opening is within 2 mm of the contralateral side.
- Grade II: The joint space opens 3–5 mm more than the contralateral side at 20 degrees of knee flexion and less than 2 mm more than the normal knee in full extension.
- Grade III: The joint space opens 5–10 mm more than that of the normal knee in 20 degrees of flexion and full extension.

More research is needed to evaluate the diagnostic accuracy and reliability of this test.

Varus Stress

The patient lies in the supine position, with the involved knee in near full extension. The clinician applies a strong varus force by

FIGURE 20-26 Varus test.

moving the lower leg medially, thereby gapping the lateral aspect of the knee (Fig. 20-26). To be able to assess the amount of varus movement, the clinician should repeat the maneuver several times, applying slight overpressure at the end of the ROM. Under normal conditions, the end-feel is firm, after slight movement. Unlike the valgus stress test, the varus test has been shown to be highly unreliable with many false-negative findings.[372]

Theoretically, if this test is positive for pain or excessive motion compared with the other extremity, the following structures may be implicated:

- LCL
- Lateral capsular ligament
- Arcuate–popliteus complex
- ACL
- PCL

If the instability is gross, one or both cruciate ligaments as well as, occasionally, the biceps femoris tendon and the ITB may be involved, leading to a rotary instability if not in the short term, certainly over a period of time.[154]

The test is then repeated at 10–30 degrees of flexion with the tibia in full external rotation to further assess the LCL, PL capsule, and arcuate–popliteus complex.

Grading of these injuries is the same as for MCL injuries and is based on the degree of opening of the lateral joint line.[64]

More research is needed to evaluate the diagnostic accuracy and reliability of this test.

One-Plane Anterior Instability

Ensuring the integrity of the ACL is crucial for maintaining the normal biomechanical properties of the knee joint, protecting its periarticular structures, and preventing premature OA. Knee joints with ACL deficiencies have rotary instabilities that expose supporting ligaments and menisci adjacent to the ACL to further damage and DJD.[26] Signs and symptoms of chronic rotary knee instabilities from ACL deficiencies include swelling, pain, a "giving way" of patients' knee joints, arthritis, and possible subsequent meniscal injuries.

Several tests have been advocated for testing the integrity of the ACL. Three of the more commonly used ones are the Lachman test, the anterior drawer test, and the pivot shift (see "Anterolateral Rotary Instability").

Lachman Test. Torg et al.[373] were the first to publish a description of the Lachman test, whereby the knee is held in 30 degrees of flexion while the tibia is anteriorly translated with respect to the femur (Fig. 20-27).

The accuracy and reliability of the Lachman appear to vary. Katz et al. found that in the hands of an experienced clinician,

FIGURE 20-27 Lachman test.

accuracy of this test was 81.8% sensitive and 96.8% specific,[374] increasing to 100% if the patient was anesthetized.[375,376] In contrast, Cooperman et al.[377] reported that the predictive value of a positive test was 47% for all examiners, whereas the predictive value of a negative test was 70%, results that would indicate that Lachman test judgments have limited reliability and may be more useful for predicting that a patient does not have an ACL injury than for predicting that the ACL is injured.

These discrepancies likely occur as there are a number of factors that can influence the results. These include

- an inability of the patient to relax;
- the degree of knee flexion;
- the size of the clinician's hand;
- the stabilization (and thus relaxation) of the patient's thigh.

According to Weiss et al.,[378] these factors can be minimized by the use of the modified Lachman test. In this modification, the patient lies in the supine position, with the feet resting firmly on the end of the table and the knees flexed 10–15 degrees. The clinician stabilizes the distal end of patient's femur using the thigh rather than the hand, as in the Lachman test and then attempts to displace patient's tibia anteriorly. If the tibia moves forward, and the concavity of the patellar tendon–ligament becomes convex, the test is considered positive.

The grading of knee instability is as follows[56,379,380]:

1 + (mild): 5 mm or less

2 + (moderate): 5–10 mm

3 + (serious): more than 10 mm

With this test, false-negatives can occur. False-negatives may be caused by a significant hemarthrosis, protective hamstring spasm, or tear of the posterior horn of the medial meniscus.[373]

Active Lachman Test. The patient lies in the supine position with a bolster under the distal femur so that the knee is flexed to 30–40 degrees. The patient is asked to actively extend the involved knee and then to relax back to the starting position. A positive test for a torn ACL is indicated by an anterior glide of the proximal tibia during the knee extension. The one study[381] that examined this test did not report reliability or diagnostic accuracy.

Anterior Drawer Test. The aforementioned Lachman test is a modification of the anterior drawer test.[290] The patient lies in the supine position with the clinician standing to the side of the patient's involved knee. The clinician grasps the lower leg of the patient just distal to the joint space of the knee and the patient's knee is flexed to 90 degrees so that the foot is flat, and the lower leg is not rotated. The clinician fixates the patient's leg by sitting on the foot. The clinician can place the thumbs either in the joint space or just distal to it to assess mobility. The clinician tests the tension in the musculature. It is important that all muscles around the knee be relaxed to allow any translatory movement to occur. With both hands, the clinician now abruptly pulls the lower leg forward (Fig. 20-28) VIDEO. This test is positive for an ACL tear when an abnormal anterior movement of the tibia occurs compared with the other extremity. Overall, there is wide variation in the reported sensitivities of the anterior drawer test. The anterior drawer test in 80 degrees of flexion without rotation has been found to be 40.9% sensitive and 96.8% specific.[374] This test appears to be a specific test helpful at ruling in a torn ACL when the test is positive.[373,382,383] False-negatives may occur with this test for the same reasons as those in the Lachman test. Given the low sensitivity of this test, the clinician should not rule out an acute ACL injury solely on the basis of a negative anterior drawer.

There are a number of variations to the anterior drawer test, all of which involve positioning the patient supine[290]:

- Anterior drawer test and maximal external rotation.[290] The initial positions of the patient and clinician are the same as in the anterior drawer test in 80 degrees of flexion without rotation, except that the lower leg is positioned in the maximum external rotation. For the performance, refer to the preceding description. The ACL and the medial and posteromedial capsuloligamentous structures are tested in this position. If this test is positive, there is likely to be an AM rotatory instability. The specific medial and posteromedial structures that are affected can be further differentiated by the abduction (valgus) stress tests previously described. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.
- Anterior drawer test and maximal internal rotation.[290] The initial positions of the patient and clinician are the same as in the anterior drawer test in 80 degrees of flexion without rotation, except that the lower leg is now maximally internally rotated. The performance of the test is the same as described earlier for that test. When in the maximal internal rotation, the PCL can completely restrict anterior translation of the tibia. Thus, for this test to demonstrate excessive anterior translation, the PCL, ACL, and lateral or PL capsuloligamentous structures have to be affected. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Comparison of the Lachman and Anterior Drawer Tests. The Lachman test has two advantages over the anterior drawer test in 90 degrees of knee flexion. First, all parts of the ACL are more or less equally taut. Second, in acute lesions it is often impossible to position the knee in 90 degrees of flexion because of a hemarthrosis. In a study of patients with an ACL rupture, the Lachman test was positive in 80% of nonanesthetized patients and 100% of anesthetized patients. In comparison, the anterior drawer sign was positive in 9% of nonanesthetized patients and 52% of anesthetized patients.[384]

Jonsson et al.[385] compared both the Lachman and anterior drawer tests in 45 patients with an acute ACL injury and 62 patients with a chronic knee injury. Patients were tested while nonanesthetized and anesthetized, and the diagnosis was verified by arthroscopy. The Lachman test results for the acute injury group was 87% (conscious) and 100% (anesthetized). The anterior drawer test results were 33% and 98%, respectively. The chronic injury group scored a positive Lachman test in 97% (conscious) and 99% (anesthetized). The anterior drawer test was positive in 92% and 100%, respectively.

According to Larson,[386] the Lachman test proved to be the most sensitive test for an ACL rupture. However, this article lacked statistical data to verify this assertion. Another study[376] that compared the two tests reported a sensitivity of 99% for the Lachman test and a sensitivity of 70% for the anterior drawer sign.

FIGURE 20-28 The anterior drawer test.

One-Plane Posterior Instability

The PCL is very strong and is rarely completely torn. It is typically injured in a dashboard injury or in knee flexion activities (falling on the patella). Several tests have been advocated to test the integrity of the PCL.[290]

Posterior Sag (Godfrey) Sign. The patient lies in the supine position with the knees flexed to approximately 90 degrees and the legs supported under the lower calf/heel by the clinician's arm. The clinician assesses the contour of the tibial tuberosities (Fig. 20-29). If there is a rupture (partial) of

FIGURE 20-29 Godfrey sign.

FIGURE 20-30 Posterior drawer.

the PCL, the tibial tuberosity on the involved side will be less visible than that on the noninvolved side.[387] T is discrepancy is caused by an abnormal posterior translation, resulting from a rupture of the PCL. In cases of doubt, the patient can be asked to contract the hamstrings slightly by pushing the heels into the clinician's arm. T is maneuver usually results in an increase in the posterior translation of the tibia and is often performed as a quick test of the integrity of the PCL. T is test may have some value as a screening test when negative due to its high sensitivity.[388,389]

Posterior Drawer Test. T e patient lies in the supine position, with the involved knee flexed to 90 degrees. T e clinician attempts a posterior displacement of the tibia on the femur (Fig. 20-30). In a blinded, randomized, and controlled study involving 39 patients to assess the clinical examination skills of orthopaedic surgeons with fellowship training in sports medicine, Rubinstein et al.[390] reported that the accuracy of detecting a PCL tear was 96%, with a 90% sensitivity and a 99% specificity. T e examination accuracy was higher for grades II and III posterior laxity than for grade I laxity.[390] Eighty-one percent of the time, the examiners agreed on the grade of the PCL tear for any given patient.[390]

Functional Posterior Drawer Test. T e patient lies in the prone position with the foot in neutral rotation and the knee flexed to 80–90 degrees.[391] T e patient is asked to isometrically contract the hamstrings while the clinician stabilizes the foot (Fig. 20-31). A positive result for a PCL tear is a posterior subluxation of the lateral tibial plateau.

Quadriceps Active Test. T e patient lies in the supine position, and the relaxed limb is supported with the knee flexed to 90 degrees in the drawer test position. T e patient is asked to execute a gentle quadriceps contraction to shift the tibia without extending the knee. If the PCL is ruptured, the tibia sags into posterior subluxation (~2 mm or more), and the patellar ligament is then directed anteriorly. Studies have shown significantly different sensitivities for this test. Rubinstein et al.[390] reported a sensitivity of 54% and a specificity of 97% whereas Daniel[392] reported a sensitivity of 98%.

Rotary Instabilities

Rotary or complex instabilities occur when the abnormal or pathologic movement is present in two or more planes. T e ligamentous laxities present at the knee joint in these situations allow the motion to take place around the sagittal, coronal, and horizontal axes.

Posterolateral Instability. T is type of instability is relatively rare because it requires complete posterior cruciate

FIGURE 20-31 Functional posterior drawer test.

FIGURE 20-32 Modified posterolateral drawer.

laxity. It occurs when the lateral tibial plateau subluxes posteriorly on the femur, with the axis shifting posteriorly and medially to the medial joint area. With a hyperextension test, this posterior displacement is obvious and has been labeled as the external rotation recurvatum sign.

Modified PL Drawer (Loomer) Test.[56,380] The patient lies in the supine position with the hip and knee flexed to 90 degrees, and the lower leg in external rotation (Fig. 20-32).[393] If the tibia rotates posteriorly during the test, the test is positive for PL instability, indicating that the following structures may have been injured:

- PCL
- Arcuate–popliteus complex
- LCL
- PL capsule

The one-plane medial and lateral stability tests, described earlier, can be used to further differentiate which lateral and PL structures are affected.

Dial Test. This test is used to assess abnormal external tibial rotation to help differentiate between an isolated PL corner injury and combined ACL/PCL injuries. The patient lies in the supine position with the knee flexed to 30 degrees over the edge of the table.[15] The clinician applies an external rotation force to the patient foot by placing the fingers and thumb alongside the talocalcaneal bone contours (Fig. 20-33). The foot–thigh angle is measured and compared with the uninjured knee. The test is then performed with 90 degrees of knee flexion and the foot–thigh angle is remeasured. When comparing the two angles, a difference of 10 degrees or more is significant. As the knee is flexed to 90 degrees, a reduction in increased rotation may occur although the amount of motion remains greater than the uninjured side if the PCL is still intact. This increased rotation occurs because the PCL is a secondary stabilizer to external rotation and gains mechanical advantage when the knee is flexed.[394]

Posteromedial Displacement with Valgus Stress Test. The patient lies in the supine position, with the involved leg slightly flexed.[393] The clinician pushes the lower leg posteriorly into hyperextension while applying a valgus stress (Fig. 20-34). If the tibia sags posteriorly during the test, the

FIGURE 20-33 Dial test.

test is positive for posteromedial instability, indicating that the following structures may have been injured:

- PCL
- Posterior oblique ligament
- MCL
- Posteromedial capsule
- ACL

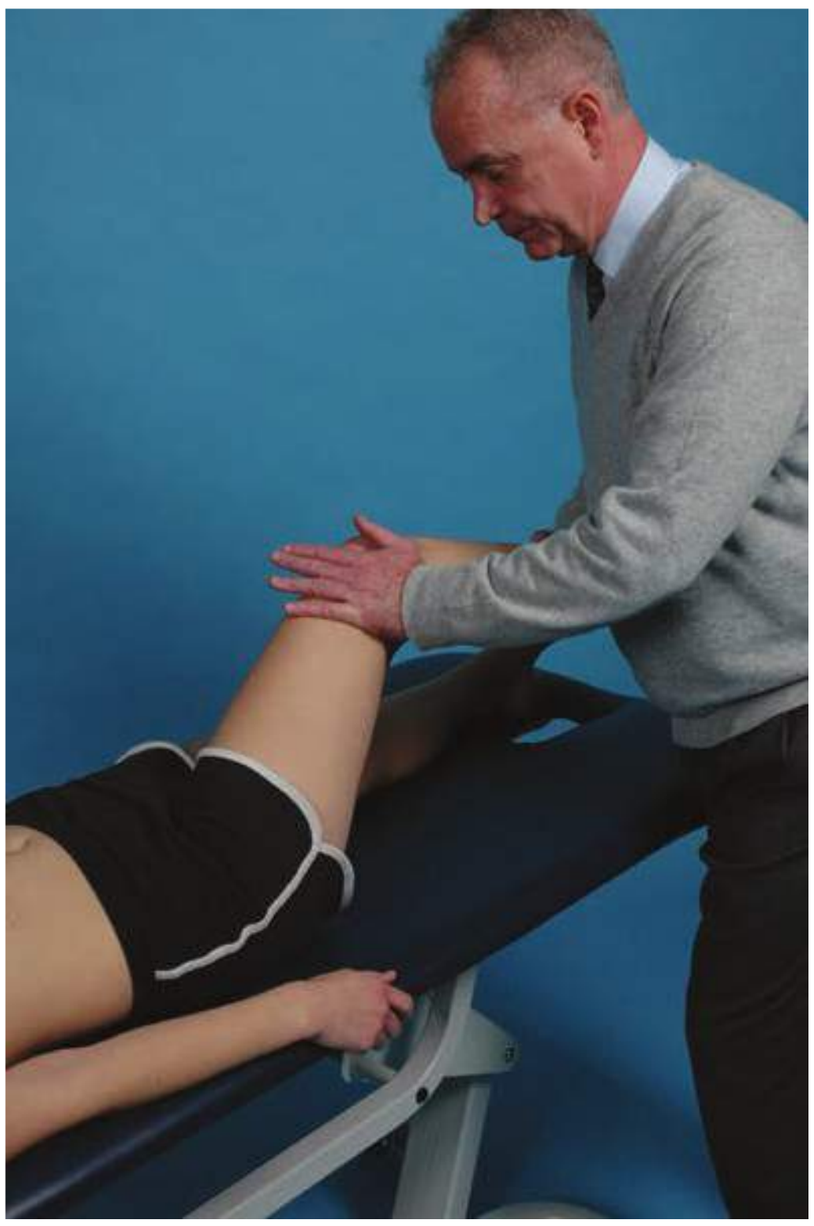

FIGURE 20-34 Posteromedial displacement with valgus stress test.

The one-plane medial and lateral stability tests, described earlier, can be used to further differentiate which medial and posteromedial structures are affected.

Anterolateral Rotary Instability. This type of instability almost certainly involves the ACL. Clinically, the instability allows the medial tibial condyle to sublux posteriorly because the axis of motion has moved to the lateral joint compartment.[154]

The diagnosis of anterolateral instability is based on the demonstration of a forward subluxation of the lateral tibial plateau as the knee approaches extension and the spontaneous reduction of the subluxation during flexion, in the lateral pivot-shift test.[154] This form of instability usually occurs when the individual is either decelerating or changing direction, and the sudden shift of the lateral compartment is experienced as a "giving way" phenomenon, often associated with pain.[154]

Pivot-Shift Test

This test was first described by Galway et al.[395] in 1972 and has been described since by a number of authors.[396–399]

The pivot shift is the anterior subluxation of the lateral tibial plateau that occurs when the lower leg is stabilized in (almost) full extension, whereby further flexion produces a palpable spring-like reduction.[400] The pivot shift is the most widely recognized dynamic instability of the knee, and it has been shown to correlate with reduced sports activity,[401] degeneration of the cartilage,[402,403] reinjuries, meniscal damage,[404] joint arthritis,[404] and a history of instability symptoms.[405,406]

Since the majority of patients with an ACL rupture complain of a "giving way" sensation, the pivot-shift test is regarded in current literature as capable of identifying rotational instability.[396,397,399]

The patient lies in the supine position with the clinician standing to the side of the patient's involved knee. There are two main types of clinical tests to determine the presence of the pivot shift: the reduction test and the subluxation test.

- Reduction test. The clinician stabilizes the patient's lower leg and flexes the knee to 90 degrees with one hand while using the palm of the same hand to medially rotate the tibia, effectively subluxing the lateral tibial plateau (Fig. 20-35).[406] A sudden reduction of the anteriorly subluxed lateral tibial plateau is seen as the pivot shift.[395]

FIGURE 20-35 Pivot-shift test—reduction.

FIGURE 20-36 Pivot-shift test—subluxation.

- Subluxation test. This test is effectively the reverse of the reduction test.[56] The test begins with patient's knees flexed. The clinician internally rotates the patient's tibia with one hand and applies a valgus stress to the knee joint with the other hand (Fig. 20-36). The clinician slowly extends the knee, maintaining rotation of the tibia. As the patient's knee reaches full extension, the tibial plateau will be felt to relocate. However, only 35–75% of patients whose knees pivot while the patient is under anesthesia will experience such a pivot when awake.[376,407–409]

Although the specificity of the pivot-shift test is very high, namely 98% (95% CI, 25–38), there is little agreement in the literature with regard to the sensitivity of the test, which varies between 0% and 98%.[376,384,410] However, in a meta-analysis that looked at 28 studies to assess the accuracy of clinical tests for diagnosing ACL ruptures, Benjaminse et al.[411] found the pivot-shift test to be very specific both in acute as well as in chronic conditions, and recommended that both the Lachman and pivot-shift tests be performed in all cases of suspected ACL injury.

It is worth noting that the pivot-shift test can be positive for an isolated ACL injury,[376,412] or a tear or stretching of the lateral capsule,[398,413] although an injury to the MCL reduces the likelihood of a pivot shift even with ACL injury.[376,414]

Patellar Stability Tests

Patellar stability is assessed by gently pushing the patella medially and laterally while the knee is in a position of 90 degrees of flexion. This is position is used because it places all of the retinacula on a stretch. If this test is positive for laxity, further testing is performed by applying medial and lateral patellar glides, tilts, and rotations, with the knee in relaxed extension, and noting any limitations of motion or excessive excursion (Table 20-8).[282]

- Glide. The glide component determines the amount of lateral deviation of the patella in the frontal plane. A 5-mm lateral displacement of the patella causes a 50% decrease in VMO tension.[415] In the normal knee when fully extended and relaxed, the patella can be passively displaced medially and laterally approximately 1 cm in each direction, or approximately one-third of the width of

TABLE 20-8 Assessing the Tilt, Orientation, and Glide of the Patella

Test and Measure	Procedure and Determination of Positive Finding	Population	Reliability Kappa Values
Superoinferior tilt[a]	Clinician visually estimates patellar alignment while palpating superior and inferior patellar poles Patellar orientation graded according to an ordinal scale extending from −2 to +2, with −2 representing inferior patellar pole below superior pole, and +2 representing inferior patellar pole above superior pole	27 asymptomatic subjects	Intraexaminer κ = 0.50 Interexaminer κ = 0 30
Anterior tilt[b]	Clinician palpates inferior patellar pole If the clinician can palpate inferior pole, no anterior tilt exists; if downward pressure on superior pole is required to palpate inferior pole, it is considered to have an anterior tilt	66 patients referred to physical therapy who would normally undergo evaluation of patellofemoral alignment	Interexaminer κ = 0.24
Anterior/posterior tilt component[c]	Clinician palpates inferior and superior patellar poles Scored 0, 1, or 2: 0 if inferior patellar pole is as easily palpable as superior pole; 1 if inferior patellar pole is not as easily palpable and superior pole; 2 if inferior pole is not clearly palpable compared with superior pole	56 subjects, 25 had symptomatic knees	Intraexaminer κ = 0.03–0.23 Interexaminer κ = 0.04
Rotation[a]	Clinician positions index fingers along longitudinal axes of patella and estimates acute angle formed Graded according to ordinal scale extending from −2 to +2: −2 indicates that longitudinal axis of patella is more lateral than axis of femur; +2 indicates that patella is more medial than axis of femur	27 asymptomatic subjects	Intraexaminer κ = 0.41 Interexaminer κ = −0.03
Patellar rotation[b]	Clinician determines relationship between longitudinal axis of patella and femur Longitudinal axis of patellar should be in line with ASIS; if distal end of patella is medial, it is considered to be medially rotated; if distal end is lateral, it is considered to be laterally rotated	66 patients referred to physical therapy who would normally undergo evaluation of patellofemoral alignment	Interexaminer κ = 0.36
Patellar rotation component[c]	Clinician determines relationship between longitudinal axis of patella and femur ccored as −1, 0, or + 1: 0 when patellar long axis is parallel to long axis of femur; 1 when inferior patellar pole is lateral to axis of femur and classified as lateral patellar rotation; −1 when inferior pole is medial to axis of femur and classified as medial patellar rotation		Intraexaminer κ = −0.06 to 0.00 Interexaminer κ = −0.03
Mediolateral tilt[a]	Clinician estimates patellar alignment while palpating medial and lateral aspects of patella Patellar orientation graded according to an ordinal scale extending from −2 to +2 with −2 representing a lateral tilt, 0 no appreciable tilt, and +2 a medial tilt	27 asymptomatic subjects	Intraexaminer κ = 0.57 Interexaminer κ = 0.18
Medial/lateral tilt[b]	Clinician palpates medial and lateral borders of patella with thumb and index finger If digit palpating the medial border is higher than that palpating the lateral border, then the patella is considered laterally tilted; if digit palpating the lateral border is higher than that palpating the medial patella, then the patella is medially tilted	66 patients referred to physical therapy who would normally undergo an evaluation of patellofemoral alignment	Intraexaminer κ = 0.28–0.33 Interexaminer κ = 0.21
Medial/lateral tilt[c]	Clinician attempts to palpate posterior surface of medial and lateral patella borders Scored 0, 1, or 2: 0 if clinician palpates posterior border on both medial and lateral sides; 1 if >50% of lateral border can be palpated but posterior surface cannot; 2 if <50% of lateral border can be palpated	56 subjects, 25 had symptomatic knees	Intraexaminer κ = 0.44–0.50 Interexaminer κ = 0.19

TABLE 20-8 Assessing the Tilt, Orientation, and Glide of the Patella (Continued)

Test and Measure	Procedure and Determination of Positive Finding	Population	Reliability Kappa Values
Patellar tilt test[c]	Clinician lifts lateral edge of patella from lateral femoral epicondyle Graded as having positive, neutral, or negative angle with respect to horizontal plane	99 knees, of which 26 were symptomatic	Interexaminer κ = 0.20–0.35
Mediolateral position[a]	Clinician visually estimates patellar alignment while palpating sides of lateral epicondyles with index fingers, and patella midline with thumbs Patellar orientation graded according to an ordinal scale extending from −2 to +2 with −2 representing a lateral displacement, 0 no appreciable displacement, and +2 a medial displacement	27 asymptomatic subjects	Intraexaminer κ = 0.40 Interexaminer κ = 0.03
Mediolateral orientation[d]	With knee supported in 20 degrees of flexion, the clinician identifies medial and lateral epicondyles of femur and midline of patella. Clinician then marks medial and lateral epicondyles and patellar midline with tape Distances between patellar midline and medial and lateral condyles are measured	20 healthy physiotherapy students	Interexaminer Medial distance: ICC = 0.91 Lateral distance: ICC = 0.94
Medial/lateral displacement[b]	Clinician palpates medial and lateral epicondyles with index fingers while simultaneously palpating midline of patella with thumbs Distance between index fingers and thumbs should be the same; when distance to index finger palpating lateral epicondyles is less, patella is laterally displaced; when distance to index finger palpating medial epicondyles is less, patella is medially displaced	66 patients referred to physical therapy who would normally undergo evaluation of patellofemoral alignment	Interexaminer κ = 0.10
Medial/lateral glide[c]	Clinician uses a tape measure to record distance from medial and lateral femoral condyles to mid-patella Scored 0 or 1: 0 if distance from medial epicondyle to mid-patella equals distance from lateral epicondyle to mid-patella; 1 if distance from medial epicondyle to mid-patella is 0.5 cm greater than that from lateral condyle to mid-patella	56 subjects, 25 had symptomatic knees	Intraexaminer κ = 0.11–0.35 Interexaminer κ = 0.02

[c]Data from Watson CJ, Propps M, Galt W, et al. Reliability of McConnell's classification of patellar orientation in symptomatic and asymptomatic subjects. J Orthop Sports Phys Ther. 1999;29:378–385; discussion 386–393.

[d]Data from Herrington LC. The Inter-tester reliability of a clinical measurement used to determine the medial-lateral orientation of the patella. Man Ther. 2002;7:163–167.

the patella.[194] Displacement of more than half the patella over the medial or lateral aspect is considered abnormal.[124] If the patient is apprehensive as the glide maneuver is being performed; the problem is likely to be one of poor patellar engagement. A decreased medial glide of the patella has been found to be related to ITB and/or lateral retinaculum tightness.[126]

- Tilt. The degree of patellar tilt is assessed by comparing the height of the medial patellar border with the height of the lateral border, which helps to determine the degree of tightness in the deep retinacular fibers. A slight lateral tilt of the patella is normal. An increased medial tilt results from a tight lateral retinaculum. If the passive lateral structures are too tight, the patella will tilt so that the medial border is higher than the lateral border (lateral tilt), making the posterior edge of the lateral border difficult to palpate.[282] A posterior tilt results in fat pad irritation.
- Rotation. The rotation component determines whether there is any deviation of the long axis of the patella from the long axis of the femur. If the inferior pole is sitting lateral to the long axis of the femur, the patient has an externally rotated patella, whereas if the inferior pole is sitting medial to the long axis, the patient has an internally rotated patella.

If the patient has one or more of these components present, the clinician needs to determine which of them, if any, is abnormal.

The moving patellar apprehension test can be used to assess lateral patellar stability. The patient is positioned in supine with the thigh supported and the leg hanging over the edge of the table. This is a two-part test. The clinician moves the knee from full extension into flexion while simultaneously translating the patella laterally as far as possible in the first part. In part two, the clinician flexes the knee to 90 degrees and subsequently returns the knee to full extension while applying a medial force to the patella. A positive test is indicated if the patient expresses apprehension and/or activates the quadriceps with flexion and lateral translation of the patella during the first part of the test while also experiencing no discomfort during the second part of the test. The moving patella apprehension test for lateral patellar instability has a sensitivity of 100% and specificity of 88.4%.[416]

Another test that can be used to help in the diagnosis of patellar instability is the Bassett sign,[417] which is positive if there is tenderness to palpation over the medial femoral epicondyle (at the medial patellofemoral ligament attachment site) with knee at full extension and the patellar tendon relaxed, which becomes nontender with the knee in flexion and the patellar tendon taut.

Meniscal Lesion Tests

McMurray Test

The McMurray test was originally developed to diagnose posterior horn lesions of the medial meniscus. The patient lies in the supine position, and the clinician, standing on the same side as the involved knee, maximally flexes the hip and knee. This is accomplished by grasping the patient's foot in such a way that the thumb is lateral, the index and middle fingers are medial, and the ring and little fingers hold the medial edge of the foot (Fig. 20-37). The thumb of one hand is placed against the lateral aspect of the patient's knee (Fig. 20-37). To test the medial meniscus, the clinician rotates the tibia into external rotation, then slowly extends the knee. To test the lateral meniscus, the clinician flexes the knee again but now internally rotates the patient's tibia and then slowly extends the knee. A positive test traditionally is indicated by an audible or palpable thud or click. In a study by Dervin et al.[418] to determine clinicians' accuracy and reliability for the clinical diagnosis of unstable meniscus tears in patients with symptomatic OA of the knee, a positive McMurray test was the only positive predictor of an unstable meniscal tear.[418]

Numerous variations exist for the McMurray test, including the addition of varus/valgus stresses. An examination of the variation seemed to indicate that the McMurray test has some value as a specific test where a positive test would rule in the disease.

Apley Test[419]

The patient is placed in the prone position, with the knee flexed to 90 degrees. The patient's thigh is stabilized by the clinician's knee. The clinician grasps the patient's foot with one hand, distracts the tibia, and rotates the tibia internally and externally, noting whether or not pain is reproduced. A positive test is indicated by worse pain with rotation and is indicative of a rotation sprain of soft tissue. The clinician

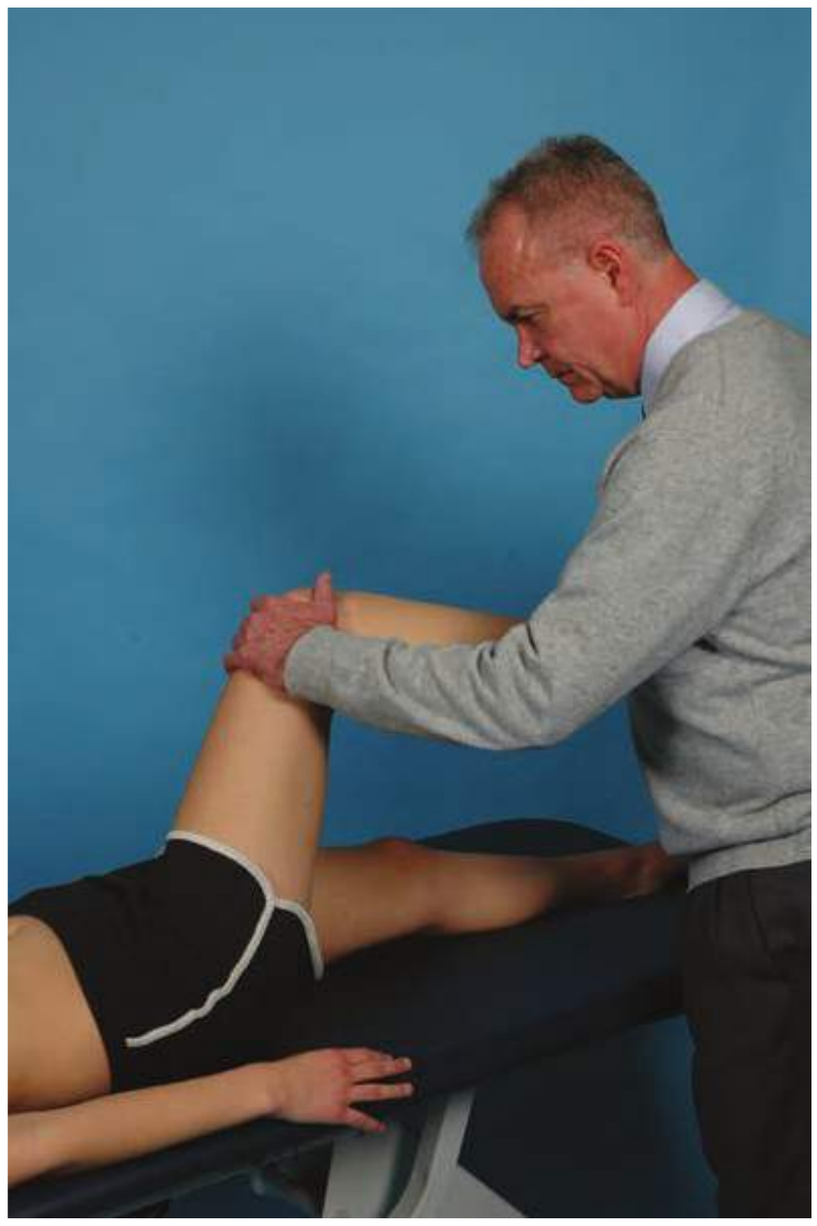

FIGURE 20-37 McMurray test.

then applies internal and external rotation with compression to the lower leg, noting any pain and the quality of motion (Fig. 20-38). A positive test for a meniscus tear is indicated by more pain in compression than a distraction. It would appear from a number of studies that the Apley test can be used as a specific test to rule in a meniscus tear when positive.

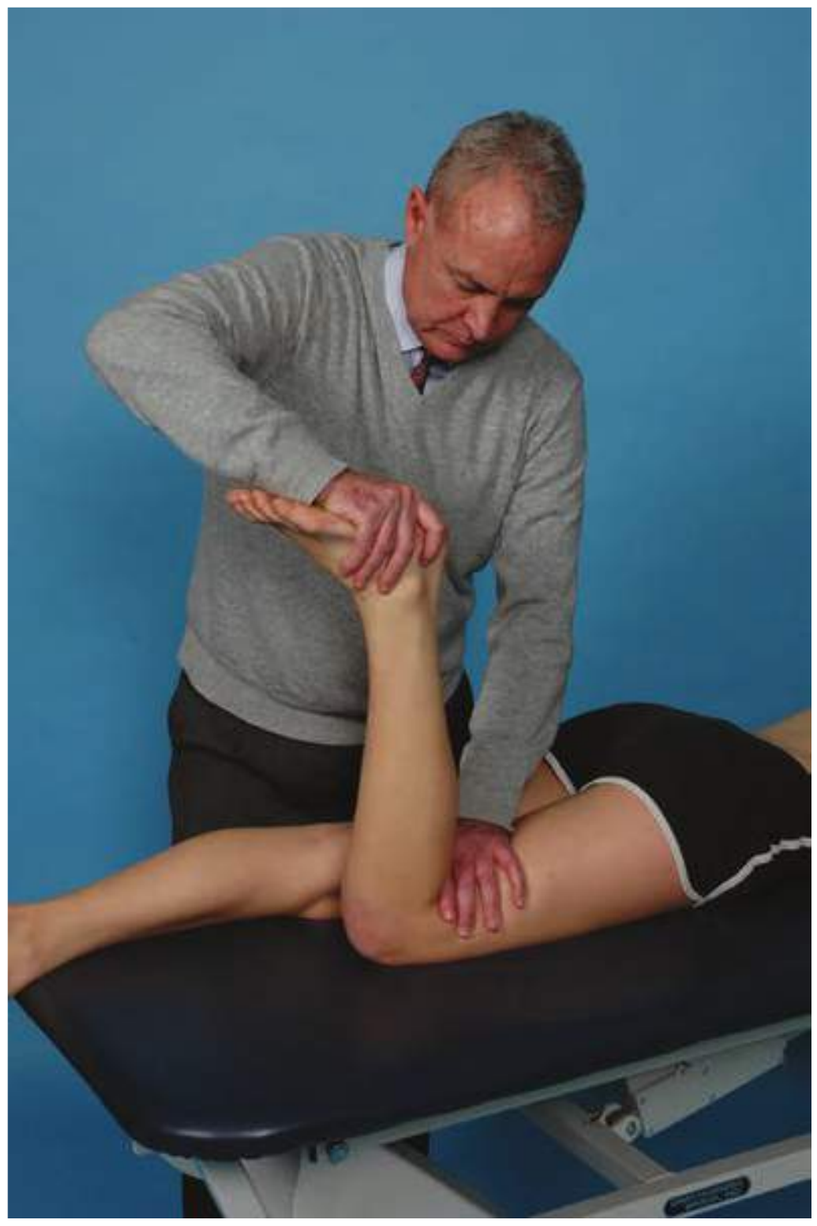

FIGURE 20-38 Apley grind test.

FIGURE 20-39 Steinmann I sign.

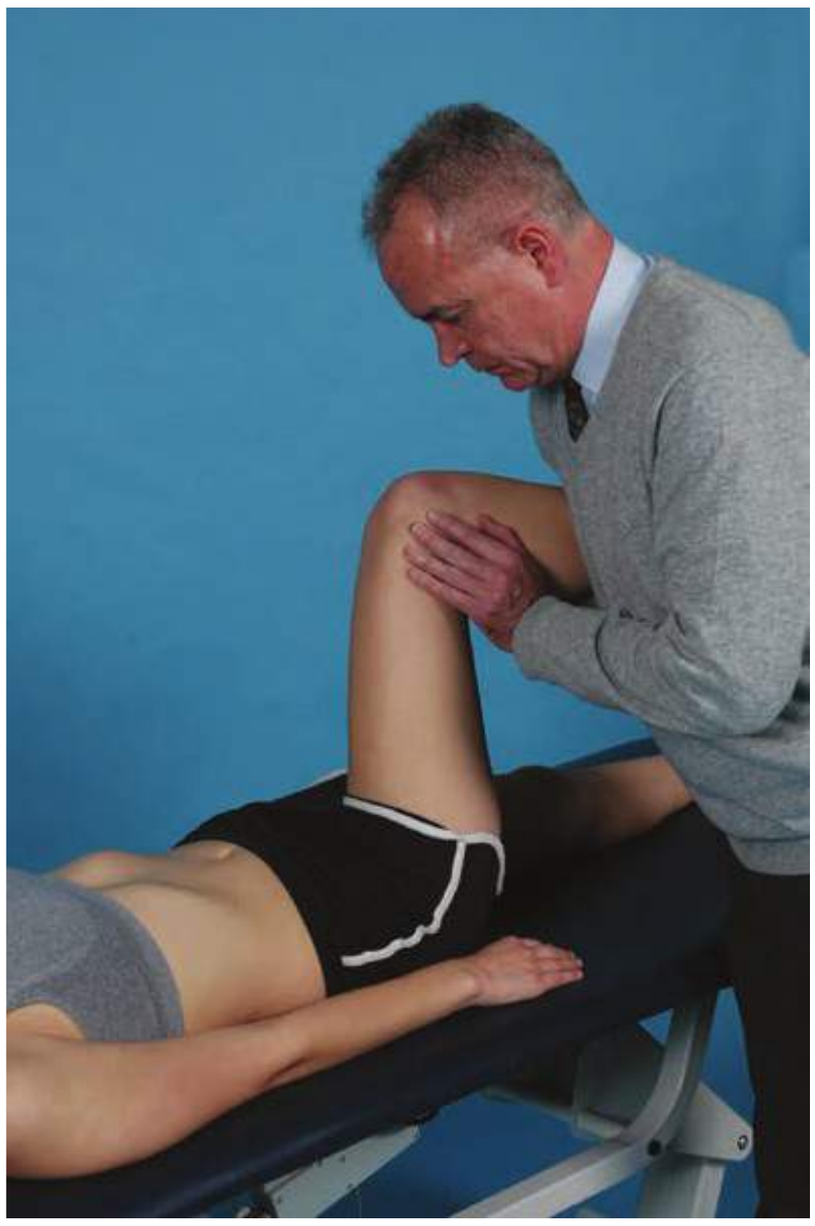

FIGURE 20-40 Anderson mediolateral grind test.

Steinmann Sign[290]

Steinmann test can be used to diagnose meniscal lesions. T e patient is placed in the supine position while the clinician stands to the side. Using one hand, the clinician grasps the patient's lower leg. T e other hand grasps the lateral side of the patient's lower leg as proximal to the knee as possible while also palpating the medial joint space with the fingers (Fig. 20-39). T e knee is extended, and the joint line between the patellar tendon and the MCL is palpated. After the painful site is located with the fingers, pressure against this site is maintained while the knee is flexed. After several degrees of motion, the pain disappears, and the painful site can sometimes again be palpated more posteriorly in the joint space. If the most painful site is found in the joint space at the level of the MCL, the test is less reliable, because both the medial meniscus and the ligament move posteriorly during flexion.

Anderson Mediolateral Grind Test

T e Anderson mediolateral grind test[420] can be used to detect meniscal lesions. T e patient is placed in the supine position, and the clinician grasps the involved leg between the trunk and arm. T e clinician places the index finger and thumb of the other hand over the anterior knee joint line. With the patient's knee flexed at 45 degrees, a valgus stress is applied as the knee is simultaneously slightly flexed (Fig. 20-40), followed by a varus component while the knee is extended, producing a circular motion of the knee. T e maneuver is repeated, increasing the valgus and varus stresses with each rotation.

In one study[420] that examined 100 knees with the Anderson mediolateral grind test, as well as arthroscopy, the test was found to have a sensitivity of 70% and a specificity of 67%. However, further research needs to be performed to corroborate the statistics reported in this study.

Bounce Home Test

T e patient is placed in the supine position, and the clinician extends the involved knee to end range (Fig. 20-41). A positive test for a meniscus tear is indicated by a block preventing full extension, or pain at the end range of extension. A number of studies indicate that neither pain at full extension nor an extension block seems to indicate a torn meniscus.[418,421,422]

Figure-4 Test

T is test was developed to detect popliteomeniscal fascicle tears, which create instability of the lateral meniscus. T e patient lies in the supine position and is asked to place the

FIGURE 20-41 Bounce home test.

FIGURE 20-42 Figure-4 test.

foot of the involved knee by the contralateral knee, forming a figure 4 (Fig. 20-42). The clinician pushes the involved knee toward the bed. A positive test is indicated by pain over the lateral joint line at the popliteal hiatus. In a very small study[423] involving only six patients, the test demonstrated a sensitivity of 100%. Further research is necessary before diagnostic conclusions can be made from this test.

Payr Sign

The patient is placed in the supine position or sits and places the foot of the involved knee on the medial aspect of the contralateral knee, forming a figure 4. The clinician pushes the involved knee toward the floor (Fig. 20-43). A positive test for a posterior horn lesion of the medial meniscus is indicated by reproduction of the patient's pain over the medial joint line. In a study by Jerosch and Riemer,[424] this test was found to have a sensitivity of 54% and a specificity of 44%, demonstrating a diagnostic value similar to that of a coin toss.

Thessaly Test

The Thessaly test[425] was introduced in 2005 as a potentially useful clinical test to detect meniscal tears. In contrast to the other meniscal tests, the Thessaly test is performed in a loaded, WB position with the knee at 20 degrees of flexion. To perform the test, the patient is asked to stand on the uninvolved leg, using the clinician for balance. The patient is then asked to flex the knee to 20 degrees and to internally rotate and externally rotate the femur on the tibia three times while maintaining the 20 degrees of knee flexion. The test is then repeated with the patient standing on the involved leg. The test is considered positive for a meniscus tear if the patient experiences medial or lateral joint line discomfort, or a sense of locking or catching in the knee during the test. In a diagnostic accuracy study by Goossens et al.[426], the results of the Thessaly test alone or combined with the McMurray test did not seem useful to determine the presence or absence of meniscal tears, despite the original study finding high sensitivity and specificity for both medial (sensitivity 89%; specificity, 97%) and lateral (sensitivity, 92%; specificity, 96%) menisci.[425]

FIGURE 20-43 Payr sign.

Other Special Tests

The remaining special tests for the knee joint complex are dependent on the clinician's needs, the structure of each joint, and the subjective complaints (Table 20-9). These tests are only performed if there is some indication that they would by helpful in arriving at a diagnosis. The special tests help confirm or implicate a particular structure and may also provide information as to the degree of tissue damage.

Plical Irritation

Plical irritation has a characteristic pattern of presentation. The anterior pain in the knee is episodic and associated with painful clicking, "giving way," and the feeling of something catching in the knee. Careful palpation of the patellar retinaculum and fat pad, with the knee extended and then flexed, can be used to detect tender plicae and to differentiate tenderness within the fat pad from tenderness over the anterior horn of the menisci.

- Medial plica test. This test can also be used to detect plical irritation. Using the heel of the cranial hand, the clinician pushes the patella medially and maintains it there (Fig. 20-44). While the patella is maintained in this position, the clinician flexes the patient's knee and internally rotates the tibia with the other hand. The knee is then extended from the flexed position while the clinician palpates for any clunks.
- Medial plica shelf test. The patient lies in the supine position on the bed, with the knee supported in about 30 degrees of flexion by either a bolster or the clinician's thigh. The clinician places both thumbs together at the lateral aspect of the patella and pushes the patella medially (Fig. 20-45). If a painful click is elicited during this test, there is likely to be a symptomatic mediopatellar synovial plica.

Suprapatellar or Infrapatellar Tendinopathy

The patient is placed in the supine position, with the lower extremity extended.

- Infrapatellar test. The clinician pushes down on the suprapatellar aspect, palpates under the inferior pole of the patella, and checks for tenderness, which may indicate infrapatellar tendinopathy.

TABLE 20-9 Subjective Complaint, Potential Diagnosis, and Confirmatory Test

Subjective Complaint	Potential Diagnosis	Confirmatory Test(s)
My knee hurts when I get up from a chair or go up steps	Patellofemoral dysfunction	Patellofemoral grind test
My knee gives out when I step down from the curb	Subluxation/dislocation of the patella	Patella apprehension test
My knee locks	1. Torn medial meniscus 2. Loose body within the knee joint	McMurray test and Apley grinding and distraction tests
My knee feels swollen and tight	Fluid within the knee	Patellar effusion tests
My knee buckles; it gives out	1. Unstable knee joint (torn collateral or cruciate ligament) 2. Torn medial meniscus	Valgus and varus stress tests, anterior drawer, Lachman, posterior sag, strength testing (neuro screen), meniscus tests
I cannot straighten my knee out	1. Fluid in the knee 2. Torn meniscus	Meniscus tests, patellar ballottement test, bounce home test
I have pain on the inside of my leg	1. Torn medial collateral ligament 2. Bursitis, pes anserinus bursa	Valgus stress test Palpation of the pes anserinus bursa
I made a quick turn while playing sports while my foot was planted, and my leg suddenly collapsed and the knee became swollen	Torn medial meniscus	Apley test and McMurray test
I have bow legs and they hurt	1. Osteoarthritis 2. Ligamentous instability	Range of motion (capsular) Patellofemoral grinding test Ligament stability tests
I have swelling in the back of my knee	Popliteal cyst	Palpation of popliteal fossa
I landed heavily on the front of my knee and it hurts	1. Patellar fracture 2. Chondromalacia 3. Fat pad syndrome 4. Prepatellar bursitis 5. Infrapatellar bursitis	Radiograph and palpation
I cannot move my knee in any direction without pain	Infected knee joint	Joint aspiration

Data from Hoppenfeld S. Physical examination of the knee joint by complaint. Orthop Clin North Am 10:3–20, 1979.

- Suprapatellar test. The clinician pushes on the infrapatellar aspect of the patella, palpates under the superior pole of the patella, and checks for tenderness, which may indicate suprapatellar tendinopathy.

Integrity of Patellofemoral Articulating Surfaces

These tests involve the application of manual compression to the patella in an attempt to elicit pain.

Zohler Sign

The patient is placed in the supine position, with the knee extended and resting on the table. The clinician pulls the patient's patella in a distal direction. While continuing to exert pressure in a distal direction, the clinician instructs the patient to contract the quadriceps muscle (Fig. 20-46). If this test is painful, there is likely to be a symptomatic patellar chondromalacia, although this test may be positive in a large proportion of asymptomatic individuals. One study[387] to examine this test did not record reliability or diagnostic accuracy.

Clarke Test

This test is similar to Zohler test, except that the clinician applies an increasing compressive force to the base of the patella while the patient actively contracts the quadriceps. Like Zohler test, this test may be positive in a large proportion of asymptomatic individuals.

Waldron Test

See "Patella Motion Tests".

Patellar Mobility and Retinaculum Tests

Patellar glides can be used to examine retinacular mobility. The patella should be able to translate at least 33% of its width both medially and laterally. Inability to do this indicates tightness of the retinacula. Hypermobility of the patella is demonstrated if the patella can be translated 100% of its width medially or laterally.

The lateral retinaculum is assessed by way of a patellar tilt and a mediolateral displacement (glide).[196,427–430] A number of

FIGURE 20-44 Medial plica test.

patient positions can be used to assess the flexibility of the retinacular tissue.

- Medial shift.[290] The patient is supine, with the knee extended. The clinician places both thumbs together at the lateral aspect of the patella and pushes the patella medially. The amount of motion and the end-feel are assessed. Often the patella is found to have less ROM medially than laterally. Whether this condition is pathologic is best determined by comparison to the noninvolved side. This is patellar movement often is limited after surgery and after immobilization.
- Lateral shift. The patient is supine, with the knee extended. The clinician places the fingertips of both hands against the medial aspect of the patella and pushes the patella laterally. The amount of motion and the end-feel are assessed. Usually, the patella has more ROM laterally than medially. When there are instabilities of the patella, the lateral mobility is usually abnormally increased. This is patellar movement often is limited after surgery and after immobilization.
- Distal shift. The patient is supine, with the knee extended. With the thenar and hypothenar eminences placed against the base of the patient's patella, the clinician pushes the patella in a distal direction. As with the previous two shift tests, the amount of motion and end-feel are assessed. The motion usually is limited in instances of patella alta (a high position of the patella), after surgery, and after immobilization.
- Prone technique. The clinician passively flexes the patient's knee to 90 degrees and internally rotates the tibia. The lower extremity is then moved into hip adduction. The test is positive for tightness of the lateral structures if the hip cannot be fully adducted. This is test also can be performed in the side-lying position, with the involved side uppermost.
- Lateral tilt of the patella. The patient lies in the supine position, with the knee extended and relaxed. The clinician attempts to lift the lateral border of the patella. An inability to lift the lateral border of the patella above the horizontal plane is an indication of a tightness of the lateral retinaculum.
- Side-lying technique.[282] With the knee of the uppermost leg flexed to 20 degrees, the patella is moved in a medial direction toward the treatment table. The clinician should be able to expose the lateral femoral condyle unless the tissues of the superficial lateral retinacula are tight. To test the deep fibers, the clinician places a hand on the middle of the patella, takes up the slack of the glide, and applies an anteroposterior pressure on the medial border of the patella. The lateral femoral condyle should move freely away from the femur. This is test also can be used as an intervention technique.[282]

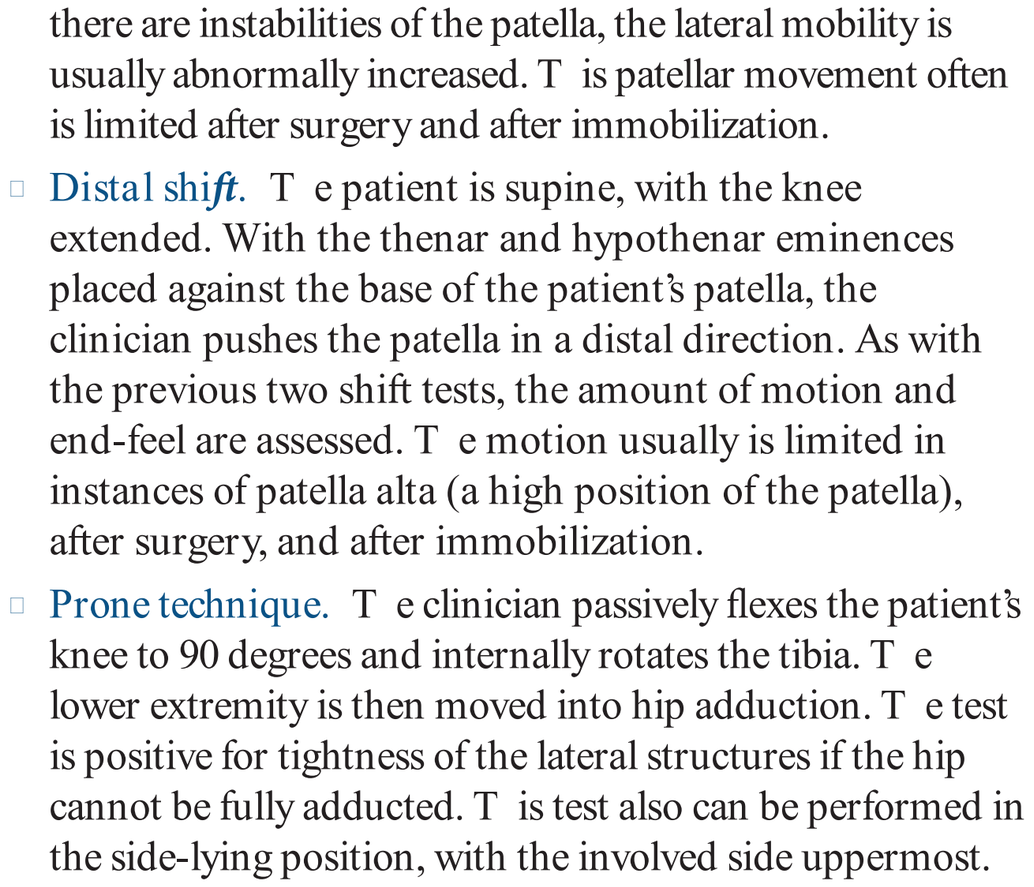

FIGURE 20-46 Zohler sign.

FIGURE 20-45 Medial plica shelf test.

Fairbank's Apprehension Test for Patellar Instability

The Fairbank test[431] is best performed with the patient in the supine position, and the patient's leg supported at approximately 30 degrees of knee flexion. The clinician places both

thumbs on the medial aspect of the patella and applies a laterally directed force to the medial aspect of the patella, attempting to sublux it laterally while applying a small amount of passive flexion to the knee.[214] This test appears to be more specific than sensitive, meaning a positive test would help rule in patellofemoral instability.[362,431]

Wilson Sign for Osteochondritis Dissecans

The following accessory test, which measures the pain produced by extending the knee while internally rotating the tibia, has been recommended when osteochondritis dissecans of the knee (see Chapter 30) is suspected. However, this test is no longer considered a reliable or specific test,[432] and is merely included here for completeness.

The patient is supine. The clinician flexes the patient's hip and knee to 90 degrees. Axial compression is exerted on the knee by pushing proximally, in line with the tibia, with the distal hand. The lower leg is held in internal rotation as the knee is slowly extended, maintaining the axial compression. In many cases of osteochondritis dissecans, the patient experiences pain between 90 degrees and 30 degrees of flexion because the pressure on the medial cartilaginous surfaces is increased significantly with this maneuver. If this pain it is alleviated by externally rotating the lower leg, the test is said to be positive.

Hamstring Flexibility

The popliteal angle is the most popular method reported in the literature for assessing hamstring tightness, especially in the presence of a knee flexion contracture.[433] The patient is placed in the supine position and the opposite hip is extended. The popliteal angle is determined by measuring the angle that the tibia subtends with the extended line of the femur when the ipsilateral hip is flexed to 90 degrees and the knee of the limb under examination is maximally passively extended to initial tissue resistance.[434] The popliteal angle is at the maximum of 180 degrees from birth to age 2 years.[433] This angle then decreases to an average of 155 degrees by age 6 years and remains steady thereafter.[433] An angle less than 125 degrees suggests significant hamstring tightness.[433]

Hamstring flexibility can also be assessed with a passive straight leg raise while ensuring that the lumbar spine is flattened on the treatment table, and the pelvis is stabilized. However, this method may be used only if full extension is available in the knee of the leg being examined. Normal hamstring length should allow 80–85 degrees of hip flexion when the knee is extended, and the lumbar spine is flattened.[282]

ITB Flexibility

The cardinal sign of iliotibial contracture is the presence in a supine patient of an abduction contracture when the hip and knee are extended, which is eliminated when the hip and knee are flexed.[435] Other tests include the following:

Retinacula Test. The patient is placed in the side-lying position, and the knee is fully flexed. This position tightens the ITB. The clinician applies a medial and oblique force to the patella with the thumbs. Approximately 0.5–1 cm of patella motion should be available.

Ober Test. The Ober test for ITB length is described in Chapter 19.

Quadriceps Flexibility. Quadriceps flexibility is examined by placing the patient in the prone position and passively flexing the knee, bringing the heel toward the buttocks. The lumbar spine is monitored and stabilized if necessary to prevent motion. The heel should touch the buttocks. An adaptively shortened rectus femoris is usually the structure that prevents this motion (see later discussion).

Functional Tests

Functional outcome following knee injury must consider the patient's perspective and not just objective measurements of instability. Functional motion requirements of the knee vary according to the specific task. In normal level ground walking, 60–70 degrees of knee flexion is required. This requirement increases to 80–85 degrees for stair climbing and to 120–140 degrees for running.[3] Approximately 120 degrees of knee flexion are necessary for activities such as squatting to tie a shoelace or to don a sock.[436] Table 20-10 outlines the amounts of knee ROM that must be available for common activities of daily living.

Subjective Functional Tests

Clinical research studies are placing an increased emphasis on the perspective of the patient with use of health-related quality-of-life instruments. Many patient-based knee-rating scales have been developed (Table 20-11). These include the following.

WOMAC Index. The Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) (Table 20-12) that was originally developed for people with OA of the hip or knee, is a self-administered questionnaire that has been recommended by the Outcome Measures in Reumatology Clinical Trials group[437] as the gold standard for TKA outcomes.[438] The WOMAC evaluates three dimensions: pain, stiffness, and physical function with 5, 2, and 17 questions, respectively[439] (Table 20-12). Each subscale is summated to a maximum

TABLE 20-10 Approximate Range of Motion Required for Common Activities of Daily Living

Activity	Required Flexion Range of Motion (Degrees)
Running	120–140
Squatting	120
Tying shoelace	120
Donning a sock	120
Climbing downstairs	110
Sitting and rising	85
Climbing upstairs	80
Swing phase of gait	70
Stance phase of gait	20

Data from Laubenthal KN, Smidt GL, Kettelkamp DB. A quantitative analysis of knee motion for activities of daily living. Phys Ther. 1972;52:34–42.

TABLE 20-11 Knee Questionnaire Indices

Indices	Indication	Reliability	Validity	Comment
Western Ontario and McMaster Universities Osteoarthritis Index Bellamy[a]	Osteoarthritis	Strong for osteoarthritis	Strong for osteoarthritis	Strong for pain, stiffness, and physical function in osteoarthritis
International Knee Documentation Committee Questionnaire[b]	Knee ligament injury	Good	Strong	Not sensitive for sports-related function Not as responsive to changes over time
Lysholm Knee Score[c]	Ligament and meniscal injuries	Good	Unclear	Not useful for high functioning individuals Score is heavily weighted on pain and instability ratings Acceptable psychometric performances as outcome measures for patients with a meniscal injury of the knee
Cincinnati Knee Rating System[d]	Nonspecific knee injury	Unknown	Unclear	Allows assessment of outcome based on the patient's usual activities
Knee Outcome Survey[e]	Nonspecific knee injury	Strong for functional limitations	Strong for functional limitations	Responsive for functional limits for a variety of impairments
Lower extremity function scale[f]	All lower extremity conditions	Strong for hip and knee total arthroplasty	Strong for hip and knee total arthroplasty	Useful with patients following arthroplasty

score of 20, 8, and 68, respectively. Lower scores represent better health or function. T ere is also an index score or global score, which is most commonly calculated by summating the scores for the three subscales.[439]

Knee Injury and Osteoarthritis Outcome Score. T e Knee injury and Osteoarthritis Outcome Score (KOOS) was developed to expand the WOMAC for use in a younger and more active patient group with knee injuries or knee OA.[440] In addition to evaluating pain, symptoms, and quality of life, the aim of the KOOS was to capture a broader range of patient-relevant functional ability using subscales that include leisure activities as well as ADL. T e KOOS is a 42 item self-report questionnaire that has five reported dimensions: pain (9 items), other symptoms (7 items), function in daily living (17 items), function in sport and recreation (5 items), and knee-related quality of life (4 items).[441] Seven items from the function in daily living and function in sport and recreation subscales of the KOOS are available as a short-form measurement. T is shortened format is known as the KOOS-Physical Function Shortform (KOOS-PS).[441]

International Knee Documentation Committee Questionnaire. T e International Knee Documentation Committee (IKDC) questionnaire was formed to set standards for the evaluation of knee ligament injury.[442] T e IKDC form uses four domains for the final rating: patient's self-reported function, self-reported symptoms, ROM, and ligament examination. T e worst rating in any one of the four domains

TABLE 20-12 Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC)

Name: _____

Primary Care Physician: _____

This survey asks for your views about the amount of pain, stiffness, and disability you are experiencing. Please answer every question by filling in the appropriate response. If you are unsure about how to answer a question, please give the best answer you can. (Please mark your answers with an "X")

SECTION A: PAIN

The following questions concern the amount of pain you are currently experiencing due to arthritis in your hips and/or knees. For each situation, please enter the amount of pain recently experienced.

Question: How much pain do you have?

	None	Mild	Moderate	Severe	Extreme
1. Walking on a flat surface.	☐	☐	☐	☐	☐
2. Going up or downstairs.	☐	☐	☐	☐	☐
3. At night while in bed.	☐	☐	☐	☐	☐
4. Sitting or lying.	☐	☐	☐	☐	☐
5. Standing upright.	☐	☐	☐	☐	☐

SECTION B: JOINT STIFFNESS

The following questions concern the amount of joint stiffness (not pain) you are currently experiencing in your hips and/or knees. Stiffness is a sensation of restriction or slowness in the ease with which you move your joints.

	None	Mild	Moderate	Severe	Extreme
1. How severe is your stiffness after first wakening in the morning?	☐	☐	☐	☐	☐
2. How severe is your stiffness after sitting, lying, or resting later in the day?	☐	☐	☐	☐	☐

SECTION C: PHYSICAL FUNCTION

The following questions concern your physical function. By this we mean your ability to move around and to look after yourself. For each of the following activities, please indicate the degree of dif culty you are currently experiencing due to arthritis in your hips and/or knees. (Please mark your answers with an "X")

Question: What degree of dif culty do you have with:

	None	Mild	Moderate	Severe	Extreme
1. Descending stairs.	☐	☐	☐	☐	☐
2. Ascending stairs.	☐	☐	☐	☐	☐
3. Rising from sitting.	☐	☐	☐	☐	☐
4. Standing.	☐	☐	☐	☐	☐
5. Bending to floor.	☐	☐	☐	☐	☐
6. Walking on flat.	☐	☐	☐	☐	☐
7. Getting in/out of car.	☐	☐	☐	☐	☐
8. Going shopping.	☐	☐	☐	☐	☐
9. Putting on socks/stockings.	☐	☐	☐	☐	☐
10. Rising from bed.	☐	☐	☐	☐	☐
11. Taking off socks/stockings.	☐	☐	☐	☐	☐

(normal, nearly normal, abnormal, or severely abnormal) determines the final rating of the knee.

Lysholm Knee Scoring Scale. The Lysholm Knee Scale[443] is commonly used as a subjective report scoring system designed to evaluate the intervention outcome and postsurgical result of knee patients. The scale consists of eight items related to limping; the need for an assistive device; ability to squat or climb stairs; and the presence of pain, swelling, locking, or "giving way," and leg atrophy.[444] Points are given for each level of ability or disability reported, with the perfect score being 100 (Table 20-13). The designers of this scale found that patients suffering from knee instability scored significantly lower than patients with minimal or no instability (average = 75.6 and 93.6, respectively).

Cincinnati Knee Rating System. The Cincinnati knee-rating system self-report version uses a combination of

Data from Tegner Y, Lysholm J: Rating systems in the evaluation of knee ligament injuries. Clin Orthop Relat Res. 1985;198:43–49.

functional level and symptom reporting to arrive at an overall disability rating for the knee.[445] The scale provides a point scoring system for the type of sports-related activity and frequency of participation, which allows an assessment outcome that is based on the patient's usual activities.

Knee Outcome Survey. The Knee Outcome Survey (KOS) consists of two separate scales: the activities of daily living scale (ADLS) and the sports activity scale (SAS). The ADLS (Table 20-14)[446] assesses the full spectrum of symptoms and functional limitations that may occur due to knee disorders.[444] The test–retest reliability of this scale is 0.97.[447] The SAS scale includes factors commonly experienced during sports activities.

Lower Extremity Function Scale. The lower extremity function scale was designed to be applicable to all lower extremity conditions of musculoskeletal origin.[448]

Although these instruments have been commonly used to evaluate patients following knee surgery or trauma, relatively little work has been done to compare these knee instruments for the evaluation of athletic patients, and those that have been cross-sectional in design and therefore have not assessed reliability or how the instruments performed over time. Marx et al. performed a study to determine the reliability, validity, and responsiveness of the Lysholm scale, the American Academy of Orthopaedic Surgeons (AAOS) sports knee-rating scale (see "Advanced Functional Tests"), the ADLS of the KOS, and the Cincinnati knee-rating system in athletic patients with a wide variety of disorders of the knee. According to the study, the reliability was high for all scales, with the ICC ranging from 0.88 to 0.95. As for construct validity, the correlations among the knee scales ranged from 0.70 to 0.85 and those between the knee scales and the physical component scale of the Short Form-36 (SF-36) and the patient and clinician severity ratings ranged from 0.59 to 0.77. Responsiveness, measured with the standardized response mean, ranged from 0.8 for the Cincinnati knee-rating system to 1.1 for the ADLS.

Patellar Joint Evaluation Scale. This scale assesses seven components of PFJ function (Table 20-15).

Objective Functional Tests

The functional tests for the knee are introduced once the patient is able to perform active and resisted motions without pain.

Aggregated Locomotor Function Score. The aggregated locomotor function (ALF) score was formed by summating the mean timed scores (seconds) from three locomotor functions (walking time, stair ascent, and stair descent) and time taken to transfer from sitting to standing.[449]

- Eight-meter walk time. The patient is asked to walk 8 m at their own naturally preferred comfortable pace with or without walking aids as appropriate. Three repetitions of the walk are undertaken and the mean time is recorded.
- Stair ascent and descent time. The patient is asked to ascend and then descend seven steps (4 of 15 cm and 3 of 20 cm) at their naturally preferred comfortable pace. The method that the patient employs to negotiate the stairs is recorded, that is, whether they use alternate legs, use the banisters, or always lead with one leg. The patient is timed

TABLE 20-14 Patient Reported Measure of Knee Function

ACTIVITIES OF DAILY LIVING SCALE

Instructions: The following questionnaire is designed to determine the symptoms and limitations that you experience because of your knee while you perform your usual daily activities. Please answer each question by checking the statement that best describes you over the last 1–2 days. For a given question, more than one of the statements may describe you, but please mark ONLY the statement that best describes you during your usual daily activities.

SYMPTOMS

1. To what degree does pain in your knee affect your daily activity level?
   - 5 I never have pain in my knee.
   - 4 I have pain in my knee, but it does not affect my daily activity.
   - 3 Pain affects my activity slightly.
   - 2 Pain affects my activity moderately.
   - 1 Pain affects my activity severely.
   - 0 Pain in my knee prevents me from performing all daily activities.
2. To what degree does grinding or grating of your knee affect your daily activity level?
   - 5 I never have grinding or grating in my knee.
   - 4 I have grinding or grating in my knee, but it does not affect my daily activity.
   - 3 Grinding or grating affects my activity slightly.
   - 2 Grinding or grating affects my activity moderately.
   - 1 Grinding or grating affects my knee slightly.
   - 0 Grinding or grating in my knee prevents me from performing daily activities.
3. To what degree does stiffness in your knee affect your daily activity level?
   - 5 I never have stiffness in my knee.
   - 4 I have stiffness in my knee, but it does not affect my daily activity.
   - 3 Stiffness affects my activity slightly.
   - 2 Stiffness affects my activity moderately.
   - 1 Stiffness affects my activity severely.
   - 0 Stiffness in my knee prevents me from performing all daily activities.
4. To what degree does swelling in your knee affect your daily activity level?
   - 5 I never have swelling in my knee.
   - 4 I have swelling in my knee, but it does not affect my daily activity.
   - 3 Swelling affects my activity slightly.
   - 2 Swelling affects my activity moderately.
   - 1 Swelling affects my activity severely.
   - 0 Swelling in my knee prevents me from performing all daily activities.
5. To what degree does slipping of your knee affect your daily activity level?
   - 5 I never have slipping of my knee.
   - 4 I have slipping of my knee, but it does not affect my daily activity.
   - 3 Slipping affects my activity slightly.
   - 2 Slipping affects my activity moderately.
   - 1 Slipping affects my activity severely.
   - 0 Slipping of my knee prevents me from performing all daily activities.
6. To what degree does buckling of your knee affect your daily activity level?
   - 5 I never have buckling of my knee.
   - 4 I have buckling of my knee, but it does not affect my daily activity level.
   - 3 Buckling affects my activity slightly.
   - 2 Buckling affects my activity moderately.
   - 1 Buckling affects my activity severely.
   - 0 Buckling of my knee prevents me from performing all daily activities.

(Continued)

TABLE 20-14 Patient Reported Measure of Knee Function (Continued)

7. To what degree does weakness or lack of strength of your leg affect your daily activity level?
   - 5 My leg never feels weak.
   - 4 My leg feels weak, but it does not affect my daily activity.
   - 3 Weakness affects my activity slightly.
   - 2 Weakness affects my activity moderately.
   - 1 Weakness affects my activity severely.
   - 0 Weakness of my leg prevents me from performing all daily activities.

FUNCTIONAL DISABILITY WITH ACTIVITIES OF DAILY LIVING

8. How does your knee affect your ability to walk?
   - 5 My knee does not affect my ability to walk.
   - 4 I have pain in my knee when walking, but it does not affect my ability to walk.
   - 3 My knee prevents me from walking more than 1 mile.
   - 2 My knee prevents me from walking more than 1/2 mile.
   - 1 My knee prevents me from walking more than 1 block.
   - 0 My knee prevents me from walking.
9. Because of your knee, do you walk with crutches or a cane?
   - 3 I can walk without crutches or a cane.
   - 2 My knee causes me to walk with 1 crutch or a cane.
   - 1 My knee causes me to walk with 2 crutches.
   - 0 Because of my knee, I cannot walk even with crutches.
10. Does your knee cause you to limp when you walk?
   - 2 I can walk without a limp.
   - 1 Sometimes my knee causes me to walk with a limp.
   - 0 Because of my knee, I cannot walk without a limp.
11. How does your knee affect your ability to go upstairs?
   - 5 My knee does not affect my ability to go upstairs.
   - 4 I have pain in my knee when going upstairs, but it does not limit my ability to go upstairs.
   - 3 I am able to go upstairs normally, but I need to rely on use of a railing.
   - 2 I am able to go upstairs one step at a time with use of a railing.
   - 1 I have to use crutches or a cane to go upstairs.
   - 0 I cannot go upstairs.
12. How does your knee affect your ability to go downstairs?
   - 5 My knee does not affect my ability to go downstairs.
   - 4 I have pain in my knee when going downstairs, but it does not limit my ability to go downstairs.
   - 3 I am able to go downstairs normally, but I need to rely on use of a railing.
   - 2 I am able to go downstairs one step at a time with use of railing.
   - 1 I have to use crutches or a cane to go downstairs.
   - 0 I cannot go downstairs.
13. How does your knee affect your ability to stand?
   - 5 My knee does not affect my ability to stand. I can stand for unlimited amounts of time.
   - 4 I have pain in my knee when standing, but it does not limit my ability to stand.
   - 3 Because of my knee, I cannot stand for more than 1 hour.
   - 2 Because of my knee, I cannot stand for more than half an hour.
   - 1 Because of my knee, I cannot stand for more than 10 minutes.
   - 0 I cannot stand because of my knee.
14. How does your knee affect your ability to kneel on the front of your knee?
   - 5 My knee does not affect my ability to kneel on the front of my knee. I can kneel for unlimited amounts of time.
   - 4 I have pain when kneeling on the front of my knee, but it does not limit my ability to kneel.
   - 3 I cannot kneel on the front of my knee for more than 1 hour.
   - 2 I cannot kneel on the front of my knee for more than half an hour.
   - 1 I cannot kneel on the front of my knee for more than 10 minutes.
   - 0 I cannot kneel on the front of my knee.

TABLE 20-14 Patient Reported Measure of Knee Function (Continued)

15. How does your knee affect your ability to squat?
    - 5 My knee does not affect my ability to squat. I can squat all the way down.
    - 4 I have pain when squatting, but I can still squat all the way down.
    - 3 I cannot squat more than ¾ of the way down.
    - 2 I cannot squat more than ½ of the way down.
    - 1 I cannot squat more than ¼ of the way down.
    - 0 I cannot squat at all.
16. How does your knee affect your ability to sit with your knee bent?
    - 5 My knee does not affect my ability to sit with my knee bent. I can sit for unlimited amounts of time.
    - 4 I have pain when sitting with my knee bent, but it does not limit my ability to sit.
    - 3 I cannot sit with my knee bent for more than 1 hour.
    - 2 I cannot sit with my knee bent for more than half an hour.
    - 1 I cannot sit with my knee bent for more than 10 minutes.
    - 0 I cannot sit with my knee bent.
17. How does your knee affect your ability to rise from a chair?
    - 5 My knee does not affect my ability to rise from a chair.
    - 4 I have pain when rising from the seated position, but it does not affect my ability to rise from the seated position.
    - 3 Because of my knee, I can only rise from a chair if I use my hands and arms to assist.
    - 0 Because of my knee, I cannot rise from a chair.

(in seconds) and asked to repeat the test four times. The mean time of the four repetitions is calculated.

- Transferring time. The patient is asked to walk, at their own natural pace, a distance of 2 m to a chair (with a seat height of 0.46 m, typical of a toilet seat) and sit down, then immediately stand up and walk back to the start. The patient is timed (in seconds) as they approach and retreat from the chair. The patient is asked to perform the test three times and the mean time is calculated.

The ALF score has demonstrated excellent intratester reliability with a high ICC statistic, narrow confidence intervals, a low standard error of measurement (SEM), and low smallest detectable difference (SDD).[449] Importantly, the measure demonstrates moderately sized correlation with two validated self-report questionnaires of physical function (SF-36 and WOMAC) and appears to be more responsive to change induced by exercise intervention, than either.[449]

Simple Functional Weight-Bearing Tests

The simplest functional WB test for the knee is the squat position. The patient should be able to perform this maneuver without pain.

Duck Walk/Childress Sign. The patient squats with the toes pointing outward and walks forward. This maneuver is similar to the McMurray test for a meniscal lesion (although more stressful). Pain, or crepitus, with this test, supposedly indicates a lesion of the posterior horn of the meniscus or the MCL.[387] A positive test for a meniscus tear is indicated by a block preventing full flexion or pain at end-range flexion. However, studies have shown that pain neither with squatting nor with a duck walk seem to indicate a torn meniscus.[422,450]

Incidentally, a patient with a patellofemoral lesion can duck walk without difficulty, but experiences difficulty coming up out of the squat.[274]

Advanced Functional Tests

More advanced functional tests for the knee include the following AAOS sports knee-rating scale, vertical jump, functional hop, single-leg squat, and running tests.[444]

American Academy of Orthopaedic Surgeons Sports Knee-Rating Scale. The AAOS sports knee-rating scale was included in the Musculoskeletal Outcomes Data Evaluation and Management System (MODEMS) for athletic patients with disorders of the knee. This instrument has five parts with a total of 23 questions: a core section (seven questions) on stiffness, swelling, pain, and function, and four sections (four questions each) on locking or catching on activity, giving-way on activity, current activity limitations due to the knee, and pain on activity due to the knee.

Vertical Jump. Vertical jumping is an explosive movement, in which the vertical velocity of the trunk is of decisive importance for jump height. The vertical jump test is commonly used in sports medicine, and investigators have found it to be significantly related to athletic performance.[451–457] The vertical jump is performed in the following manner. A baseline measurement is made of the highest point that the patient can reach while remaining flat footed. The patient's fingertips are covered with chalk, and he or she is then asked to jump as high as possible, marking the wall with the chalk on the fingertips. The patient is allowed three jumps, after which the clinician subtracts the baseline reach from the maximum vertical jump to obtain the vertical jump distance.

Functional Hop Tests

- Single-leg hop for distance. This test has good test–retest reliability (0.79–0.99),[454,455,457–462] although its correlation with power and isokinetic strength testing is unclear.[357,453,455,462–465] The patient stands on the involved leg, with the toes as close to the starting position as

Scoring: 90–100 points, excellent; 80–90 points, good; 60–79 points, fair: < 60 points, poor.
Data from Karlson J, Thomee R, Sward L. Eleven year follow-up of patellofemoral pain syndromes. Clin J Sports Med. 1996;6:22–26.

possible. The hands are placed behind the back or on the hips. The patient then tries to hop as far as possible, landing on the same extremity. Three attempts are permitted. The distance is measured from the take-off toe to the landing heel and is compared with the hop distance of the uninvolved leg, and scored as a percentage. The distances hopped are influenced by age and sex.[461] Norms for this test in high school athletes are an average of 155 cm for boys and an average of 121 cm for girls.[466] The sensitivity of this test has been found to be 52% and the specificity to be 97%.[467] Barber et al.[455] found a significant relationship between the one-legged hop and the subjective limitations of sprinting, jumping, and landing.

- **Triple hop.**[454,468] The triple-hop test is similar to the hop-for-distance test, except that the patient hops for three consecutive hops, and the score is the distance measured from the take-off toe to the landing heel of the third jump. One study reported a high correlation between concentric isokinetic strength of the quadriceps muscle and the triple hop for distance.[465]
- **Timed 6-m hop.**[455,457,459] This test is reliable, with an ICC ranging from 0.66 to 0.77,[454,458] and is considered to be one of the best indicators of function.[463] The clinician marks off a distance of 6 m and the patient performs single-leg hops over the distance. The time taken is measured to the nearest 0.01 second and compared with the uninvolved leg. This is functional test evaluates the strength, endurance, proprioception, balance, and power of the various knee structures. The test is recommended for use with athletes returning to sports. The sensitivity of this test has been found to be 49%, and the specificity to be 94%.[467]
- **Crossover hop.** The crossover hop has an ICC of 0.96 for test–retest reliability.[454] The results of this test have a relationship with the isokinetic parameter of acceleration range and are considered to be the best indicator of knee function.[463] The test is performed as follows: the patient places his or her feet behind the start line, and a tape measure is laid perpendicular to that line. The patient is asked to stand on one leg to the right of the tape measure. The patient is then asked to jump, on one leg, to the left side of the tape, back to the right, and then back to the left, attempting to propel himself or herself as far as possible with each hop. The score is the distance measured from the take-off toe to the landing heel of the third jump. Three attempts are permitted, and two sides are compared as a percentage of each other.
- **Stairs hop.** The patient is timed as he or she hops up and down several steps (20–25 steps are recommended), first on the uninvolved leg and then on the involved leg.[468]
- **Side-to-side hop.** Steadman[469] advocates the use of the side-to-side Heiden hop. The Heiden hop involves the patient jumping from side to side, to a line placed approximately 5–6 ft (1.5–1.8 m) apart. The landing is controlled with a soft flexion of the knee, balancing the body on the foot closest to the line. The patient then leaps sideways to the other line, landing on the opposite foot in a controlled fashion, gently assuming a semisquat position on the single leg.[470] This is exercise is performed side to side for 5–10 minutes. Evidence of an ungraceful landing, loss of balance, or shaking muscles on the involved side indicates weakness of the quadriceps.[470]

Single-Leg Squat Test. The patient is asked to balance on one leg and then to squat down on that leg while keeping the trunk erect. The amount of flexion at the knee is measured with a goniometer and is compared with a similar measure of the uninvolved leg. If a hand or the opposite extremity touches the ground, the measurement is retaken. Although seemingly

a static test, this is a test of the dynamic ability of the quadriceps, hamstring, gluteal, and gastrocnemius muscles to maintain eccentric control, and for the patient to maintain balance.

Running Tests

- Figure-of-eight running. Two cones are positioned 10 m apart. The patient is asked to run around the cones in a figure-of-eight pattern, for a certain number of rotations, rounding the turns rather than planting and cutting, while the clinician times the run. The time ratio of figure-of-eight running to straight running is one of the most definitive ways to compare patients with an ACL-deficient knee to those with normal knees.[471]
- Carioca test. The carioca test involves the patient running laterally with a crossover of the legs and a weaving of the feet, beginning with the trailing leg in front, then trailing the leg in back of the leading leg, for a distance of either 8 ft[472] or 24.4 m.[473]
- Shuttle run.[464,474] The shuttle run involves having the patient run between cones or varying distances.

Imaging Studies

Radiographic imaging of the knee is described in Chapter 7. Arthrograms of the knee are used primarily to diagnose tears in the menisci and plica, although their use is gradually being replaced by arthroscopy, which allows the surgeon to diagnose and repair lesions simultaneously.

THE EVALUATION

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This diagnosis can be structure related (medical diagnosis) (Table 20-16), or a diagnosis based on the preferred practice patterns as described in the Guide to Physical Therapist Practice.

INTERVENTION STRATEGIES

Acute knee injuries are a common occurrence. One study[475] demonstrated, perhaps not surprisingly, that the most common type of acute knee injuries were sports related, occurred in men younger than 35 years of age, and were of moderate severity. Studies[475–477] that compare the two sexes report higher rates of sports injuries in men. This finding could be a result of the greater numbers of men participating in sports activities or the greater frequency of injuries in men who do participate in sports.

Of particular interest are non–sports-related falls, which are experienced two to three times more frequently in women than in men, except in the group older than 55 years, for whom the incidence of falls is equal in both sexes.[475]

Most knee pain of nontraumatic origin improves with conservative intervention.[478] Different approaches have been emphasized over the years, including patient education,[479–481] modification of activity,[142,480,482,483] progressive muscle stretching and strengthening,[131,142,479,481–486] functional lower extremity training,[487] external patellar supports and braces,[142,479,481,488,489] foot orthotics (Table 20-17),[489,490] and taping to improve patella tracking.[479,482,485,491,492]

This wide range of interventions raises the question of whether any of them is efficacious, or whether a combination of some is to be recommended. What is clear is that the impairments and functional limitations found during the examination must guide the intervention. The successful intervention requires detailing the factors that influence these impairments and functional limitations and determining the stage of healing.

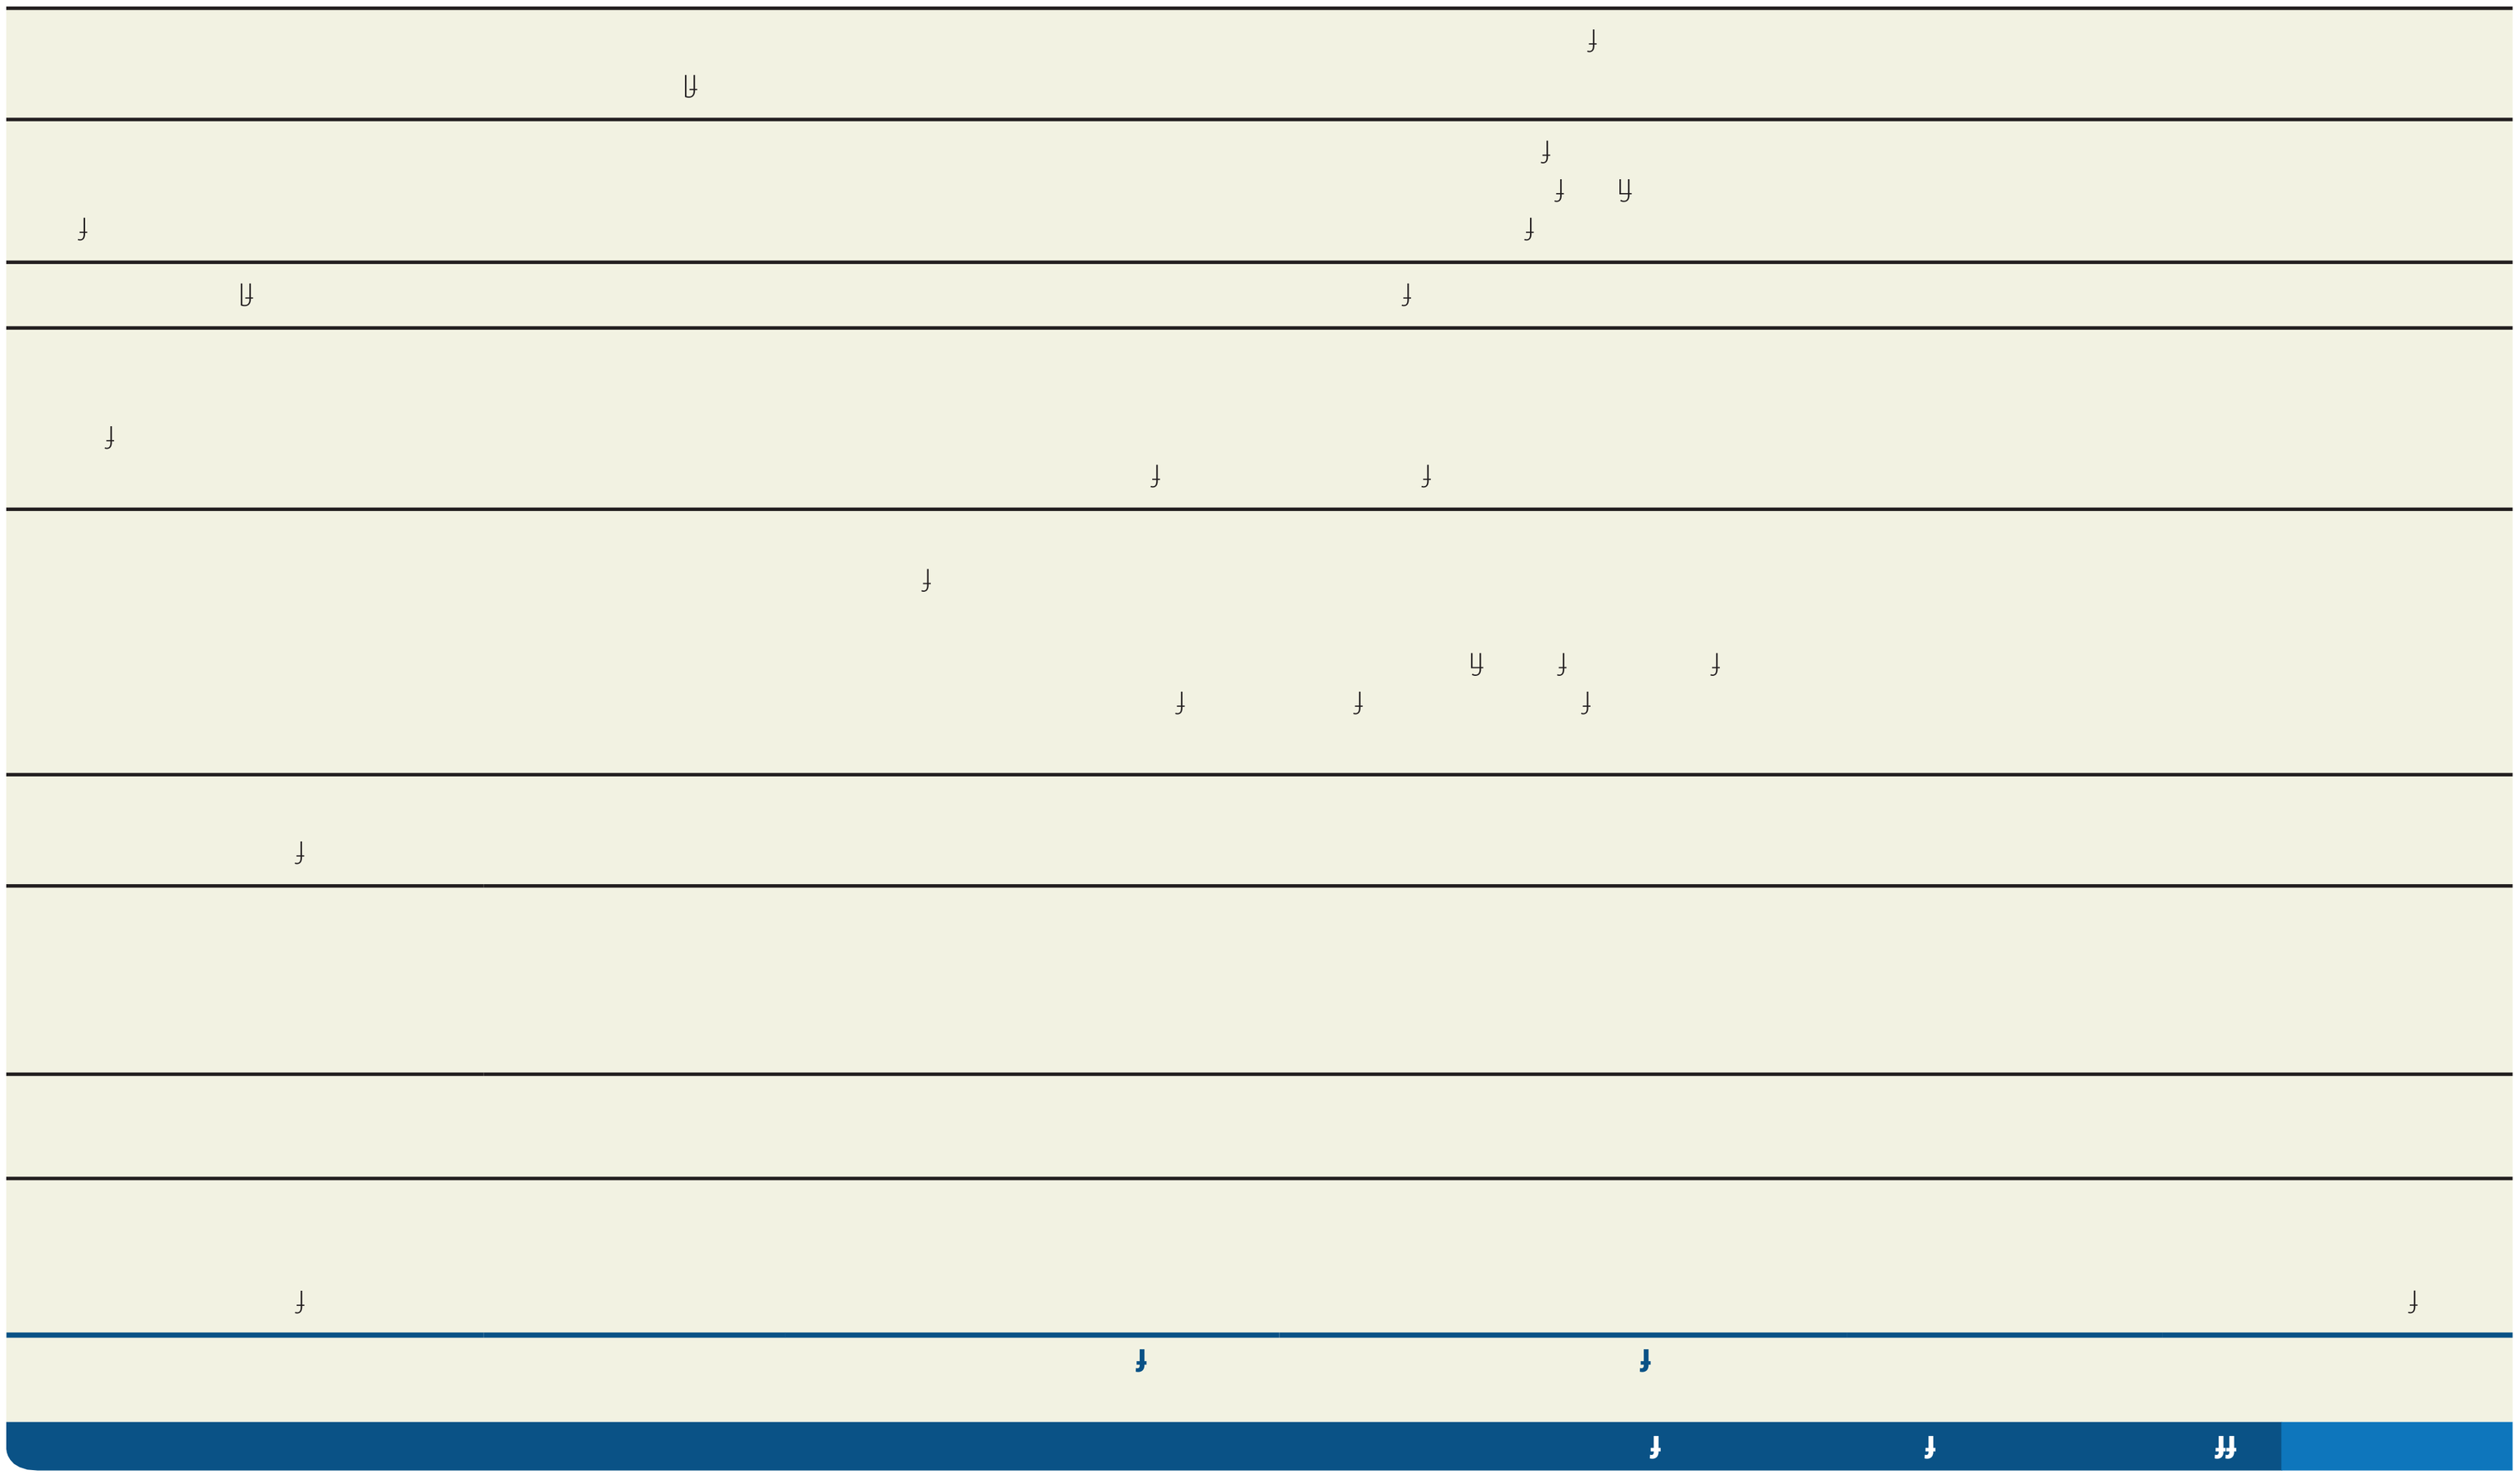
CLINICAL PEARL

There is a growing empirical evidence that impaired muscular control of the hip can affect joint kinematics and kinetics in multiple planes at the knee.[217]

Whatever the knee injury, the goal of the rehabilitation program is to return the patient to an optimum level of function. The emphasis during knee rehabilitation must focus on achieving a balance between allowing the damaged structures to heal, improving muscle control, and increasing the competence of the static restraints. Consideration must also be given to the various forces placed on the knee during CKC and OKC exercises. The techniques to increase joint mobility and soft-tissue extensibility are described in "Therapeutic Techniques".

Acute Phase

Every attempt is made to protect the joint to promote and progress the healing. The goals during the acute phase are to



- reduce pain and swelling;
- control inflammation;
- regain ROM;
- minimize muscle atrophy and weakness;
- attain early neuromuscular control;
- maintain or improve the patient's general cardiovascular fitness.

The reduction of pain and the control of swelling are extremely important as both can inhibit normal muscle function and control. The principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication) are used to minimize pain, swelling, and inflammation.

Therapeutic Exercises

Numerous clinical trials have used therapeutic exercise as part of a comprehensive intervention program for both the tibiofemoral and PFJs.[251,259,266,493–495,496)]

Once the pain, swelling, and inflammation are under control, early controlled ROM exercises are initiated. In the acute phase of healing, the interventions focus on decreased loading of the joint complex, which might include postural

| | | |

f						
					fi	

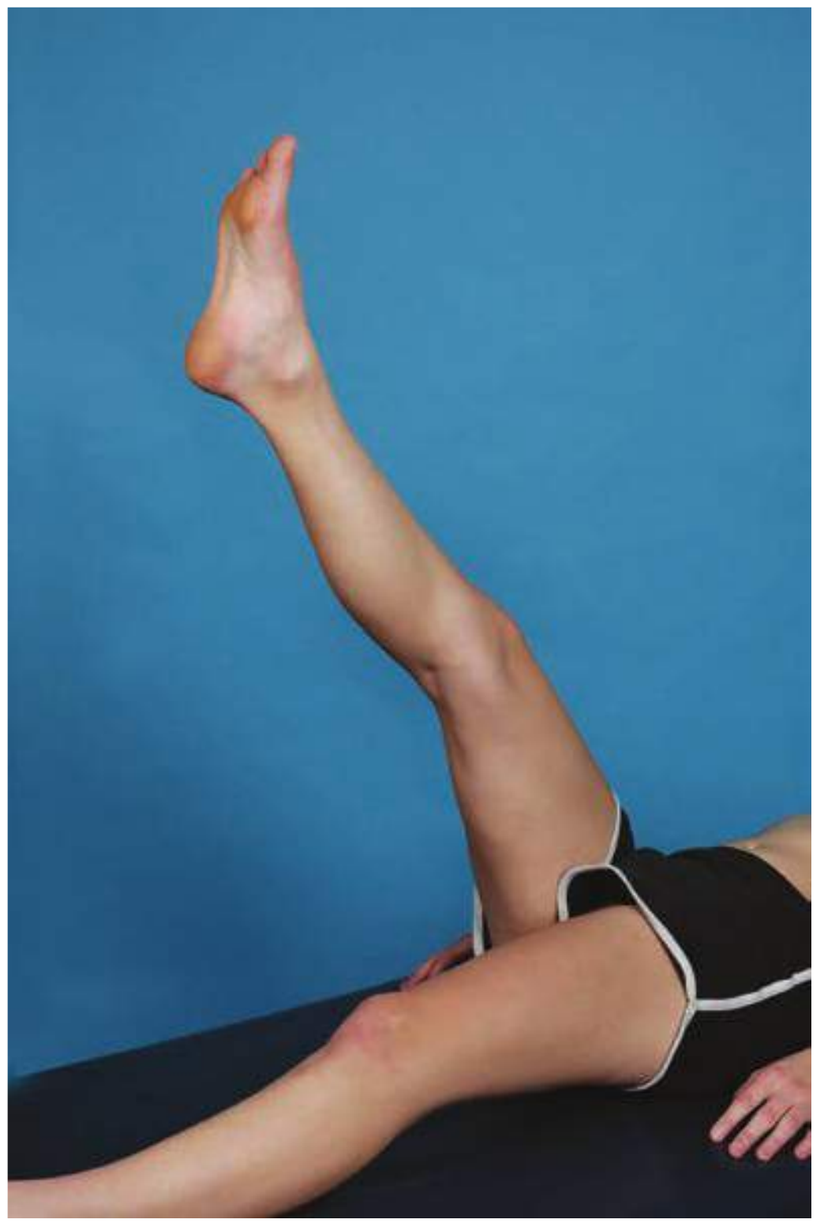


FIGURE 20-47 Straight leg raise.

correction, activity modification, or the use of an assistive device. Bracing may be needed to provide adequate protection (see the discussion in "Functional Phase"). Exercises prescribed for the knee joint complex must include those that promote neuromuscular control, timing, balance, and proprioception.

Exercises recommended for this phase include isometric muscle setting (quadriceps sets VIDEO, hamstring sets, gluteal sets), active knee flexion (heel slides VIDEO), straight leg raises (if appropriate) (Fig. 20-47), hip swings VIDEO and patellar mobilizations. Proprioceptive neuromuscular facilitation (PNF) activities may be initiated with slow-speed, low-force, controlled exercises. Electrical stimulation can be used to facilitate muscle activity and to promote muscle reeducation.[497] The training of the VMO should be regarded as a motor skill acquisition rather than a strengthening procedure,[145,498] with the goal of the training to produce a modification of the length–tension relationship between the VMO and its antagonist, the VL. This may result in a change of the equilibrium point, which will enable the appropriate alignment of the patella.[499] If the muscle control of the VMO is poor, biofeedback can be used to augment the hip adductor training.[500] Taping can be used as an adjunct (see later discussion).

Once the muscle control is achieved, gentle CKC exercises are initiated. CKC exercises initially include small-range wall slides and heel raises. Contractions of the quadriceps should be encouraged in the functional knee positions that provoke pain, such as sitting, and stair negotiation. The benefit of CKCEs is that they decrease shear forces and emphasize cocontractions.[501,502] General recommendations for CKC exercise at the knee are from 0 to 20 degrees,[496] or 0–40 degrees of flexion.[250] All the exercises performed in the clinic should be performed by the patient at home whenever possible.

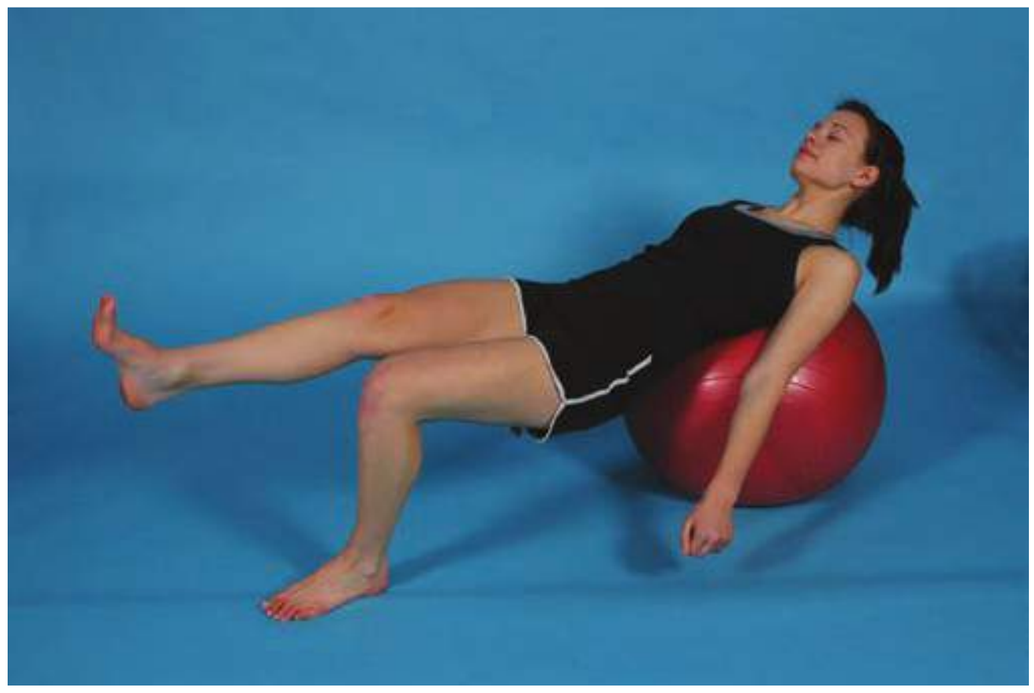

FIGURE 20-48 Single-leg bridges on Swissball.

Tibiofemoral Joint

The CKC exercises previously mentioned are progressed to include the supine leg press, the hip sled with minimal resistance.[503] These exercises are performed bilaterally initially and then unilaterally once there is evidence of good dynamic stability.

Cocontraction exercises for the hamstrings and quadriceps, which further reduce tibiofemoral shear forces,[259,260,327,504,505] can be achieved by having the patient perform single-leg bridges by leaning back on a Swiss ball (Fig. 20-48) and raising the uninvolved leg off the floor, while the involved leg is used to maintain balance. Cocontraction also can be accomplished by "single-leg" wall slides using the Swiss ball (Fig. 20-49), with the uninvolved leg supporting most of the body weight.

FIGURE 20-49 Wall slide with Swissball.

Stationary bicycling has long been recognized as a useful therapeutic exercise for knee rehabilitation to control the ROM and impact forces at the knee.

- The ROM at the knee can be controlled by adjusting the seat height.
- The impact forces can be adjusted on most exercise bicycles by varying the resistance at the pedal–foot interface.

The amount of strain on the ACL during stationary bicycling is relatively low compared with other rehabilitation activities (Table 20-1).[506]

Patellofemoral Joint

Rehabilitation that includes a combination of painless muscle strengthening, stretching, and patellofemoral taping often is beneficial in creating an internal biomechanical environment that encourages maximal tissue healing.[507] A number of classification systems have been used to categorize individuals with patellofemoral disorders (Table 20-18). As with any disorder, although the use of a classification system may help, the clinician must formulate effective treatment interventions based on the findings from the history, subjective examination, physical examination, functional assessment, and the patient's response to the prescribed exercises.

Quadriceps strengthening is a common component of the rehabilitation program for persons with PFPS and typically includes NWB exercises (OKC) and WB exercises (CKC). WB exercises are considered more functional in nature and incorporate contractions of multiple agonist and antagonist muscle groups. In contrast, NWB knee exercises require less cocontraction of antagonist's muscles and thus provide better quadriceps muscle isolation.[508] When designing a rehabilitation program for individuals with PFPS, it is important to select exercises that promote muscle loading and adaptation while minimizing PFJ stress and pain. However, there is conflicting evidence in the literature as to where the PFJ reaction forces are highest during WB and NWB tasks:

- Steinkamp et al.[250] These authors reported a contrast in the patterns of PFJ stress during WB and NWB exercises performed at 0 to 90 degrees of knee flexion. During the WB task (leg press), PFJ stress increased linearly from 0 to 90 degrees of knee flexion. During the NWB knee extension exercise, however, PFJ stress was greatest at 0 degrees and decreased with knee flexion.
- Escamilla et al.[251] These authors, using similar WB and NWB tasks as Steinkamp et al. (squat and knee extension, respectively), reported that the PFJ reaction force increased in both exercises as the knee flexed from 0 to 60 degrees. Beyond 60 degrees, however, the curves diverged. While the PFJ reaction force during the WB exercises continued to increase with increasing knee flexion, the PFJ reaction force during NWB knee extension decreased. At 90 degrees of knee flexion compared to 0 degrees of

TABLE 20-18 Classification Systems for Nonoperative Patellofemoral Syndrome

Lohman[a]	Wilk et al.[b]	Holmes et al.[c]
1. Overconstrained—tight lateral or inferior structures (tilt, glide, anteroposterior tilt)	1. Patellar compression syndrome—excessive lateral pressure syndrome; global pressure syndrome	1. Patellofemoral instability—subluxation or dislocation, single episode; lateral or medial subluxation or dislocation, recurrent; chronic dislocation of patella, congenital or acquired; associated fractures, osteochondral or avulsion
2. Combination—tight lateral structures and loose medial structures	2. Patellar instability—chronic patellar subluxation; recurrent patellar dislocation	2. Patellofemoral pain with malalignment—increased functional quadriceps angle (femoral anteversion, external tibial torsion, genu valgum, foot hyperpronation); tight lateral retinaculum; grossly inadequate medial stabilizers; patella alta; patella baja; dysplastic femoral trochlea
3. Underconstrained—loose lateral and medial structures (excessive joint play) resulting in instability (subluxation or dislocation)	3. Biomechanical dysfunction	3. Patellofemoral pain without malalignment—tight medial and lateral retinaculum; plica (medial, lateral, suprapatellar); osteochondritis dissecans; traumatic patellar chondromalacia; fat pad syndrome; patellofemoral osteoarthritis; patella tendinitis; quadriceps tendinitis; prepatellar bursitis; apophysitis; symptomatic bipartite patella; other trauma (quadriceps tendon rupture, patella tendon rupture, patella fracture, proximal tibial epiphysis fracture, contusion, turf knee or wrestler's knee, cruciate ligament instability)
4. Normal—normal alignment but painful (e.g., tendinitis, apophysitis, or bursitis)	4. Direct patella trauma—articular cartilage lesion (isolated); fracture and dislocation; articular cartilage lesion with associated malalignment	
5. Unable or not specified—the underlying cause of patellofemoral pain syndrome cannot be determined	5. Soft-tissue lesions—suprapatellar plica, fat pad syndrome; medial patellofemoral ligament pain; iliotibial band friction syndrome	
6. Other causation—osteochondrosis dissecans, chondromalacia patellae, sympathetically maintained pain, fractures, synovial plicae	6. Overuse syndromes—tendinitis; apophysitis	
	7. Osteochondritis dissecans	
	8. Neurologic disorders—complex regional pain syndrome; sympathetically maintained pain

flexion, the NWB exercise exhibited higher PFJ reaction forces. T e conflicting findings between the Steinkamp et al. and Escamilla et al. studies are the result of the direction used to apply resistance. T e resistance applied in Steinkamp study was not perpendicular to the tibia throughout the range of knee extension which would result in a progressive increase in the moment arm of the external resistance as the knee is extended from 90 to 0 degrees.[509] In contrast, Escamilla et al. evaluated knee extension on an exercise machine that applied external resistance perpendicular to the tibia which would result in a constant external moment arm throughout the range of knee extension.[509]

- Powers et al.[509] T is study investigated a WB squat exercise to NWB knee extension exercises. One of the knee extension exercises involved variable resistance (similar to the study by Steinkamp et al.) while the other knee extension exercise involved constant resistance (similar to the study by Escamilla et al.). T e results from the study found that to minimize PFJ stress during the squat exercise, the exercise should be performed from 45 to 0 degrees of knee flexion, and the knee extension with variable resistance exercise should be performed from 90 to 45 degrees of knee flexion.

T us, when prescribing OKC and CKC exercises, it would appear that the clinician should be aware of the following:

- During OKC extension, the flexion moment arm for the knee increases as the knee extends from 90 degrees of flexion to full extension (0 degree), resulting in increased quadriceps and patellar tendon tension and increasing PJRFs. Clinicians most often allow OKC exercises at 90–45 degrees of knee flexion as this range provides the lowest PJRF while producing the greatest amount of patellofemoral contact area.
- During CKC exercises, the flexion moment arm of the knee increases as the angle of knee flexion increases (Fig. 20-7). Maximum force in the quadriceps muscle and patellar tendon is generated at 60 degrees of flexion with values approaching 3,000 N.[227] CKC, such as the leg press and wall squat, should be prescribed initially at 0–20 degrees and then progressed to 0–45 degrees.

In addition, a number of activities of daily living have been identified that increase patellofemoral compression. T ese include stair climbing, squatting, prolonged sitting with the knee flexed beyond 40 degrees, prolonged kneeling, arising from chairs, prone lying, or standing in genu recurvatum.[124,142] During the early stages of healing, the patient must try to avoid these activities or at least minimize exposure. In the presence of biomechanical dysfunctions of the foot, including pronation, correct footwear must be worn. If the malalignment of the lower extremity is severe, a foot orthosis can be prescribed.[488,499] T e type of orthosis used is dependent on the diagnosis. Most commonly, an orthosis is used to correct a flat foot so that the patella no longer squints. Foot pronation imparts internal torsion to the tibia and a valgus moment at the knee. Klingman et al.[510] have shown that medial rearfoot-posted orthoses result in a more medial position of the patella during static WB radiographs. In the presence of genu recurvatum, a heel raise can be issued for use during exercise. It is, therefore, reasonable, for selected patients, to prescribe an orthotic device for the shoe.[195,511]

It remains unclear to what extent there are specific exercises to strengthen the VMO.[10,141,512] A study by Mirzabeigi et al.[513] attempted to isolate the VMO from the VL, vastus intermedius, and VML, using nine sets of strengthening exercises. T ese exercises included isometric knee extension with the hip in neutral, 30 degrees of external rotation, and 30 degrees of internal rotation; isokinetic knee extension through full range; isokinetic knee extension in the terminal 30-degree arc; side-lying ipsilateral and contralateral full knee extension; and stand and jump from a full squat. Although the study concluded that isometric exercises in neutral and external rotation of the hip challenged both the VMO and VL, none of the exercises demonstrated isolation of the VMO.[513] Indeed, a thorough review of the existing literature shows that isolated contraction of the VMO, independent of the VL has never been documented.[514] T e VMO does not extend the knee and is not, therefore, activated by the traditional straight leg raise,[515] even with the addition of adduction.[516] However, because of the relationship of the VMO to the adductor magnus, and its separate nerve supply in most cases,[132] the clinician should still emphasize adduction of the thigh, while minimizing internal rotation of the hip, to facilitate a VMO contraction.[500] According to Hodges and Richardson,[517] activation of the adductor magnus significantly improves the VMO contraction in WB, but a maximum contraction of the adductor magnus in NWB is required before facilitating VMO activity.

T e hip external rotators and abductors affect lower limb control, and a strengthening program that addresses these muscle groups should be integrated into the overall progression. For example, weakness of the hip external rotators may allow uncontrolled and excessive pronation of the foot to occur along with excessive femoral internal rotation, both contributing to an increase in the valgus alignment of the knee, thereby increasing the Q-angle.[162] Strengthening of the hip rotators may need to be initiated in the OKC, but should be advanced to strengthening in the CKC as soon as functional muscular control is present.[162]

Exercises during this phase include the following:

- Isometric quadriceps sets at 20 degrees of flexion, progressing to multiple angle isometrics.
- Heel slides with the tibia positioned in internal and then external rotation.
- Straight leg raises performed with the thigh externally rotated, and the knee flexed to 20 degrees. Performing the exercise in this fashion is reported to allow the least amount of patellofemoral contact force while maximally stressing the vastus medialis component of the quadriceps muscle.[216,248,518] T e resistance is progressed from 0 to 5 lb.
- Straight leg raises performed into abduction with the thigh externally rotated to enhance strengthening of the gluteus medius.
- Low-resistance knee extension (short-arc quadriceps) exercises, performed with the leg externally rotated, from 50 to 20 degrees (avoiding terminal knee extension)

FIGURE 20-50 Short arc quad in external rotation.

(Fig. 20-50). During NWB knee extension, the amount of quadriceps muscle force required to extend the knee steadily increases as in the moves from 90 degrees to full knee extension. T e resistance is progressed from 0 to 5 lb.

- Hip adduction exercises performed in the side-lying position on the involved side (Fig. 20-51). T e exercise can also be performed with the hip internally rotated, and the knee flexed to 20 degrees.[135,519] T is position of knee flexion places the patella midway between the two femoral condyles.

Functional exercises that incorporate the entire lower kinetic chain are implemented as soon as tolerated. Kibler[520] advocates the following protocol:

- Active hip extension and quadriceps activation with the foot flat on the floor or stepping on or off a flat step (Fig. 20-52). T is reactivates the normal sequencing pattern for the entire leg.
- Isolation and maximal activation of the quadriceps in a CKC position by working with the foot on a slant board (Fig. 20-53), effectively removing the hip and ankle from full activation, but placing maximal load on the slightly flexed knee. Care must be taken not to exercise through pain as this may indicate that muscle control is insufficient.[145] During WB exercises, the quadriceps muscle force is relatively minimal when the knee is extended and steadily increases as the knee flexes.
- Unilateral stance with hip extension, slight knee flexion, and hip and trunk rotation.

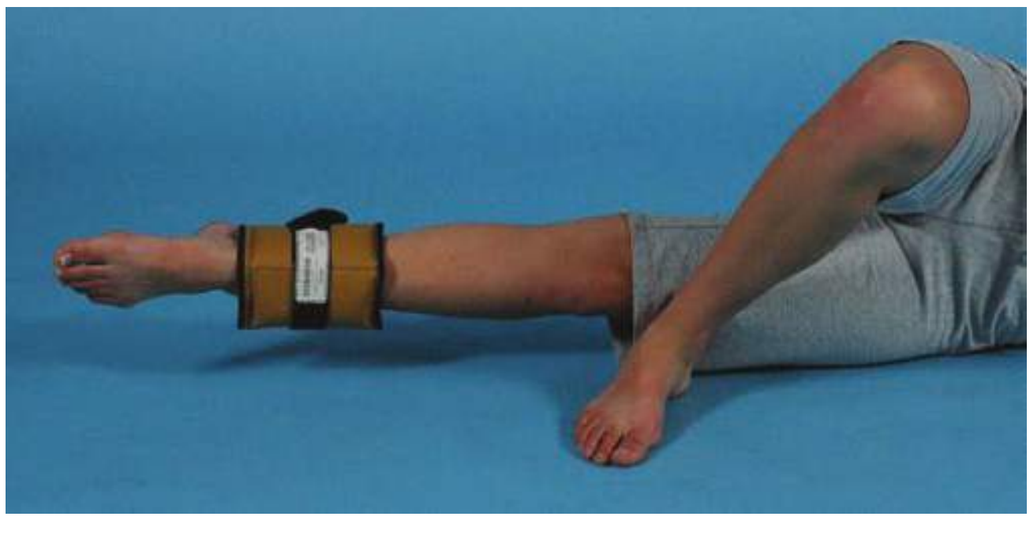

FIGURE 20-51 SLR into adduction.

FIGURE 20-52 Step downs.

T e correction of muscle inflexibilities is very important in the rehabilitative process. T is activity can be made more challenging using softer surfaces (Fig. 20-54).

Stretching of the quadriceps VIDEO hip flexors, ITB, lateral retinaculum, hamstrings, and gastrocnemius are usually initiated during this phase. T e rationale for stretching the ITB

FIGURE 20-53 Squat on slant board.

FIGURE 20-54 Unilateral stance on soft surface.

and lateral retinaculum is well recognized.[123,479,521] Adaptive shortening in the hamstrings and gastrocnemii has been associated with a compensatory pronation.[341] In addition, adaptively shortened hamstrings may cause increased flexion of the knee and increased patellofemoral compression forces, especially during the stance phase of gait.[319] Correction of muscle imbalances is based on a full analysis as to the effect that these interventions will have on the pathologic process, or on other structures within the kinetic chain. For example, stretching the hamstrings of an elderly patient to relieve the stresses at the knee may exacerbate the symptoms of lateral recess stenosis, because the adaptively shortened hamstrings may be helping to maintain the pelvis in a posterior pelvic tilt.[522]

Functional Phase

The functional phase of the knee rehabilitation program should be designed to addresses any tissue overload problems and functional biomechanical deficits once the painful symptoms have improved. During this phase, the patient gradually and incrementally increases joint-loading activities. As an approximation, patients typically progress to this phase when terminal knee extension exercises can be done with 25–30-lb weights.[124] Among the goals for this phase are to

- attain full range of pain-free motion;
- restore normal joint kinematics;
- improve muscle strength;
- improve neuromuscular control;
- restore normal muscle force–couple relationships.

ROM exercises during this phase include flexion and extension exercises; stationary cycling progressing to moderate resistance; and standing wall slides VIDEO. The stationary bike exercises are initially performed with a high seat (providing about 15 degrees of knee flexion in the extended leg).

There is controversy about whether knee exercises should be performed in an OKC or CKC manner.[250] CKCEs, such as the squat, leg press, dead lift, and power clean, have long been used as core exercises by athletes to enhance performance in sport.[523,524] These multijoint exercises have biomechanical and neuromuscular similarities to many athletic movements.[251] OKCEs appear to be less functional in terms of many athletic movements and primarily serve a supportive role in strength and conditioning programs. However, it is advised that a combination of the OKC and CKC exercises be used.

Closed-Chain Exercises

CKCEs during this phase include a continued progression of those exercises introduced during the acute phase. Other exercises are introduced including sideways step-ups (Fig. 20-55) and step-downs VIDEO, single knee toe raises VIDEO (Fig. 20-56) and dips, partial (Fig. 20-57) to full squats with added resistance,[479] the seated leg press, front and side lunges VIDEO (Fig. 20-58), jumping and landing exercises VIDEO (Fig. 20-59 and Fig. 20-60), Fitterboard exercises (Fig. 20-61), resisted walking in all four planes VIDEO (flexion, extension, abduction, and adduction) using elastic tubing (Fig. 20-62), balance activities VIDEO and obstacle jumping[525] VIDEO (Fig. 20-63).

In the presence of knee version, an adjunct to the usual exercise regimen may be strengthening of the internal tibial rotators (semimembranosus, gracilis, semitendinosus, sartorius), with greater emphasis placed on hamstring stretching,

FIGURE 20-55 One-quarter step-up to the side.

FIGURE 20-56 Single-leg heel raises.

particularly the biceps femoris, while adding stretching of the ITB.[305] CKCEs to strengthen the hamstrings, gastrocnemii, and quadriceps in a functional manner include a variety of exercises on a stair climber. T e patient stands on the machine backward for the quadriceps and forwards for the hamstrings.

FIGURE 20-57 Partial squat.

FIGURE 20-58 Resisted side lunges.

FIGURE 20-59 Jumping and landing.

FIGURE 20-60 Jump roping as a plyometric exercise.

FIGURE 20-61 Fitter board exercises.

FIGURE 20-62 Resisted walking exercise.

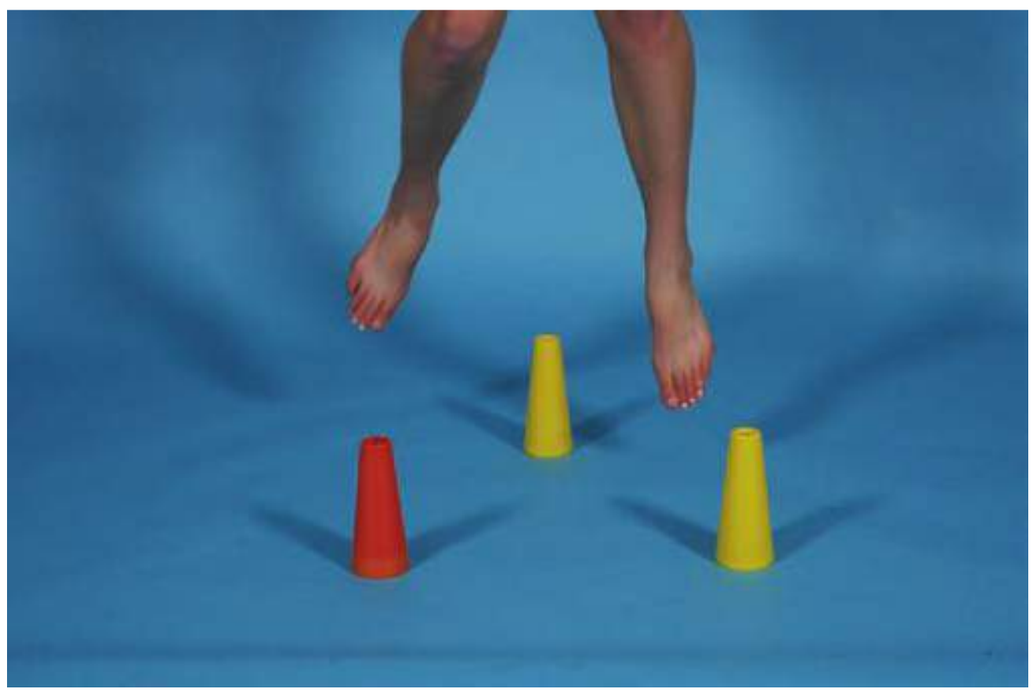

FIGURE 20-63 Obstacle jumping.

T e use of an inclined treadmill can also be used to selectively exercise the hamstrings, gastrocnemii, and quadriceps as follows:

- Walking or running downhill works the quadriceps eccentrically.
- Walking or running uphill works the gastrocnemii and hamstrings concentrically.
- Walking or running downhill backward works the gastrocnemii and hamstrings eccentrically.
- Walking backward uphill uses the quadriceps concentrically.

Uphill and retrotreadmill walking have been found to produce less PFJ restrictive forces than forward walking.[526]

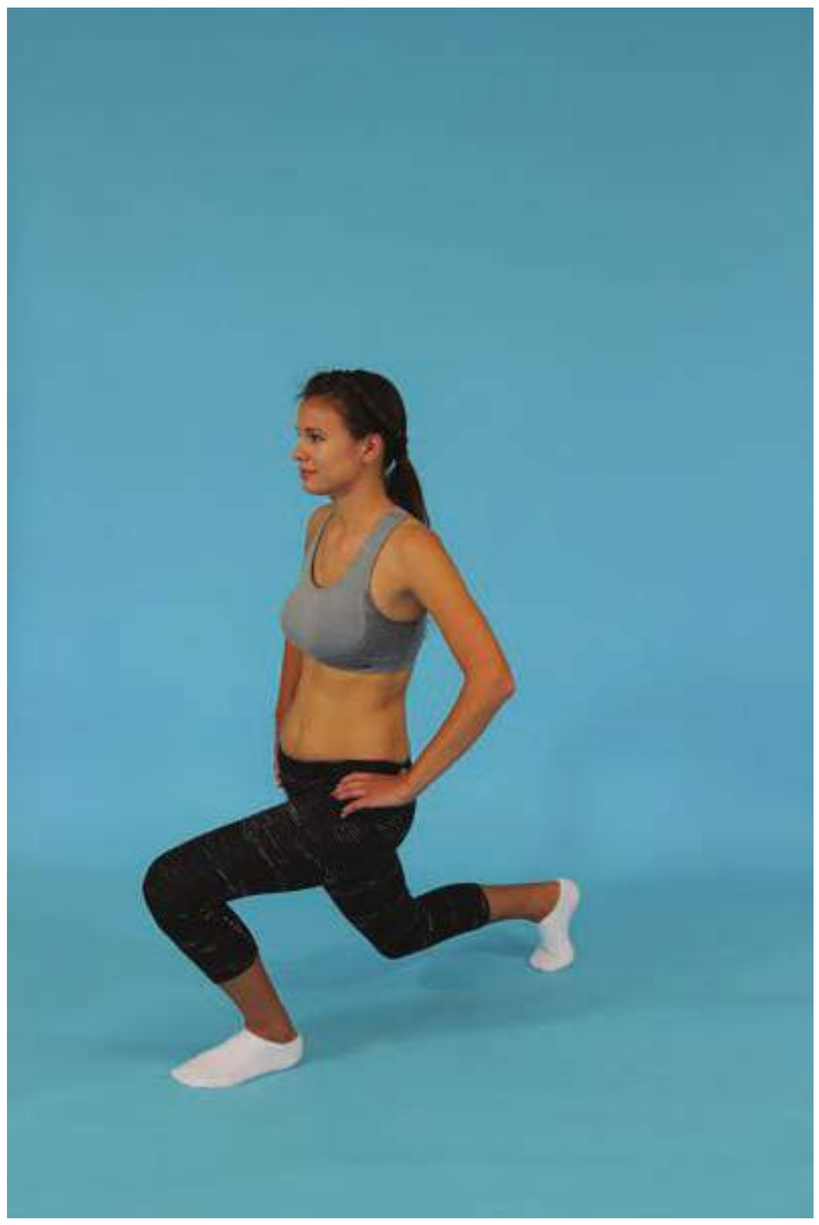

FIGURE 20-64 Stationary lunge.

For those patients with patellofemoral pain or weak hip abductors, hip abductor action can be facilitated during a lunge task by creating an adduction force using elastic tubing that the patient is instructed to counteract.

For the athletic population, the following closed-chain progression is advocated[238]:

- Stationary lunge. T e patient is positioned in standing with both feet together. Using one leg, the patient is asked to take a large step backwards while keeping most of the weight on the standing leg (Fig. 20-64). After 3–5 seconds, the patient is asked to slowly stand back up.
- Bulgarian split squat (Fig. 20-65).
- High box step-ups (Fig. 20-66).
- Stepping lunge. T is exercise incorporates and gradual progression of height for the advancing foot. T e exercise is initially performed on the level (Fig. 20-67), and then steps of varying heights are gradually introduced.
- Walking lunge with rotations (Fig. 20-68).
- T ree-way lunges—forward, sideways (Fig. 20-69A), and crossover (Fig. 20-69B).
- Split squat jump (Fig. 20-70).
- Split squat jump with a weight vest (Fig. 20-71A,B).

Open-Chain Exercises

OKCEs during this phase can include a wide variety of exercises including seated knee extension and knee flexion exercises that are viewed as single-joint, single-muscle-group exercises.[251] Using the knowledge of the compressive forces at the joint, OKCEs (e.g., short-arc quadriceps VIDEO, multiple-angle isometrics) should be performed in the 50–90-degree

FIGURE 20-65 Bulgarian split squat.

FIGURE 20-67 Stepping lunge.

or 90–50-degree range of knee flexion.[250,515] Other exercises include

- straight leg raises in all four planes (flexion, extension, abduction, and adduction), progressing to about 10% of body weight in resistance;
- supine leg lowering;
- seated leg lowering;
- short-arc quadriceps progression to about 10% of body weight in resistance; and

FIGURE 20-66 High box step-up.

FIGURE 20-68 Walking lunge with rotations.

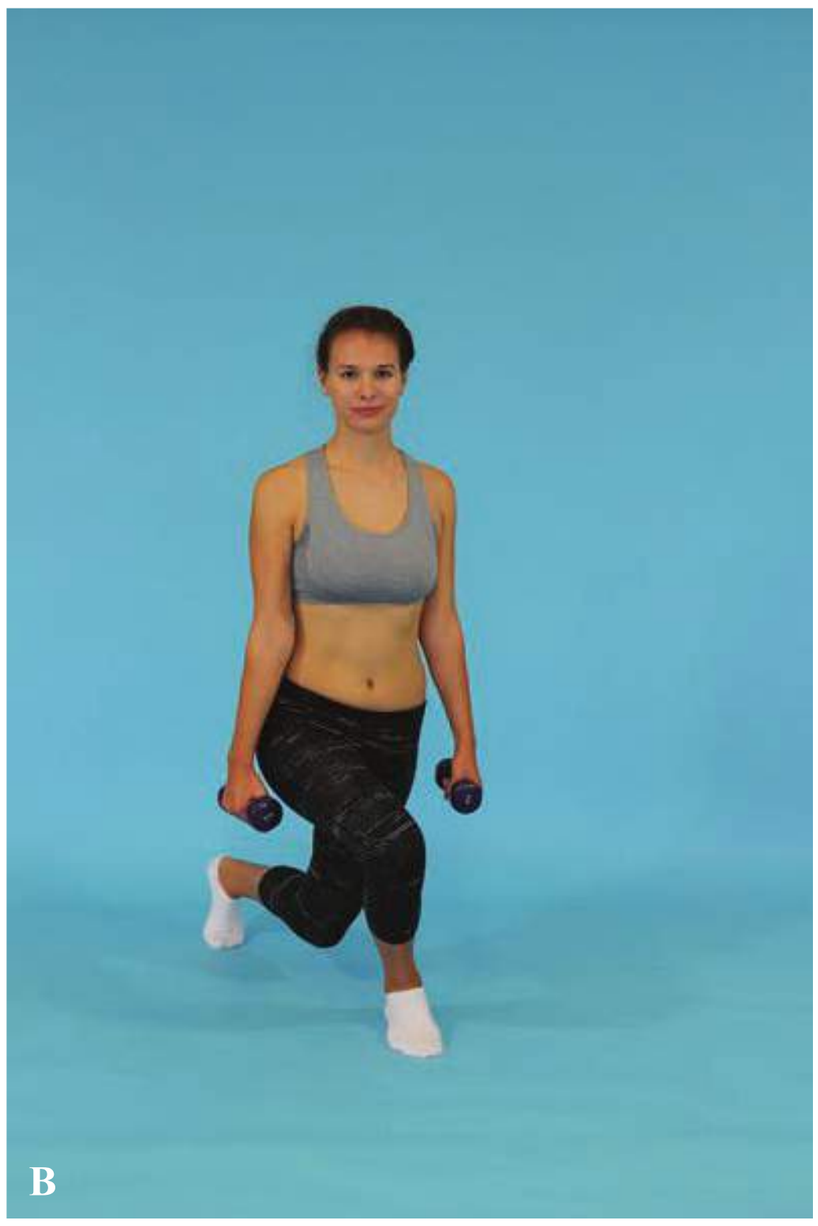

FIGURE 20-69 A,B: Three-way lunges—forward, sideways, and crossover.

- Side-lying (clam) exercise to strengthen the gluteus medius (see Chapter 19). T e patient is positioned in side lying with the hips and knees flexed to about 45 degrees. A piece of T eraband is wrapped around both sides, and the patient is asked to abduct and externally rotate the uppermost leg against the resistance of the T eraband.

FIGURE 20-70 Split squat jump.

Swenson et al.[527] recommend the use of the 4-minute OKC exercise for patellofemoral pain. T e exercise protocol was developed by Glen Porter, ATC, a basketball trainer at Michigan State University, MI, and Alan Glock, MD, an orthopaedic surgeon in Richmond, IN. T e exercise is performed as follows.

T e patient sits on the edge of a chair, with the upper leg supported. T e patient is asked to contract the quadriceps muscle with the knee in full extension. T e contraction is held for 1 minute, after which the leg is flexed to 45 degrees for 30 seconds. Four cycles of extension and flexion constitute the 4-minute VMO program. Initially, the exercise is performed four to six times a day. Ankle weights are added after 1–2 weeks and the number of sets is decreased.[527]

T e functional rehabilitation strategy should be to progressively improve 3D dynamic lower extremity postural stability. T is can be achieved using a multiplanar task progression integrating both NWB and WB lower extremity function.[155] An example of a NWB exercise is standing in unilateral knee flexion in conjunction with tibial internal rotation and hip external rotation, performed either actively or with a resistive band.[155] To make efficient use of elastic resistance, quick concentric activation should be followed by a slower eccentric activation.[155] For WB exercises, both forward and side lunges on varying surfaces can be used. Task speed can be progressively increased, and spontaneous responses can be achieved by having the patient respond to random cues to provide the direction of movement. Simultaneous use of different size and weight balls for catching and tossing may increase specificity and serve as a distractor to better assess the patient's true ability to maintain appropriate, well-controlled, 3D, dynamic, lower extremity postural stability.[155]

For some patients, return to sports may be a goal. Since strenuous activities may exert five times more force than is

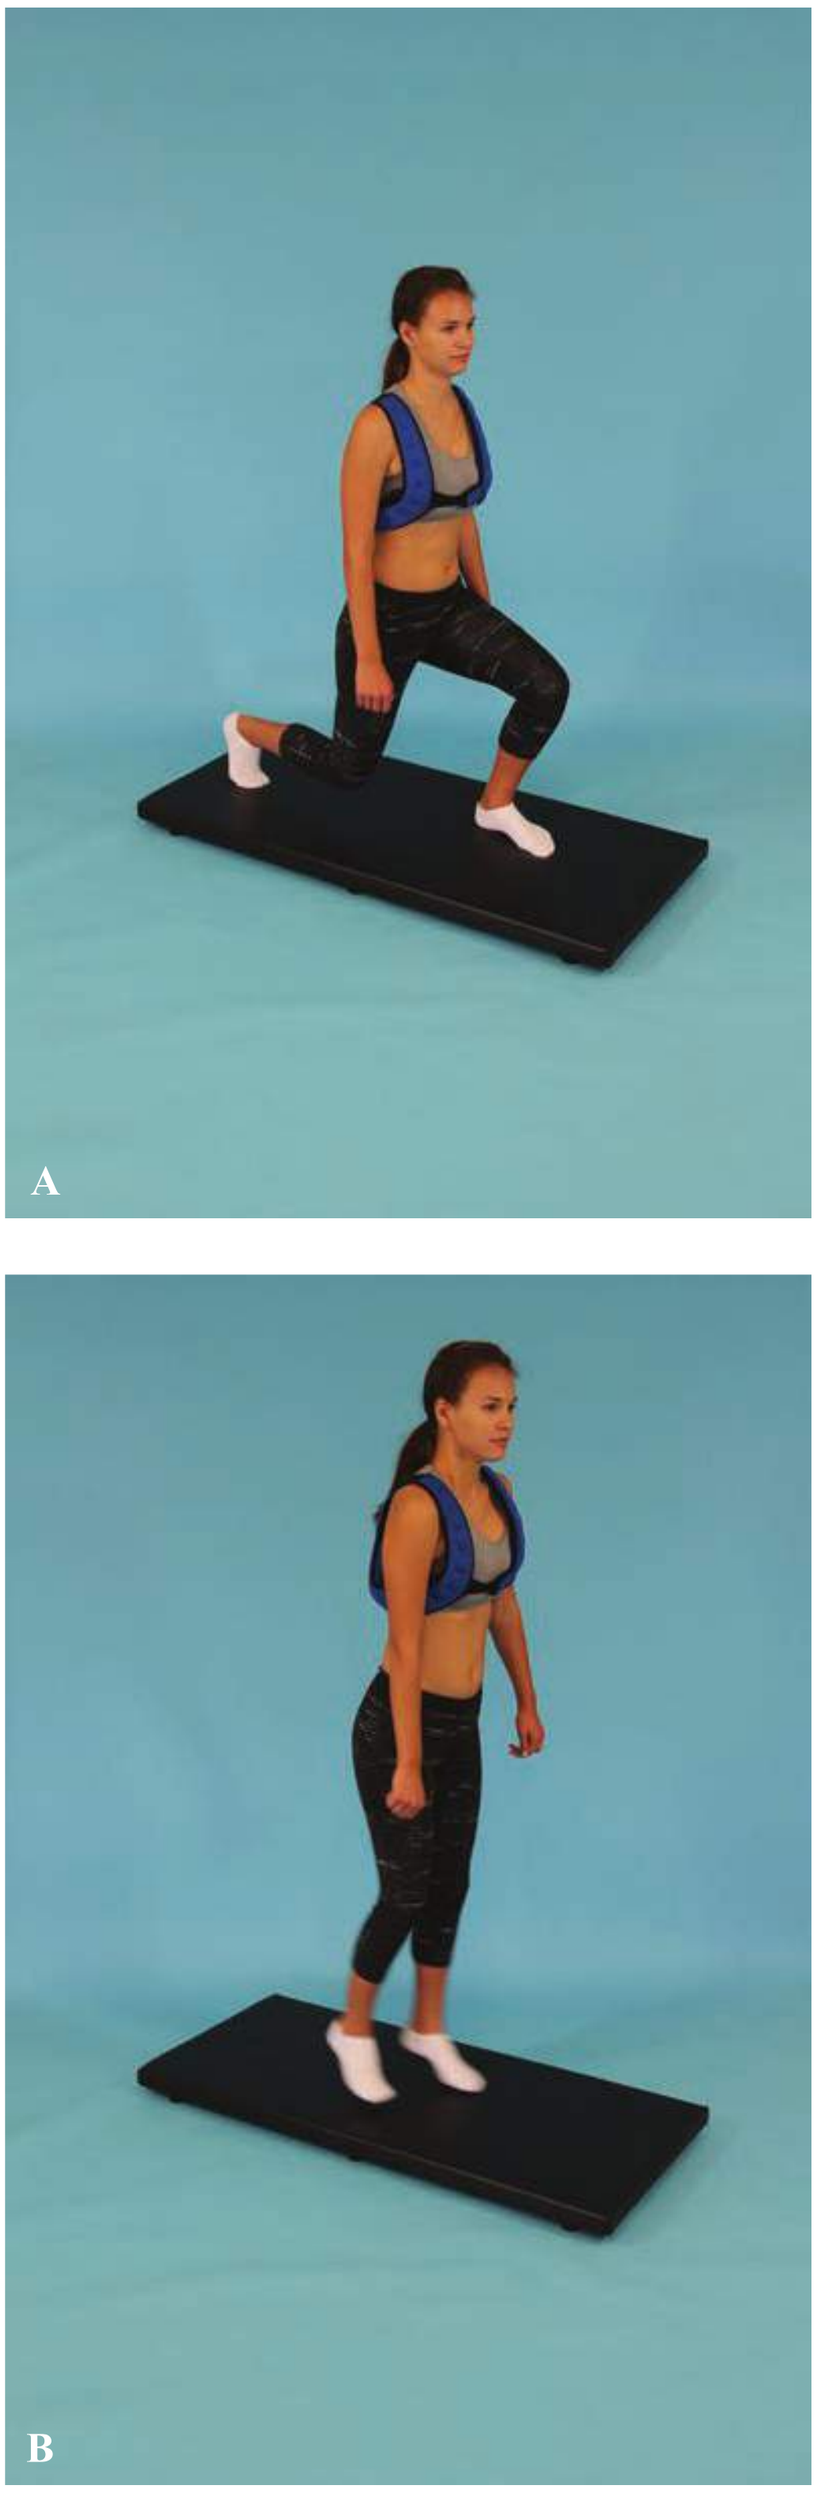

FIGURE 20-71 A,B: Split squat jump with weight vest.

imparted with the various ligament stress tests,[528] the clinician cannot rely on the results of the ligament stress tests as a means to assess a patient's readiness to return to sport. Once strength and endurance have reached at least 70% of the uninvolved extremity with isokinetic testing, the more advanced (PNF) exercises involving high-speed, high-force, uncontrolled movements are initiated, stopping short of cutting, jumping, and twisting maneuvers if symptoms of instability develop.[529,530] In addition, there must be an emphasis on plyometric exercises that closely resemble the intended sporting activity. Plyometric and balance training have been shown to improve drop jump kinematics in the sagittal plane.[531] Running, jumping, and twisting activities must be included in the clinical examinations of such patients to enable true assessment.[468] Criteria for progression into the return to sports phase include the following:

- Full AROM and PROM compared with the uninvolved knee. It has been suggested that the patient should have 8–118 degrees of knee motion, demonstrate a normal gait pattern, ascend and descend stairs, and demonstrate no gait deviation when running, before participating in athletic activity.[470,532]
- A quadriceps-to-hamstring ratio of 2:3 and equal to or greater than 75% of the uninvolved leg.
- Ability to perform a one-leg squat for 15–20 repetitions.
- Normal joint kinematics.

A return to cutting sports at the competition level is permitted when the quadriceps strength index is 85–90% of the uninvolved leg at 60 degrees per second with isokinetic testing. Sport-specific drills are added late in the functional phase as the athlete approaches return to play. Activity-specific progressions must be completed to test all of the working parts involved in the activity before a full return to function is advised.

Bracing

Patellofemoral Bracing

External patellar supports are commonly employed in the management of patellofemoral pain as an adjunct to other intervention methods. Although they relieve symptoms in many patients, their mode of action remains theoretical, and their usefulness is unpredictable.[283]

Theoretically, the brace is designed to centralize the patella within the patellar groove, thereby reducing symptoms and improving function.[488,533] The various commercially available patellofemoral braces use a number of methods to improve patellar tracking, including patellar cut-outs, lateral buttresses, air bladders, and positioning straps.

Despite the wide use of patellofemoral bracing, only a few studies have attempted to document their effectiveness in correcting patellar alignment. Using MRI, Koskinen and Kujala[534] reported a quantitative decrease in lateral patellar displacement using the safety brace (Axini, Boliden, Sweden), while Worrell et al.[535] found that the Palumbo brace (Dynorthotics LP, Vienna, VA) reduced lateral patellar displacement and increased patellofemoral congruence at 10 degrees of flexion. These studies, however, used static imaging techniques and, therefore, actual patellar tracking was not assessed. This is an important limitation because patellar tracking is considered to be a dynamic entity. Studies comparing active and passive procedures have shown that patellar motion is significantly influenced by the degree of quadriceps contraction.[227,283,536,537] Finestone et al.[538] found that some braces were less effective and more harmful to the skin than conservative therapy (i.e., maintaining activity and

avoiding pain-causing activity, or no therapy, or simple muscle stretching and strengthening).[539]

Although it is debatable whether bracing can influence patellar tracking, it appears that external supports must, in some way, interact mechanically with the PFJ because many patients report significant clinical improvements.

Tibiofemoral Bracing

Functional knee braces are commonly prescribed following an ACL injury or reconstruction to promote healing, by reducing anterior translation of the tibia with respect to the femur and thereby restoring normal joint kinematics.[20,540,541]

The efficacy of knee bracing with regard to providing adequate protection is controversial because the compliance of the soft tissues around the thigh decreases the ability of the brace to function correctly, particularly at high loads.[541,542]

A study by Fleming et al.[541] using the Legend brace (DJ Orthopaedics LLC, Vista, CA) indicated that a functional knee brace can protect the ACL during anteroposterior shear loading in the NWB and WB knee and during internal torques in the NWB knee. However, this study used only one brace and one knee-flexion angle (20 degrees).

Risberg et al.,[543] who used randomized, prospective clinical trials of bracing after ACL injury or reconstruction, found no difference in joint laxity, pain, muscle strength, and functional knee tests between patients who wore a functional knee brace and those who did not wear a functional brace during postsurgical rehabilitation.

Several studies have indicated that subjects with chronic ACL-deficient knees have impaired proprioception.[544–546] Whether functional knee braces enhance proprioception in ACL-deficient knees remains unclear. Although a few studies have addressed the relationship between proprioception and functional outcome measures,[544,545] the studies that have compared the effect of functional braces on proprioception between ACL-reconstructed knees and the contralateral uninvolved knee have as yet demonstrated no improvement in proprioception with the wearing of such braces,[547] and no effect on long-term outcome.[20]

Interestingly, bandaging of the knee, or the use of a neoprene brace, has been shown to improve proprioception in both normal individuals and those with different types of knee disorders, including knee OA and an ACL tear.[20,548]

Taping

The primary goal of taping[196,549] is to pull the patella away from a painful area, thereby unloading it and reducing pain, rather than as an adjustment for patellofemoral malalignment.[479,550,551] The extent to which this is possible and the amount of displacement required to provide pain relief varies from patient to patient and from study to study (Table 20-19).[10] Indeed, the displacement does not need to be perceptible to effect improvement. Bockrath et al.[550] found that taping did affect perceived pain but was not associated with patellar position changes. A recent computed tomography (CT) study,[550] involving 16 female

TABLE 20-19 The Effects of Patellofemoral Taping on Patellofemoral Pain

Investigators	Study Design	Number of Interventions	Percentage Improvement and Clinical Importance
Eburne and Bannister[a]	Single-blind randomized control trial	3 months or until pain-free	Both groups 50%—no clinical importance
McConnell[b]	Experimental	Eight sessions	92%, no control—could not determine
Gerrard[c]	Experimental	Five sessions	96%, no control—could not determine
Powers et al.[d]	Experimental	One session	78%, no control—clinical importance
Salsich et al.[e]	Experimental	One session	92.6%, no control—clinical importance
Bockrath et al.[f]	Experimental	One session	54%, no control—clinical importance
Kowall et al.[g]	Randomized control trial	Eight sessions over 1 month	44%, no control—no statistical difference between groups but clinical importance
Clark et al.[h]	Single-blind randomized control trial	Six sessions (five taping sessions)	No statistical difference between groups or clinical importance

patients (aged 16–25 years) who had anterior knee pain related to patellofemoral incongruence, evaluated the effect of patellar taping on patellofemoral incongruence. The subjects underwent CT examination with their quadriceps muscles relaxed and contracted, both before and after patellar taping. The study found that patellar taping did not significantly affect patellofemoral lateralization, or tilt, and concluded that although patellar taping may well be effective in controlling anterior knee pain, it does not do so by medializing the patella.[552] Another study found that McConnell taping was effective in moving the patella medially but ineffective in maintaining this difference after exercise.[553]

A secondary function of taping is to increase the beneficial proprioceptive characteristics of the PFJ.[554,555] Grabiner et al.[556] have postulated that the VMO needs time to develop force, relative to the VL, to optimally track the patella. This lag time can cause the patella to track laterally. By applying tape across an overly powerful VL, the clinician may be able to change the relative excitation of the VMO and VL, diminishing the pull of the VL,[10,196,549] although the mechanisms by which this works are unknown.

One other function of taping for malalignment of the patella is to position the patella optimally so that the area of contact between the patella and femur is maximized.[282] This position places the patella parallel to the femur in the frontal and sagittal planes, and the patella is midway between the two condyles when the knee is flexed to 20 degrees.[282]

Once the tape is applied, the clinician assesses the following:

- The overall limb alignment. This includes an assessment when walking normally, on the heels, and with the feet in the inverted and everted positions; stair climbing; and squatting.
- The effect on functional painful and pain-free ranges.

From this information, the patellar position is adjusted by taping. The most obvious deviation is always corrected first. The glide component can be corrected by firmly gliding the patella medially and taping the lateral patellar border (Fig. 20-72). The tilt component can be corrected by firm taping from the middle of the patella medially, which lifts the lateral border and provides a passive stretch to the lateral structures (Fig. 20-73). To correct external rotation of the patella, firm taping from the middle inferior pole upward and medially is required. For correction of internal rotation, firm taping from the middle superior pole downward and medially is needed.

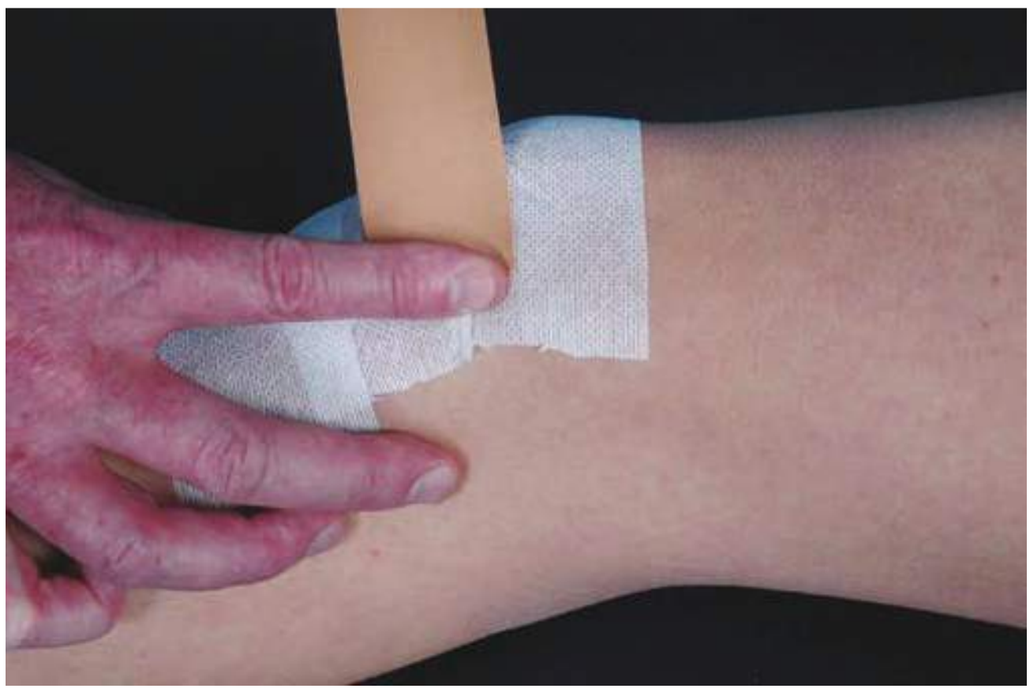

FIGURE 20-72 Patellar taping for correction of tilt.

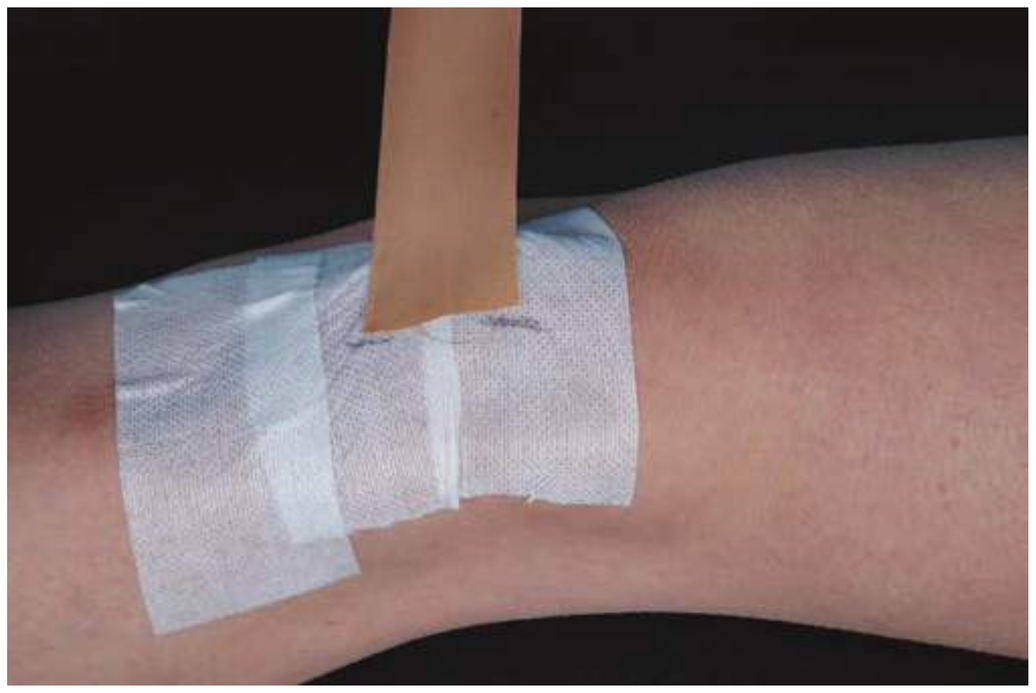

FIGURE 20-73 Patellar taping for correction of glide.

In addition to the taping, biofeedback, stretching of the lateral structures, and a home exercise program are recommended. For a more detailed description of the application of the tape, the reader is referred to an excellent book, The Patella: A *Team* Approach.[195]

Lesher et al.[557] attempted to determine the predictive validity and interrater reliability of selected clinical examination items and to develop a clinical prediction rule (CPR) to determine which patients would respond successfully to a medial glide patellar taping technique. A CPR is, by definition, an optimum number of clinical examination items use for predicting a diagnosis or prognosis. Two examination items (positive patella tilt test or tibial varum > 5 degrees, + LR = 4.4 [95% CI = 1.3–12.3] and a −LR of 0.53 [0.38–0.86]) comprised the CPR. Application of the CPR improved the probability of a successful outcome from 52% to 83%. As the CPR in this study represented a level IV CPR, it requires validation in a separate sample before it can be implemented on a broad basis.[558]

Taping can also be used with patients who have patellar OA. A controlled clinical trial[559] found that patients achieved a significant reduction in pain after medial knee taping to realign the patella.

Walking Poles

Results from a number of studies[560–562] have demonstrated that walking poles reduce the forces to the lower extremity during level walking when walking velocity is controlled. Schwameder et al.[563] reported 12–25% reduction in peak and an average ground reaction force, knee joint moments, and tibiofemoral compressive and shear forces walking down a 25-degree gradient.

A study by Willson et al.[560] found that the use of the poles tended to reduce the vertical joint reaction forces at the knee over the no-poles condition. Differences of 4.4% were found in vertical joint reaction forces at the knee between the no-poles, pole-back, and pole-front conditions.[560] However, knee extensor angular impulse was greater with all pole conditions compared with no-poles. Thus, walking with poles caused a more flexed knee position through stance, reducing the vertical bone-on-bone forces and increasing the internal (muscular) knee extensor kinetics.[560] This is reduction of lower extremity stress during a faster walking velocity may symbolize a less

harmful mode of exercise for healthy and pathologic populations alike. T us, the use of walking poles may lead to an increased training stimulus as a result of the greater walking velocity and reduced lower extremity loading conditions compared with a self-selected walking velocity.[560]

PREFERRED PRACTICE PATTERN 4C: IMPAIRED MUSCLE PERFORMANCE

Patellofemoral Pain Syndrome

PFPS, a common reason for referral to physical therapy, is one of the most common overuse injuries of the lower extremity, affecting 10–20% of the general population.[564] PFPS is worsened by sitting, climbing stairs, inclined walking, and squatting.[565]

Although PFPS can occur in anyone, women have a higher prevalence than their male counterparts (2:1), with an even higher incidence within the population for athletic women (4:1).[566] As mentioned in the Biomechanics section, imbalance of the quadriceps musculature and maltracking of the patella are two potential factors that may lead to PFP. Other cited reasons include onset timing of vasti muscles, knee extensor strength, structural abnormalities, and other kinematic variables.[567] It has been proposed that PFPS is the result of elevated PFJ stress.[568] Stress is defined as force per unit area (see Chapter 2). T us, elevated PFJ stress could occur as a result of an increase in the PFJ reaction force and/or a decrease in contact area between the patella and the trochlear groove of the femur. In turn, an increase in the PFJ reaction force could occur with an increase in the knee extensor moment and/or knee-flexion angle.[569–571] Additionally, PFJ contact area increases with knee flexion and decreases with knee extension.[571,572]

As PFPS is a multifactorial condition, classification systems can be used to aid in proper diagnosis based on impairment. To help in the determination of the classification, the clinician must answer the following questions:

- Is the problem truly related to the PFJ or its related structures?
- Is a muscle imbalance present?
- Is inflammation present?
- Is instability present?

Determining the classification gives significant guidance to intervention options. Patellofemoral instability, especially recurrent, usually requires surgical intervention, whereas patellofemoral pain resulting from inflammation, or a muscle imbalance, usually responds well to conservative intervention.[302] T e term malalignment implies that the static or dynamic restraints of the PFJ are insufficient to allow normal patellar tracking. Malalignment appears to be a necessary but not sufficient condition for the onset of PFJ pain.[572a] Symptoms seem to be set off by a trigger, or combination of structural and dynamic factors, the nature of which varies from patient to patient.[302,572a] An altered lower extremity movement pattern, which is termed dynamic knee valgus (see "Biomechanics"), has been implicated in the pathogenesis of PFPS. It has been suggested that altered hip, knee, foot, and ankle kinematics combine to result in the excessive medial collapse of the lower extremity during various functional activities.[185] While such altered movement patterns can be detected using 3D motion analysis, this is usually not practical. A study by Rabin et al.[573] recommends using the lateral step down test to rate the quality of movement based on the alignment of the trunk, pelvis, and knee. T e study reported that WB dorsiflexion ROM was more limited among participants with a moderate quality of movement compared to those with a good quality of movement and that those with good quality of movement had greater hip external rotator and knee extensor muscle strength compared with those with a moderate quality of movement.[573]

Anatomic Variance

A number of anatomic features appear to have an impact on the function of the PFJ and subsequent dysfunction:

- Femoral trochlear dysplasia.
- Patellar morphology and the amount of congruence of the PFJ
- T e natural positioning of the patella (alta or baja)

Gender

A commonly cited reason as to why women have more anterior knee pain than men is the difference in the orientation and alignment of the lower extremity. T e broader pelvis of the female moves the hip joints farther lateral relative to the mid-line. T is produces an increased valgus angle from the hip to the knee and then to the ground. Females also have a higher prevalence of increased femoral anteversion, which also increases the valgus angle. Although the increased valgus thrust on the patella is not necessarily a problem, it increases the tendency for excessive lateral pressure on the patella, which then can lead to retinacular stress around the patella and, in some people, concavity of the lateral facet and anterior knee pain.

Tibial Rotation

T e Q-angle can be influenced distally through motions of the tibia. For example, external rotation of the tibia moves the tibial tuberosity laterally, thereby decreasing the Q-angle, whereas tibial internal rotation increases the Q-angle by moving the tibial tuberosity medially.

Subtalar Joint Position

Tibial rotation is influenced by subtalar joint motion. For example, subtalar joint pronation causes internal rotation of the tibia, whereas subtalar joint supination causes the tibia to rotate laterally.

Femoral Rotation

As with tibial rotation, the Q-angle can be influenced by motions of the femur. For example increased femoral internal rotation results in a larger Q-angle, whereas femoral external rotation minimizes the Q-angle.

Muscle Imbalances

T e impairments resulting from patellofemoral dysfunction have been related to problems that cannot be improved by

physical therapy and those that can. EMG evidence of poorly coordinated muscle activation has been documented in other joints. At the knee, the VMO may be proximally positioned and abnormally oriented, and the timing of its contractions may be poorly synchronized with those of the surrounding muscles.[574–576] Because coordinated firing of the dynamic stabilizing muscles is important for the normal functioning of the PFJ it would be reasonable to assume that physical therapy would be of benefit to enhance the dynamic stabilizers. T us, the intervention for a maltracking patella must seek to restore the balance of force production of the medial and lateral stabilizers of the PFJ and to attempt the reestablishment of functional control of the VMO (see "Intervention Strategies").[574–576] In addition, the clinician must assess and address strength deficits of the proximal hip musculature, particularly the hip abductors. Several studies have reported that females with PFPS demonstrate weakness of the hip external rotators and hip abductors.[577–579] It is theorized that during functional activities, especially single-leg activities, the hip muscles prevent hip adduction and internal rotation, which may result in dysfunctional lower extremity joint alignment and can lead to the development of PFPS.[580] In addition, it is been suggested that the hip muscles may control the amount of hip adduction and internal rotation that can lead to a greater dynamic knee valgus. A recent study by Ramskov et al.[581] found that, among novice runners, a level of peak eccentric hip abduction strength that is higher than normal may reduce the risk of PFP during a self-structured running program.

Landing Pattern

Approximately 75% of runners make initial contact with the ground using a rear foot strike pattern,[582] which results in a very distinctive vertical impact peak. T is force peak may be eliminated or significantly reduced with the midfoot strike or forefoot strike landing pattern.[583]

Intervention

Some patient characteristics are known to be related to the prognosis in those with PFPS including a longer duration of knee complaints, gender (females have the poorer prognosis), older age, lower function, bilateral symptoms, and greater difference in side to side knee extension strength.[584] T e intervention for PFPS is based on the cause. Typical rehabilitation goals for an individual with PFPS include:

- anti-inflammatory measures;
- stretching of the lateral retinacular structures;
- improve lower extremity strength, especially the strength of the knee extensors (including the VMO), and hip extensors, abductors, and external rotators. While some studies have suggested that quadriceps strengthening exercises should be emphasized to improve knee pain,[585,586] a 2012 systematic review[587] concluded that multimodal treatments that address factors proximal to the PFJ, in addition to quadriceps strengthening, are preferred to improve pain in patients with PFPS. T ere is strong evidence that individuals with PFPS have weakness of the hip abductors, external rotators, and extensor muscles as well as less trunk side flexion strength.[217,588] Indeed, a randomized clinical trial with one year follow-up by Fukuda et al.[589] concluded that knee stretching and strengthening exercises supplemented by hip PL musculature-strengthening exercises were more effective than knee exercises alone in improving long-term function and reducing pain in sedentary women with PFPS. Strengthening exercises for the PL hip musculature included hip abduction in side lying, hip external rotation, hip abduction in standing, and hip extension in standing. In addition, a more recent study by Baldon et al.[588] reported that an intervention program consisting of hip muscle strengthening and lower limb and trunk movement control exercises was more beneficial in improving pain, physical function, kinematics, and muscle strength compared to a program of quadriceps-strengthening exercises alone.
- Patellar taping techniques;
- stretching of the hamstrings, hip flexors, quadriceps, gastrocnemius, and ITB;
- activity modification through minimization of stair ambulation, prolonged sitting, and deep knee squats.

Care must be taken to minimize PFJ loading while using both CKC and OKC exercises. For example, converting from a rear foot to a forefoot or midfoot strike pattern has been promoted as a means to reduce the peak impact force, loading rate, and knee extensor moment while running.[571,583] Furthermore, barefoot running, which typically results in a forefoot or midfoot strike pattern, has been reported to decrease peak PFJ stress by 12% in asymptomatic runners.[590] In addition, a forward trunk lean posture has been found to be associated with lower knee extensor moments while running, walking, stair ascent, and single-leg-hop landing.[571,591–593]

Patellar Compression Syndromes

Patellar compression syndromes result from an overconstrained patella whose motion is severely restricted by surrounding soft tissues. Two compression syndromes are commonly cited: LPCS and infrapatellar compression syndrome (IPCS).

Lateral Patellar Compression Syndrome[126,141,194,594]

LPCS results from a tight lateral retinaculum, which in turn results in a patellar tilt and excessive pressure on the lateral patellar facet, producing the excessive lateral pressure syndrome.[281] T e patient typically complains of pain over the lateral retinaculum.[194,595,595] T e diagnosis is confirmed clinically by a decreased medial patellar glide and evidence of a lateral patellar tilt.

T e medial stabilizers play a role in the lateral pressure syndrome, and the VMO frequently becomes atrophied, probably as a result of the new patellar position, the associated pain, and the resultant inflammation.[123,194,340] T e major long-term problem with excessive lateral pressure syndrome is a chronic imbalance of facet loading and the subsequent effect on the articular cartilage and surrounding soft tissue.

Fortunately, this condition seems to respond well to a conservative approach consisting of[340]

- stretching of the lateral retinacular structures;
- patellar taping to correct the excessive lateral tilt and to apply a long duration, low-load stretch of the lateral retinaculum;
- stretching of the hamstrings, quadriceps, and ITB;
- strengthening of the VMO;
- anti-inflammatory measures; and
- activity modification through minimization of stair ambulation and deep knee squats.

Infrapatellar Compression Syndrome[597]

IPCS, also referred to as global patellar pressure syndrome,[340,360] is characterized by a painful restriction of patellar movement because both the medial and lateral retinaculum are excessively tight. This restriction may result in a decrease in knee flexion and extension.[340]

The development of this condition appears to be related to direct trauma and subsequent pathologic fibrous hyperplasia in the peripatellar tissues or secondary to prolonged immobilization after surgery.[360]

Early detection of IPCS is important because it is amenable to nonsurgical intervention. Rehabilitation should be initiated with early patellar mobilization, stretching of the hamstrings, hip flexors, quadriceps, gastrocnemius, and ITB, with the emphasis on restoring full knee extension. Other components should include active ROM, multiangle isometric strengthening of the quadriceps, neuromuscular stimulation, transcutaneous electrical nerve stimulation (TENS), and NSAIDs. When performing the patella mobilizations, the glides should be held for a long duration (1–12 minutes) to enhance the remodeling of the soft tissue.[340,598] Activities such as bicycling, resisted knee extensions, deep knee bends, or deep squats (beyond 60 degrees) should not be initiated until patellar mobility is restored to prevent excessive patellar compression and PFJ contact pressures.[340]

PREFERRED PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Articular Cartilage Defects

Articular cartilage-related injuries affect approximately one million patients each year within the United States[599] and pose a significant problem due to poor healing and long-term disability.[600] In two large-scale studies of more than 25,000 knee arthroscopies, 60% of the operated knees demonstrated articular cartilage defects.[601] In the short term, these defects may lead to a loss of function and a significant decline in activity participation.[602] Since nonoperative rehabilitation and palliative care for this condition are frequently unsuccessful, many patients opt for surgical procedures designed to facilitate the repair or transplantation of autogenous cartilage tissue.[603] Reparative techniques include the following:

- Arthroscopic lavage and debridement. This procedure is performed to reduce the inflammation and mechanical irritation within a given joint. Debridement can include smoothing of the fibrillated articular or meniscal surfaces, shaving of motion-limiting osteophytes, and removal of inflamed synovium.[604]
- Microfracture. The surgical objective of microfracture is the controlled perforation of the subchondral bone plate to permit an efflux of pluripotent marrow elements into a chondral defect.[605]
- Autologous osteochondral mosaicplasty grafting. This is a method to transplant bone and hyaline cartilage, using small osteochondral plugs, to a region of the chondral or osteochondral defect.
- Autologous chondrocyte implantation (ACI). This is a cartilage restorative procedure in which a concentrated solution of autologous chondrocytes is implanted into a defect with the goal of restoring hyaline cartilage to the injured area.[604]
- Osteochondral autograft transfer (OAT). Osteochondral autograft is most clearly indicated for a symptomatic, unipolar lesion of the distal femoral condyle in a nondegenerative joint that has proper limb alignment, as well as ligamentous stability and meniscal competence.[604]
- Osteochondral allograft transplantation. In contrast to OAT, osteochondral allograft transplantation relies on tissue taken from cadaveric donors rather than from the patient's own knee. The benefits of allografting include the elimination of donor site morbidity and the ability to provide fully formed articular cartilage without specific limitation with respect to defect size. The drawbacks to the procedure are graft availability, cell viability, immunogenicity, and risk of disease transmission.[604]

A 2010 systematic review[605] evaluated the influence of patient characteristics, defect characteristics, and surgical factors on patient-reported outcomes and return to pre-injury activity levels following surgical cartilage procedures in the knee. The review found that younger patient age, smaller defect size (less than 2 cm), preoperative duration of symptoms less than 18 months, higher levels of activity (preinjury and postsurgery), and no prior surgical treatment all correlated with improved outcomes following articular cartilage surgical procedures.[605] However, return to preinjury activity levels remains moderate (66–68%).[605] This would tend to indicate that the best possible outcome following surgical procedures to address articular cartilage defects not only requires optimization of the surgical technique for a given individual and defect, but also requires optimization of the rehabilitation program following the surgical procedure.[606]

The postsurgical rehabilitation progression can either be accelerated (for WB by 8 weeks) or traditional (for WB by 11 weeks). The traditional rehabilitation progression is designed

based on the four biologic phases of cartilage maturation: proliferation, transitional, remodeling, and maturation. The duration of each phase that follows varies depending on the lesion, patient, and the specifics of the surgery.[603]

- Proliferation phase. This phase generally lasts 4–6 weeks following surgery. The goals during this phase are to protect the repair, decrease swelling, gradually restore PROM and WB and to enhance volitional control of the quadriceps.
- Transition phase. This phase typically consists of weeks 4 through 12 postsurgery. During this phase, the patient progresses from partial to full WB while full ROM and soft-tissue flexibility are achieved.[603] It is during this phase in which patients typically resume most normal activities of daily living.
- Remodeling phase. This phase generally takes place from 3 to 6 months postoperatively. At this point, the patient typically notes improvement of symptoms and has normal ROM. During this phase, low-to-moderate impact activities, such as bicycle riding, golfing, and recreational walking, are gradually incorporated.
- Maturation phase. This phase begins in a range of 4–6 months and can last up to 15–18 months postsurgery. The duration of this phase varies based on lesion size and location, and the specific surgical procedure performed.

Interestingly, a systematic literature review by Schmitt et al.[606] reported that surgical repair and restoration of articular cartilage defects showed positive outcomes in terms of patient's symptoms, but that there is limited evidence regarding functional outcomes, particularly with regard to quadriceps strength deficits, gait deviations, and deficits/asymmetries in performance-based function.

Tibiofemoral Osteoarthritis

Tibiofemoral OA has been acknowledged as the most common cause of disability in the United States.[607] Ten percent of persons older than 55 years are affected by painful, disabling tibiofemoral OA of the knee, of whom 25% are severely disabled.[608]

OA may affect one or more of the three compartments of the knee: medial tibiofemoral, lateral tibiofemoral, and patellofemoral.

OA has long been regarded as a "wear-and-tear" or "degenerative" condition associated with certain occupations and life choices and an increased prevalence with advancing age. Recognized risk factors include physically demanding occupations, particularly jobs or sports that involve kneeling or squatting, older age, female sex, evidence of OA in other joints, obesity, and previous meniscal injury (see "Meniscal Tears") or surgery of the knee.[609]

The clinical findings of OA at the knee include swelling, which can vary from minimal to severe, depending on the clinical stage and severity. The joint can also be warm to touch, although that again depends on the stage and severity. Usually, the patient reports pain with WB activities and, at times, pain at rest. The loss of motion, if present, is typically in a capsular pattern. Muscle weakness is probably the longest documented and best established correlate of functional limitation in individuals with OA, particularly with knee OA.[610–613]

Physical activity and weight loss has been recognized for several years as being of benefit in the management of knee OA.

Physical therapy has been shown in many clinical trials to result in a improvement of symptoms and physical function in patients with OA,[614–617] and exercises to strengthen the quadriceps are becoming established as a useful adjunct in the treatment for OA of the knee.[618] Increasing muscle strength may reduce the loads applied to the knee joint during functional movements,[619] and also improve the stability of the knee joint.[620] Although there is agreement that strengthening exercises can be helpful, the effect of exercise therapy on pain, quadriceps strength, and physical function appears to be small to moderate in most clinical trials. Deyle et al.[494] conducted a randomized trial comparing the use of manual therapy techniques to the knee, hip, foot and ankle, and lumbar spine combined with exercises for lower extremity strengthening, ROM and endurance to a group of patients with knee OA that received a placebo ultrasound treatment. The study concluded that patients with OA of the knee who were treated with manual physical therapy and exercise experienced clinically, and statistically significant improvements in self-perceptions of pain, stiffness, and functional ability, and the distance walked in 6 minutes. The beneficial effects of the intervention, which were achieved in eight clinic visits, persisted at 4 weeks and 1 year after the conclusion of clinical treatment.[494] An important aspect of the treatment described by Deyle et al. was that the impairments that were present at other joints in addition to the knee were addressed. This emphasizes the need to evaluate and address a variety of problems that a patient with knee OA may have to optimize the response to treatment.[621]

In addition to the exercises that recover lower extremity strength, ROM, and cardiovascular endurance, it is now being recommended that therapy programs also include techniques to improve balance and coordination and provide patients with an opportunity to practice various skills that they will likely encounter during normal day activities.[622]

Other conservative interventions for OA of the knee include NSAIDs, cortisone injections, patient education, weight loss, and thermal modalities.[494,618] The use of shoes with a well-cushioned sole is recommended, as are frequent rest periods during the day. Wedged insoles with an angle of 5–10 degrees on a frontal section have been shown to be helpful for OA of the medial compartment knee OA.[623,624] The patient is instructed in principles of joint protection, and advised to seek alternatives to prolonged standing, kneeling, and squatting.[618]

CLINICAL PEARL

Isokinetic and other exercises must be prescribed carefully to avoid excessive compressive forces or shear forces at the knee.

Total Knee Arthroplasty

More than 3.4 million total knee arthroplasties (TKAs) are expected to be performed by 2030.[625] The main reasons for undergoing a TKA are pain and physical limitations caused by knee OA, although the procedure can also be used to correct knee instability and lower extremity alignment and for the treatment of isolated but severe patellofemoral disease.[67]

TKA has been shown to be an effective long-term intervention for the elderly population to relieve knee pain, improve function, increase social mobility and interaction, and contribute to psychological well-being.[626] However, the recovery of strength and function to normal levels is rare.[627]

Since TKA is generally contraindicated in younger and more active patients, those with unicompartmental OA of the knee may be considered candidates for a high tibial osteotomy or a distal femoral osteotomy. The high tibial osteotomy is used with isolated medial compartment arthritis. The distal femoral osteotomy is used in lateral compartment arthritis. The short-term results of these procedures have been very successful,[628,629] even to the point where the need for TKA is eliminated.[630] However, permanent pain relief with high tibial osteotomy is as yet unlikely.

Absolute and relative contraindications for a TKA include, but are not limited to

- active infection of the knee;
- significant genu recurvatum;
- severe obesity;
- return to high-impact sports or occupations;
- arterial insufficiency;
- neuropathic joint; and
- mental illness.

Several techniques are at the surgeon's disposal. The choice of approach is determined by surgeon's familiarity and comfort. Three approaches are commonly described: anterior, subvastus, and lateral.[631]

- Anterior approach. The anterior approach is generally through an anterior midline longitudinal skin incision and median parapatellar arthrotomy. The advantages of this approach include its extensile potential and its wide exposure medially and laterally. The disadvantages include its violation of the quadriceps mechanism and the potential for patellar devascularization.[631]
- Subvastus approach. The subvastus approach uses the same midline anterior skin incision as the anterior approach. The advantages of this approach include maintenance of the quadriceps mechanism with decreased postoperative pain and earlier functional recovery.[631] The disadvantage is its somewhat limited exposure.
- Lateral approach. The lateral approach occurs lateral to the patella and through the medial edge of Gerdy tubercle. Proponents of this technique feel that it is a superior method for the correction of valgus deformity.[631]

Most primary arthroplasties rely upon the patient's anatomy to confer stability to the articulation. Anatomic structures that can confer stability include the PCL and a balancing of the soft tissues around the knee. The fate of the PCL in primary TKA remains controversial. If the PCL is sacrificed, a posterior stabilizer (see later) is used. However, the long-term results of PCL-retaining and posterior-stabilized TKAs are similar.[632,633] PCL substitution may be indicated in patients requiring TKA who present with end-stage DJD with varus or valgus malalignment and an associated flexion contracture, with a combined deformity greater than 15 degrees.[634,635]

Many of the earlier designs of TKA replaced only the tibiofemoral joint and did not address the patellofemoral articulation. The posterior stabilizer was developed to increase the arc of motion of these earlier models and thereby improve the functional results of TKA. Although the ROM improved substantially with these components, patellofemoral complications emerged as a key problem after knee replacement. Errors in sizing, alignment, and rotation of the tibial and femoral components were eventually highlighted as contributing factors to many of these patellofemoral problems. In addition, many of these complications appear to be secondary to patellar resurfacing which may be a part of the procedure. Whether to resurface the patella remains among the most controversial topics in TKA.

CLINICAL PEARL

Following a knee replacement, there is a decrease in the contact area and consequent increase in the contract stress at the PFJ.[636] A study by Matsuda et al.[636] showed that resurfacing the patella reduced the contact area to a larger degree compared with not resurfacing the patella. In addition, kinematic studies of motion of the PFJ after knee replacement have consistently shown some degree of altered kinematics.[637]

Preoperative instruction is believed to be invaluable and should include education regarding an ice–compression–elevation program, ROM exercises, isometric quadriceps strengthening, patellofemoral mobilization, and gait training with the appropriate postoperative assistive devices.

Complications associated with TKA include the following[638,639]:

- Thromboembolic disease
- Fat embolism
- Poor wound healing
- Infection
- Periprosthetic fractures
- Neurologic problems, including fibular nerve palsy
- Vascular injuries
- Arthrofibrosis
- Disruption of the extensor mechanism

Postoperative rehabilitation for the TKA continues to be studied in an effort to decrease the cost while still providing the quality of clinical results expected by the surgeon and the patient. A 2007 meta-analysis of the effectiveness of physical therapy following TKA concluded that physical therapy has no long-term benefits.[640] These apparent poor outcomes are related to a number of factors. One month after TKA, quadriceps strength drops to 60% of preoperative levels, even when

traditional postoperative rehabilitation is initiated within 48 hours after surgery.[641] T is quadriceps weakness persists years after surgery, based on comparisons with age-matched controls.[642] Similarly, functional performance declines precipitously by up to 88% in the first month after TKA,[643] and persists evidenced by an 18% slower walking speed and a 51% slower stairclimbing speed compared to age-matched controls at 12 months after TKA.[644]

CLINICAL PEARL

A prospective cohort study by Bade and Stevens-Lapsley[627] concluded that a high-intensity rehabilitation programs post-TKA resulted in better short- and long-term strength and functional performance outcomes compared to a low intensity rehabilitation program, without resulting in impaired knee ROM or incurring any musculoskeletal injuries.

T e success of the rehabilitation program for this patient population is dependent on knowledge of the surgical procedure, communication with the surgeon and the patient, and above all, the ability of the rehabilitation team to focus on strength and functional deficits, and educate the patient to participate actively in the treatment program.[645]

Patellofemoral Osteoarthritis

Patellofemoral OA is diagnosed by correlating patellofemoral pain with radiographic changes consistent with joint degeneration. Differentiation of idiopathic and posttraumatic subtypes is based on the history. Intervention for patellofemoral OA is usually conservative unless it coexists with a severe tibiofemoral DJD, in which case a total knee replacement may be warranted.

T e term chondromalacia patella has long been a catch-all category of anterior and, specifically, retropatellar knee pain. T e term chondromalacia was first used by Aleman in 1928.[646] He used the term "chondromalacia posttraumatica patellae" to describe lesions of the patella found at surgery and thought to be caused by prior trauma. With time, "chondromalacia" became an all-inclusive term with no agreed-on classification system or definitions of terms.[302]

True chondromalacia refers to a softening of the cartilage on the posterior aspect of the patella and is estimated to occur in fewer than 20% of persons who present with anterior knee pain.[213] T e syndrome is most common in the 12–35-year-old age group and most studies show a predominance in females.[119,212,213,486,527,647]

Two types of chondromalacia have been described. One type involves surface degeneration of the patella that is age dependent and most often asymptomatic. T e other type involves basal degeneration. T is type results from trauma and abnormal tracking of the patella and is symptomatic.[188]

Chondromalacia is classified into four grades, according to the degree of degeneration noted arthroscopically[648]:

- Grade 1. Closed disease. T is grade is characterized by an intact joint surface that is spongy. T e softening is reversible. A blister or raised portion of the articular surface is seen.
- Grade 2. Open disease. T is grade is characterized by fissures that may or may not be obvious initially.
- Grade 3. Severe exuberant fibrillation or "crabmeat" appearance.
- Grade 4. T e fibrillation is full-thickness, and the erosive changes extend down to the bone, which may be exposed. T is is, in effect, OA and its extent depend on the size of the lesion.

Since cartilage has no nerve supply, chondral lesions themselves are usually asymptomatic,[649] although cartilage that is worn down to bone remains a potential source of pain due to irritation of, or abnormal pressure on, the richly innervated subchondral bone.[527]

T e conservative intervention for patellofemoral OA includes the removal of any muscle imbalances of flexibility or strength. Occasionally, surgical realignment may prove beneficial when the articular degeneration is isolated to the lateral PFJ.

Arthrofibrosis

T e term arthro*fi*brosis has been used to describe a spectrum of knee conditions in which loss of motion is the major finding.[524,650–654] It is perhaps best defined as a condition of restricted knee motion characterized by dense proliferative scar formation, in which intra- and extraarticular adhesions can progressively spread to limit joint motion.[655] T is dense scar tissue can obliterate the parapatellar recesses, suprapatellar pouch, intercondylar notch, and eventually the articular surfaces.[359] Patella infera and chronic patellar entrapment also may develop as a consequence of this process.[359]

Arthrofibrosis may occur as the result of the inflammatory cascade after injury or operative treatment. Although inflammation is undoubtedly present in a large number of individuals, it is not clear why an aggressive form of this condition may develop in some patients.

To diagnose arthrofibrosis accurately, other causes of restricted active and passive motion of the knee must first be eliminated. Mechanical causes include loss of articular congruency (e.g., as a result of fracture, meniscal tear, or loose body), interruption of the extensor or flexor mechanism, substantial effusion,[656,657] or nonisometric placement of a graft during reconstruction of the ACL.[336,360,652] Some investigators believe that an ACL reconstruction performed within 3 weeks after an injury may increase the likelihood of arthrofibrosis[658,659] although others disagree.[660] Poor or unsupervised rehabilitation[336] preoperatively or postoperatively, with delayed motion protocols, may further increase the risk.[661]

Symptoms vary and often do not correlate with the severity of the condition. Since arthrofibrosis usually occurs after trauma or an operative procedure, pain and stiffness may be the initial symptoms.

- T e presence of pain may complicate pre-existing knee stiffness.[359,662] Although pain can be present early, it often becomes more prominent when joint degeneration and arthritis occur because of long-standing arthrofibrosis. Pain may also be constant, especially when it is associated with CRPS.[359,662]

- Stiffness is usually the primary symptom and is often worse in the morning hours.[655] Patients may complain of a warm, swollen knee that is painful with attempted motion.

Global arthrofibrosis of the knee manifests as marked limitation of flexion, extension, and patellar glide associated with widespread joint inflammation as well as the intraarticular formation of fibrous tissue. T is can progress to chondrification and ossification of soft tissues.[655]

Quadriceps function can be decreased or absent because of pain.[662] As the function of the quadriceps muscle decreases, the ability of the muscle to act as a shock absorber is lessened, which may lead to additional articular degeneration. Often, the knee is held in a flexed position, which encourages tightening of the posterior part of the capsule and the hamstrings.

Crepitus and weakness are frequently present with swelling following prolonged standing or walking. Even when the patient does not have pain, loss of motion and quadriceps weakness can be substantial impediments to the performance of activities of daily living. An antalgic, flexed-knee gait is often seen.[360] Although effusion may be present, swelling is more often a result of inflamed, thickened capsular and pericapsular tissues.

Active and passive knee flexion and extension often are restricted in a capsular pattern, and the mediolateral and superoinferior patellar glides are reduced. T is restriction of passive motion often has a spring-like end-feel, reflecting the density and stiffness of the thickened, inflamed, or scarred peripatellar tissue.

Intervention includes ROM exercises and the stretching of specific structures. When a plateau has been reached during rehabilitative efforts to restore motion or when there is a progressive loss of motion, additional intervention of a gentle manipulation of the knee under anesthesia may result in improvement. Closed manipulation or vigorous attempts to gain passive motion may cause indiscriminate tearing of intraarticular tissue,[651] excessive tibiofemoral and patellofemoral compression with the risk of chondral damage or fracture,[346,651,663] rupture of the patellar ligament,[651,663] and even femoral fracture.[651] Manipulation has also been noted to initiate CRPS.[663]

Anteroposterior Slide Dysfunction: Tibia on Femur

In this condition, the tibia demonstrates a restricted anterior or posterior joint glide. T is motion is coupled to knee flexion–extension.[355] Movement of the tibia on the femur into extension is coupled with an anterior glide. Movement of the tibia on the femur into flexion is coupled with a posterior glide. T e initial complaints or findings are restrictions of flexion or extension movements.

T e technique used to treat this dysfunction is a modification of the anterior drawer test. T e patient is placed in the supine position, with the involved knee flexed and the foot flat on a table, while the clinician sits on the patient's foot, anchoring it to the table. T e clinician wraps both hands around the proximal tibia, placing the thumbs in front of the medial and lateral condyles and pressing on them. T e clinician's hand encircles the leg and grasps it firmly below the popliteal space. T e clinician creates a direct anteroposterior translatory glide of the tibia on the femur by first pulling the tibia forward with both hands, before pushing it backward with both thumbs.

Tibiofemoral Instability

Both intrinsic and extrinsic trauma to the knee occurs frequently. Several factors can predispose an individual to knee joint laxity:

- Repetitive microtrauma. Low-energy mechanisms have been associated with football, wrestling, and running.
- Severe macrotrauma. Knee dislocations frequently result in the disruption of the anterior and PCLs in addition to the joint capsule and collateral ligaments.[664]
- Genetics[665]
- Gender[665]
- Ethnic factors[665]

Knee laxity may contribute to the development and progression of knee OA. It may also be a consequence of moderate to severe OA although some knees become more stable with time because of the formation of osteophytes. Laxity is associated with more abrupt joint motion, large displacements, and suboptimal distribution of larger forces over the articular cartilage.[666,667] Since significant instability or damage to the internal structures of the knee joint can damage the articular surfaces and lead to degenerative changes, it is imperative that these injuries be treated as soon as possible.

Despite its potential severity, the multi-ligament injured knee is potentially a challenge to diagnose. T ere is no typical clinical presentation for knee instability in terms of the history. However, a history of "giving way" should always be taken seriously, as well as any evidence of locking or "catching" or feeling of instability within the joint.[154] T e physical examination may reveal deformity, malalignment, or other clinical signs such as massive soft-tissue swelling and disproportionate pain. If the capsule is damaged, there may be no true joint effusion; rather, blood may diffuse into the adjacent soft tissues.[668] In addition, a thorough neurological examination must be performed to document sensory and motor function, as well as a complete vascular examination. In any patient who has a history suggesting a knee dislocation, plain radiographs must be obtained.

T e direction of the laxity will determine the intervention. T e intervention usually consists of muscle strengthening, correcting muscle imbalances, and the use of passive restraints, such as orthotics.

Anterior Cruciate Ligament Tear

ACL rupture is one of the most common sports related injuries to the knee.[669] An ACL injury in a skeletally immature individual is covered in Chapter 30. Injury to the ACL can be functionally debilitating and often requires surgical intervention followed by an extensive course of rehabilitation. In contemporary orthopedics, the desire to return to the preinjury level of sports participation is one of the most important reasons athletes choose surgical treatment.[670]

ACL injury factors have been divided into intrinsic and extrinsic factors[671]:

- Intrinsic factors include a narrow intercondylar notch, weak ACL, generalized overall joint laxity, and lower extremity malalignment. Gender has also been implicated, with women being two to eight times more likely to sustain an ACL injury than men participating in the same sports (see Chapter 30).[671,672]
- Extrinsic factors include quadriceps and hamstring imbalances, altered neuromuscular control, shoe-to-surface interface, playing surface, and athlete's playing style.

The observation about the varying orientation and tensions of the ACL has clinical importance in a number of ways, and can help to define the following[34]:

- Mechanism of injury. Since the PL portion of the ligament is taut when the knee is in extension, it is the most commonly injured portion.[34]
- How diagnostic tests are performed. When the ACL is tested for torn fibers, the knee joint should be assessed for stability in various positions, especially in slight flexion.
- Operative reconstruction. Reconstruction should be aimed at replacing the damaged portions of the ACL at the relevant angles of the joint.

All ACL tears (i.e., sprains) are categorized as grade I, II, or III injuries. Ligament tears are classified according to the degree of injury, which ranges from overstretched ligament fibers (i.e., partial or moderate tears) to ligament ruptures (i.e., complete tears or disruptions). The term midsubstance tear refers to the site of the ACL injury and indicates a central ligament tear as opposed to a tear at one of the ligament's bony attachment sites. Almost all ACL tears are complete midsubstance tears.[38,39] Young athletes may sustain growth plate injuries (e.g., avulsion fractures) rather than midsubstance tears because the epiphyseal cartilage in their growth plates is structurally weaker than their ligaments, collagen, or bones. In the past, research has shown that tears in ACL complexes of young athletes usually resulted in avulsion fractures, not midsubstance tears. Recent studies, however, now suggest that young athletes may sustain midsubstance tears similar to those in adult athletes.[2,673]

Symptomatic ACL deficiencies in young athletes' knee joints are subject to the same long-term detrimental effects that occur in adult athletes.[674] Young athletes also may be more predisposed to more long-term degenerative knee conditions as the result of more years of chronic rotary knee instabilities from ACL deficiencies.[675]

Mechanism of Injury

Most published studies of the ACL are directed toward the basic mechanics of the ligament, method of surgical repair, and rehabilitation.[263,676–679] Unfortunately, little is known about the actual mechanism of injury during sport activity, although one sport that has been studied in some detail is alpine (downhill) skiing,[680,681] in which three common causes of ACL injury have been discussed:

- The first is referred to as the "phantomfoot" mechanism.[681] This mechanism occurs when a skier falls backward with the knee flexed and the tibia internally rotated. The combination of a strong quadriceps contraction (to maintain balance) with a rigid boot that fails to release may lead to an ACL disruption.[682] As a result, the ligament disruption occurs during a hard landing when the skier is off balance.
- In the second mechanism, when the skier lands on the ski's tail, the stiff posterior shell of the boot combined with a strong quadriceps contraction to maintain balance slides the tibia anteriorly, leading to an anterior drawer maneuver.
- The third mechanism, valgus rotation, seems to be more common in men who participate in downhill or cross-country skiing. It occurs when the inside (medial) edge of the front of the ski becomes caught in the snow. The leg is abducted and externally rotated while the skier is driven forward by momentum. High-speed skiing and poorly groomed ski slopes also are factors that contribute to this type of injury.

Regrettably, little attention has been directed to the mechanism of ACL injuries in other sports, although sudden deceleration, an abrupt change of direction, and a fixed foot have all been cited as key elements of an ACL injury.[682] For example, a common mechanism of injury to the ACL occurs when an excessive lateral force (i.e., valgus stress) is applied to the outer aspect of the knee joint. This type of injury often is seen in contact sports activities (e.g., football, soccer, and rugby), resulting from tackles or blows to the lateral side of the knee. A twisting injury to the ACL occurs when the knee is in full extension, and the femur is rotated externally on a fixed tibia. This mechanism of injury usually occurs because of abrupt changes in speed, direction, or velocity that torque the knee. Maneuvers repeatedly seen in sports activities, such as football, basketball, and soccer, can cause twisting injuries to the ACL. Snowboarders also may experience the same mechanism of injury when their feet and ankles are locked in ski boots, and their knees are torqued. A less common mechanism of injury to the ACL occurs with extreme hyperflexion or hyperextension of the knee joint.[26]

Associated Knee Injuries

ACL injuries rarely occur in isolation, because the ACL functions in conjunction with other structures of the knee. For example, when the outer aspect of the knee sustains a direct blow that produces a valgus stress, the MCL is often torn first, followed by the ACL.[26] Debate continues regarding clinical intervention for the patient with combined ACL and MCL injury. For example, the following protocol is used at the University of Cincinnati Sports Medicine:[683]

- Grade 1 MCL: an injury with or without meniscus damage. ACL surgery performed within 1 week; no presurgery motion restriction.
- Grade 2 MCL: an injury with or without meniscus damage. ACL surgery performed within 2 weeks; a 7-day period of motion limitation (brace locked at 30 degrees of full motion performed in rehabilitation on a daily basis, and after 7 days the brace is unlocked to full motion).

- Grade 3 MCL: an injury with or without meniscus damage. ACL surgery performed after 3 weeks with a 10-day motion restriction (brace locked at 30 degrees, and full motion is performed in rehabilitation starting day 7 after injury, and brace unlocked after 14 days).

Meniscal injuries can also occur, with the medial meniscus being more commonly involved. Approximately 49% of patients with sports-related ACL injuries have meniscal tears.[684]

Transection of the ACL leads to slight degenerative changes in the cartilage, but additional deafferentation of the knee joint produces severe degenerative changes.[685,686] T is suggests that sensory input from the joint may play a role in adapting movement strategies so that potentially harmful positions and loads are prevented.

Examination

Diagnoses of sports-related ACL injuries can be difficult, and clinicians must consider many factors when determining the best treatment options for patients with ACL injuries. A thorough patient history and physical examination are essential for accurate diagnoses of ACL injuries. Patients commonly describe the sensation of their knee "popping" or "giving out" as the tibia subluxes anteriorly. Other signs and symptoms of ACL injuries include pain, immediate dysfunction, instability in the involved knee, and the inability to walk without assistance. In rare instances, when patients have isolated ACL injuries that do not involve related collateral or meniscal tears, local tenderness around the knee joint may be absent.[675]

T e classic sign of ACL injuries is acute hemarthrosis (i.e., extravasation of blood into a joint or synovial cavity).[687] T e signs and symptoms of hemarthrosis (i.e., pain, edema, and joint stiffness) make clinical examinations more difficult for clinicians and very uncomfortable for patients.

Atrophy of the quadriceps is a regular finding with patients who have a torn ACL.[688–692] Several authors found a decrease in extensor torque that was larger than would be expected on the basis of the decrease in the volume of the quadriceps as measured with CT,[689,690,693–695] whereas the hamstring muscles do not have a comparable force deficit. It would appear that even specific conservative intervention can only partially correct the deficit.[696] T e difference in torque has been reported to persist after reconstruction of the ACL with the use of autogenous grafts or allografts from the patellar ligament,[696,697] or with the use of semitendinosus grafts.[698,699]

During the examination, it is important for the clinician to examine the patient's contralateral knee for baseline comparisons. T is especially is true in children who have inherent or congenital laxities, such as knock-knee (genu valgum) or saber legs (genu recurvatum). It is also important to remember that the pain the patient experiences during the examination may affect the accuracy of the test results. Common manual tests to assess the ACL include the anterior drawer and the Lachman test (see "Stress Testing").

Arthrometer

An arthrometer, such as a KT1000, is a noninvasive mechanical testing device for measuring anteroposterior knee motion. T is device assesses the amount of displacement of the femur and the tibia at a given force in millimeters. Intratester reliability and intertester reliability for the KT1000 have been reported to be high, both within and between days.[379] in addition, based on a number of studies, the KT1000 appears to be a clinically applicable instrument that can be used to assess anterior laxity in patients with an ACL deficient knee.[64] Before using the KT1000 to assess anteroposterior laxity of the knee, the clinician must screen for PCL injury.

Although most patients who have a complete tear of the ACL have increased tibial translation on instrumented testing,[700] it is not known exactly how many of these patients will have "giving way" of the knee or how many knees will have overt or latent damage of the cartilage within a few years.[34,701,702]

Imaging Studies

Radiographs can identify arthritic changes that may be associated with chronic rotary instability from ACL deficiencies. T ey can also demonstrate avulsion fractures of the tibial spine, or hypoplastic intracondylar notches with diminished tibial spines, which indicate a congenital absence of the cruciate ligaments.[25]

MRI scans are useful for diagnosing ACL injuries, although their use in discriminating between complete and partial ACL tears is limited. Diagnostic MRI scans, however, can detect associated meniscal tears that routine radiographs cannot show.[2] Both MRI scans and radiographs are necessary to assess whether young athletes' growth plates are closed or open, a factor that may affect treatment decisions.

Intervention

T e primary healing potential of the ACL has been reported to be extremely poor in both clinical and experimental studies due to its minimal blood supply and the presence of joint fluid, both of which contribute to a reduced healing potential.[703] One study[703] did report two rare cases of spontaneous healing of an acute tear of the ACL, although the injuries were either near the origin or near the insertion of the ACL.

Patients with either partial (grades I and II) ACL tears (negative pivot shifts) or "isolated" ACL tears, who lead a less active lifestyle and participate in linear, nondeceleration activities are considered to be candidates for conservative intervention.[529] However, to return to normal preinjury activity levels, patients must be thoroughly rehabilitated, and protective measures (e.g., knee bracing and activity restrictions) must be taken to prevent further knee injuries. It is also important to remember that cruciate ligament instabilities can lead to secondary patellofemoral pain through increased patellofemoral contact pressures and abnormal joint loading patterns.

Conservative intervention for these patients does not mean "nonintervention," because these patients require aggressive treatment to decrease pain and swelling, protect the joint from further injury, regain motion, increase strength and endurance, and return to function.[529] Numerous lower extremity rehabilitation protocols following injury or surgery have been reported in the literature.[249,284,469,661,704–714] For the middle-aged and older athlete, physical therapy often is the treatment of choice, unless the patient plans to participate in sports activities that expose the knees to vigorous twisting forces. Certain

sports activities, however, must be avoided, especially those involving jumping, quick starts and stops, and abrupt lateral movements (e.g., soccer, basketball).

ROM exercises, which are initiated as early as possible, must be performed carefully so as not to further aggravate soft-tissue injury and prolong pain and effusion. Failure of the pain and effusion to resolve, and ROM to improve should arouse suspicion of a displaced torn meniscus.[529]

Most authors stress the importance of strengthening the quadriceps, gastrocnemius-soleus and hamstrings muscles to prevent, or minimize atrophy and maintain or improve strength.[715–718] The strengthening exercises should be performed through a limited ROM, determined by patient tolerance and response to the exercises.[719–721] CKC exercises are recommended to promote cocontraction of the thigh musculature and limit anterior tibial translation.

ACL reconstruction is one of the most commonly performed orthopedic surgeries in the United States. Surgical treatment of the torn ACL includes direct repair, repair with augmentation, and reconstruction with autographs or allografts (single-bundle or double-bundle). The clinical evidence for double-bundle ACL reconstruction is mounting but is still inconclusive.[43] Currently, arthroscopic reconstruction remains the treatment of choice.

CLINICAL PEARL

The various graft options chosen for ACL reconstruction have their own advantages and disadvantages:[722]

- Allograft, bone–tendon. The advantages of this type of graft include bone to bone healing, decreased surgical time, predictable graft size, and availability. The disadvantages include cost, infectious disease transmission, the risk of bridging physis, higher failure rate, and delayed incorporation.
- Allograft, soft tissue. The advantages of this type of graft include decreased surgical time, predictable graft size, availability, and less risk with bridging physis. The disadvantages include cost, infectious disease transmission, higher failure rate, and delayed incorporation.
- Autograft, bone–tendon. The advantages of this type of graft include faster incorporation and healing, and better outcomes in young, active patients. The disadvantages include prolonged surgical time, donor site morbidity (anterior knee pain), the risk of bridging physis, and risk of fracture.
- Autograft, soft tissue. The advantages of this type of graft include faster incorporation and healing, better outcomes in young, active patients, and less risk with bridging physis. Disadvantages include prolonged surgical time, donor site morbidity (knee flexion weakness), unpredictable graft size, and compromise of medial structures.

Numerous postsurgical rehabilitation protocols exist that are beyond the scope of this text, except to report that current rehabilitation programs following ACL reconstruction are more aggressive than previous. Typically included are an early emphasis on full passive knee extension, immediate motion, immediate partial WB, and functional exercises, which incorporate proprioception, dynamic stability, and neuromuscular control drills.

CLINICAL PEARL

The Multicentered Orthopedic Outcomes Network (MOON) have published ACL rehabilitation guidelines (available at http://sph.sagepub.com/content/suppl) that necessitate that only treatment methods that can be employed without purchasing expensive equipment be included. Amongst their recommendations are:

- Early WB and motion.
- Limiting open chain exercises in the first six weeks to light load, short arc, quadriceps exercises.
- Neuromuscular training, including proprioceptive and balance training, perturbation training, and vibratory stimulation.

Generally speaking, the more accelerated rehabilitation progression following ACL reconstruction is used for young, athletic patients who underwent an ipsilateral patella tendon reconstruction, while a slightly slower progression is used following a hamstring reconstruction. The rehabilitation for both occurs before surgery whenever possible with the aim to restore full-motion before surgery to reduce the risk of postoperative arthrofibrosis.[723] Both WB and NWB exercises have been used and shown to be effective for rehabilitation post ACL reconstruction and return to sport. However, there is evidence to suggest that individuals who perform predominantly WB exercises, compared to NWB exercises, in their rehabilitation tend to have less knee pain and more stable knees, are generally more satisfied with the end result, and return to their sports sooner.[724] When designing an exercise program, it is prudent to choose exercises that minimize loading of the ACL graft following ACL reconstruction. For example, to begin strengthening important hip and thigh musculature, while minimizing loading of the ACL graft, it would be best to exercise at higher knee-flexion angles (e.g., 50 to 100 degrees), using both WB and NWB exercises.[725] However, postsurgery pain and swelling and inadequate knee ROM may prevent exercising at these higher knee-flexion angles. Therefore, because ACL loading is less with WB as compared to NWB exercises, and because ACL loading is relatively low using WB exercises at lower knee-flexion angles, early after surgery it may be appropriate to begin with WB exercises like mini squats and lunges performed in a range of 0- to 45-degree knee flexion range using partial body weight initially, and gradually progressing to full WB and a 0- to 90-degree knee flexion range.[725] Once higher knee flexion ranges are obtained, high-intensity loads can be employed between 50-degree and 100-degree knee flexion during exercises such as the NWB seated knee extension and the WB leg press.[725] Cycling can also be performed, initially using a partial knee ROM with low intensity and progressing to higher knee-flexion angles and higher intensity.[725] Another approach of reducing ACL

loading while performing lower extremity exercises is to facilitate a greater hamstring contraction during squatting, lunges, and balance activities. T is can be accomplished by maintaining an anterior trunk tilt (using hip flexion) between 30 degrees and 40 degrees or higher at the lowest position of lunging and squatting exercises, and by maintaining the heels on the ground and the knees over the feet.[725]

CLINICAL PEARL

Unfortunately, studies have shown that 40–90% of patients who undergo ACL reconstruction have radiographic knee OA 7 to 12 years after surgery.[726,727]

Despite mechanical stabilization, surgical reconstruction of the ACL does not guarantee a return to previous levels of activity, good knee function, or the preservation of future joint health.[728] While return to activity is expected for many athletes following ACL reconstruction and postsurgical rehabilitation, reported success rates range from 43% to 93%.[729] In addition, for those who do resume their previous level of activity, the risk of a second ACL injury may range from 6% to as high as 30%[730] and can be associated with several factors, including surgical technique, age, activity level, gender, time since surgery, and biomechanical adaptations during dynamic tasks.[731] Although several of these factors are nonmodifiable, some could potentially benefit from an emphasis on neuromuscular training. It is important to remember that deficits in the neuromuscular control may not be a result of the initial knee injury and subsequent surgery, but may be a factor of the athlete's preinjury movement patterns, which necessitates a thorough biomechanical examination.[731] Stasi et al. recommend a selective exercise progression that includes those exercises listed in Table 20-20.

CLINICAL PEARL

A central tenant of postoperative rehabilitation is to assist athletes to regain physical capacity so that they may participate safely and at their desired performance level.[732] However many athletes with apparently good knee function do not return to their preinjury level of the sport. There is growing evidence to suggest that psychological factors, including motivation, confidence, self-ef cacy, and optimism, matter when it comes to returning to the preinjury level following an ACL reconstruction.[732] Up to 24% of patients with ACL reconstruction do not return to sport because of kinesiophobia, better known as fear of reinjury.[733,734] Methods to detect, and better understanding of factors that influence, kinesiophobia levels are needed so that interventions can be targeted to individuals who will benefit the most.[735]

Since not all individuals regain optimal knee function after ACL reconstruction, it is critical that the clinician base the decision to allow a patient to return to sport on sound evidence. T e International Knee Documentation Committee 2000 subjective knee form (IKDC 2000), which can be accessed at https://www.sportsmed.org/Research/IKDC_Forms/ has been used frequently after ACL reconstruction to measure knee function.[736] T e benefit of the IKDC 2000 is that it can differentiate among individuals with low versus high knee function, as well as those with more versus fewer knee symptoms.[737] However, the IKDC 2000 is not designed to determine a patient's readiness to return to activity. While there are batteries of tests that have been developed to predict the risk for musculoskeletal injuries, classify individuals early after ACL injury and identify important limb asymmetries after ACL injury and reconstruction, these

TABLE 20-20 Selected Exercises to Emphasize Neuromuscular Retraining Following ACL Reconstruction

Key Motions	Muscles Involved	Intended Ef ect
Sagittal plane trunk and lower extremity joint motion	Gluteals, quadriceps, and hamstrings	Single-leg squat progression
Frontal plane trunk and lower extremity joint motion	Gluteals, trunk musculature, quadriceps, and hamstrings	Lateral single-leg squat progression
Three-dimensional trunk and lower extremity joint motion	Gluteals, quadriceps, and hamstrings	Forward lunge progression
Symmetry of lower extremity movement; frontal plane trunk and lower extremity joint motion	Gluteals, trunk musculature	Tuck jump progression
Three-dimensional lower extremity joint motion	Gluteals, quadriceps, and hamstrings	Lateral jump progression
Frontal and transverse plane trunk motion	Trunk musculature	Sidelying flexion
Sagittal and transverse plane trunk motion	Gluteals, trunk musculature	Prone bridge
Three-dimensional trunk motion	Gluteals, trunk musculature	Kneeling trunk progression
Transverse plane trunk and hip motion	Gluteals, trunk musculature, hamstrings	Single-leg bridge
Three-dimensional trunk and lower extremity joint motion	Gluteals, trunk musculature, and hamstrings	Single-leg dead lift
Three-dimensional trunk and lower exremity joint motion	Gluteals, trunk musculature, quadriceps, and hamstrings	Lunge jump progression

Data from Di Stasi S1, Myer GD, Hewett TE. 'Neuromuscular training to target deficits associated with second anterior cruciate ligament injury.' J Orthop Sports Phys Ther. 2013;43:777–792, A1–A11.

tests can be time-consuming for both athlete and clinician.[728] A study by Logerstedt et al. attempted to determine if use of the IKDC 2000 could discriminate between successful and non-successful performance on return to activity criteria tests after ACL reconstruction and found that it may be a clinically relevant tool. T e study concluded that low IKDC 2000 scores were reasonably indicative of failure on the return to activity criteria test battery (thigh strength and ability to hop), whereas normal IKDC 2000 scores were not predictive of passing scores on the return to activity criteria test battery.[728]

Genu Recurvatum ("Saber Legs")

Genu recurvatum is a position of the knee joint complex in which the ROM occurs beyond neutral or 0 degrees of extension.[152] Genu recurvatum appears to be more common in females than in males and may exist due to postural habit, increased joint laxity, or knee injury.[738]

Traditionally, rehabilitation has only been used to address this condition when poor muscle control of the knee exists, such as occurs following trauma or a neurologic insult such as a cerebral vascular accident (CVA). However, one might question whether genu recurvatum predisposes an individual to a knee injury. Certainly, the posterior structures of the knee (the capsular and noncapsular soft-tissue structures, including the arcuate complex, posterior capsule, lateral meniscus, fabellofibular ligament, and biceps femoris muscle) are likely to be stressed with genu recurvatum. T e posterior capsule forms two pouches that extend over the articular surface of the femoral condyle and tibial plateaus.[151] T e capsule is thin over the posterior aspect of the femoral condyles but is supported by the two heads of the gastrocnemius and reinforced by the oblique popliteal ligament. T e arcuate ligament also reinforces the capsule laterally. Stability is further enhanced internally by the lateral meniscus, which forms a concave articular surface for articulation with the convex lateral femoral condyle.[5]

A thorough history will guide the clinician to suspect genu recurvatum as a contributing factor in a knee or another lower-leg injury. Individuals with genu recurvatum may present with one of a variety of lower extremity diagnoses as it is doubtful that their primary diagnosis will be genu recurvatum. Patients may have a history of an injury that forced them into hyperextension. Examples include landing from a jump on an extended knee; a blow to the AM aspect of the proximal tibia, forcing the knee into hyperextension; and a noncontact external rotation hyperextension injury. From the anatomic and biomechanical review, it appears that the possible consequence of genu recurvatum in the active individual may be an increase in stress placed on the ACL, the anterior joint, or the PL corner of the knee. Symptoms attributable to genu recurvatum include the following:

- AM joint pain. T is pain results from the compressive forces at the medial tibiofemoral compartment. T is pain may be accentuated if a varus alignment is present.
- PL knee pain. T is pain results from the tension placed on the posterior structures and is aggravated by stepping or forceful knee extension in WB.[739]

T e patient may also complain of knee instability during activities of daily living. Noyes et al. have described the PL syndrome as an injury to the PL structures in conjunction with a torn ACL.[740] T is syndrome is usually characterized by no history of injury and a gradual onset of knee pain. Loudon et al.[741] found a positive correlation between genu recurvatum and ACL injury in female athletes. Hutchison and Ireland[742] attributed the recurvatum posture and laxity in the posterior capsule to habitual posture.

Patients with genu recurvatum are easily identified during static standing, with the sagittal view best demonstrating this posture. Individuals also may present with excessive femoral internal rotation, genu varum or valgum, tibial varum, or excessive subtalar joint pronation, which is more noticeable in the frontal plane.

When performing activities such as step-ups, patients will use momentum to straighten the lower extremity, and they will be unable to control WB terminal knee extension. Kendall et al.[148] report that the hyperextension posture of the knee is caused by weakness in the gastrocnemius.

Proprioception in individuals with genu recurvatum may be deficient, especially near the end range of extension. One study[741] demonstrated that individuals who stood in hyperextension and without knee injury were unable to reproduce knee joint angles in the last 15 degrees of extension compared with other knee angles of 45 and 60 degrees on a leg-press machine. Individuals may perceive the hyperextended knee position as "normal" and, when they are introduced to a more vigorous activity, they may have a tendency to stay in hyperextension, putting the knee at risk for injury.[741,742]

If genu recurvatum is suspected as contributing to the patient's symptoms, special attention is needed to identify PL instability. T is can be achieved using the PL drawer test and the varus stress test at 30 degrees. If the recurvatum is unilateral, the clinician should assess the lumbar spine and pelvis for obliquity or muscle imbalance. In addition, the hip should be evaluated for excessive internal rotation, which contributes to genu recurvatum, and the subtalar and midfoot joints should be checked for excessive pronation, which allows excessive internal rotation of the tibia (see Chapter 19).

Patients with genu recurvatum need to learn that 0 degree of knee extension is the normal knee position, and hyperextension is to be avoided.[743] T e patient is taught to keep the knee in the same plane as the foot. Verbal cueing is helpful, but other strategies, such as the temporary use of posterior knee taping, can give the patient direct sensory feedback. T is neutral position should then be carried over to dynamic strengthening exercises.

Muscle sequencing is the key, with the hamstrings and gastrocnemius firing in conjunction with the quadriceps to guide the knee into extension rather than using the passive force of gravity.[744] Patients should progress through WB exercises that require sequential use of eccentric and concentric control of the lower extremity, such as resistive terminal extension, single-leg balance, mini-dips, squats, forward and backward step-ups, lunges, and jump landings.

Knee control during gait can be taught in conjunction with the previously mentioned exercises. Noyes et al. recommend that the patient maintain knee flexion of 5 degrees throughout the stance phase of gait. A 1–2-in elevated heel may be used in the initial training to create a flexion moment at the knee, and the trunk should be maintained in

an upright position versus a forward lean or flexed hip during midstance to avoid an anterior shift of body weight.[740] Excessive internal femoral rotation also should be controlled during this phase of gait.[740]

Continued training of the patient with genu recurvatum should focus on functional tasks. T ese include stair climbing and sit-to-stand transfers. During the pull-up phase of stair climbing, patients should be trained to refrain from thrusting into knee extension. Individuals may have a tendency to hyperextend their knees with other daily activities, such as bending forward to brush their teeth or prolonged standing.

T e final phase of rehabilitation focuses on more complex activities and sports-specific skills. It is important that athletes involved in jumping and cutting sports master a flexed knee position. Henning et al.[247] have suggested that extreme loads are placed on the ACL when the knee is straight or near-straight during planting and cutting, landing from jumps, and sudden stops while running. Emphasis should thus be placed on flexing the knee during these sports activities to prevent injuries to the ACL. Hamstrings that are adaptively shortened offer protection to these joints and should not be stretched.

Meniscal Tears

Because of the interrelationship of the menisci with other structures of the knee, a torn meniscus (see Chapter 2) is the most common cause of mechanical symptoms in the knee.

Despite its prevalence, little is known about the epidemiology of meniscal injury. A number of risk factors have been cited including squatting, kneeling, crawling, chair sitting while driving, stairclimbing, lifting items, and walking.[745] A study by Mcmillan and Nichols[746] concluded that work occupations involving frequent kneeling or squatting doubled the risk of developing knee OA. Another risk factor identified for meniscal tears is the elapsed time between ACL injury and reconstruction surgery.[747,748] Collagen and proteoglycan damage can be caused by mechanical factors (tears or surgical resection), enzymatic degradation, or synthesis of new, poorly functioning molecules.[84] Meniscal lesions usually occur when the patient attempts to turn, twist, or change direction when WB, but they can also occur from contact with the lateral or medial aspect of the knee while the lower extremity is planted.[67] Collagen damage leads to abnormal hydration and an irreversible cascade of tissue alteration.[84] When proteoglycans are damaged (and the collagen remains intact), these tissue changes are reversible. For example, immobilization leads to proteoglycan loss, which is reversed after the return of motion stimulates fibrochondrocytes to synthesize new proteoglycan molecules.[84] With aging, the meniscal tissue degenerates and can delaminate, thus making it more susceptible to splitting from shear stress, resulting in horizontal cleavage tears.[749] Without the menisci, the loads on the articular surfaces are increased significantly, leading to a greater potential for articular cartilage injuries and degenerative arthritis. Since the menisci are without pain fibers, it is the tearing and bleeding into the peripheral attachments as well as traction on the capsule that most likely produce a patient's symptoms.[273] In fact, 16% of asymptomatic patients have meniscal tears demonstrated on MRI, with the incidence increasing to 36% for patients older than 45 years.[750] Meniscal tears can be classified as follows[751]:

- Longitudinal tear, which involves a vertical tear in the meniscus in a longitudinal direction that is usually located on the periphery of the meniscus. Longer tears tend to be more unstable resulting in a dislocation of the central part of the meniscus (bucket handle tear).
- Horizontal tear, which involves a horizontal cleavage in the meniscal tissue.
- Radial tear, which involves a vertical tear that starts in the free (central) margin of the meniscal tissue.
- Flap tear, which involves an oblique vertical cleavage causing a flap tear (parrot beak), or a horizontal tear.
- Tear in degenerative meniscus which involves a tear or multiple tears in a degeneratively changed meniscal tissue. With advancing age, the menisci become stiffer, lose elasticity, and become yellow.[752] Histologically, there is a gradual increase in fibrous tissue in comparison with an elastic tissue, which results in an increased potential for tearing with a torsional force by the femoral condyle. Knee injuries may result in isolated or combined meniscal lesions. In addition, such injuries can be limited to the superficial layers of cartilage or extend deep into the subchondral bone.

Patients with a meniscal injury typically present with a history of swelling, popping, or clicking, and pain along the joint line. With posterior horn tears, the meniscus may return to its anatomic position with extension. If the tear extends anteriorly beyond the MCL, creating a bucket-handle tear, then the unstable meniscus fragment cannot always move back into an anatomic position.[273] Such a meniscal tear can result in locking of the knee in a flexed position. T e lateral meniscus, being more mobile, is less likely to be associated with locking when torn. T e patient may also note a "clicking" sensation while walking as a result of traction against a torn medial or lateral meniscus.[750] Locking of the knee is more common in younger patients with meniscal tears because older patients are more likely to have degenerative meniscal tears with less mechanical symptoms and an insidious onset.[273]

T e joint line pain is thought to result from capsular irritation. Meniscal tears are symptomatic as they render a portion of the meniscus abnormally mobile.[753] T e shape and location of the meniscal tear determines the symptoms and clinical findings.

T e poor regenerative capacity of articular cartilage has led to innovative approaches to treating symptomatic lesions and alleviating patient's symptoms.

If the knee is locked or cannot be fully extended, the torn meniscal fragment is displaced and must be treated surgically. Current surgical options for full thickness cartilage defects are[754]:

- Palliative. T is includes simple arthroscopic debridement and lavage.
- Reparative. T e reparative approach consists of marrow stimulation techniques that result in the formation

of fibrocartilage. T is includes abrasion arthroplasty microfracture, autologous chondrocyte cell implantation, mosaicplasty with either autologous tissue or fresh allograft.

- Restorative. T is includes osteochondral or chondrocyte transplantation and involves inducing the newly attracted or transplanted chondrocytes to become mature chondrocytes using growth factors. Bone morphogenic proteins (BMPs) are members of the TGF-superfamily and have a regulatory role in the differentiation of cartilage-forming and bone-forming cells.[755]

Each technique has specific criteria pertaining to previously provided treatments, surgeon expertise, patient age, chronicity, concomitant pathology, and lesion depth.[754]

CLINICAL PEARL

Meniscal lesions that can be treated conservatively (approximately one-third) include the diffusely degenerative meniscus. Unless a tear is acute, peripheral, and stable, the relative avascularity of the middle third and the inner third of both menisci indicates a poor healing potential in these areas.

The conservative intervention for meniscal tears focuses on the resolution of impairments such as swelling, restricted ROM, and strength by using exercises, bracing, and oral medications.[756]

Overall, the rehabilitation protocols differ by lesion location and by surgical technique and are typically governed by surgeon instructions. However, independent of the inherent differences between cartilage repair techniques, the process of rehabilitation is based on the healing phases: an initial protection and joint activation phase, followed by a progressive joint loading and functional restoration phase, and finally an activity restoration phase. Patients may progress through the rehabilitation process at different rates, depending on individual characteristics, lesion features, and concomitant pathology. Cartilage repair in older individuals may be slower, due to age dependent changes in metabolic activity, repair processes, and matrix synthesis.[757] Similarly, patients with a body mass index (BMI) greater than 30 kg/m² may need a slower progression during rehabilitation.[758] T e progression through the rehabilitation phases must be based on healing criteria rather than fixed timelines. T is can be accomplished by monitoring any progressions in exercise and activity to ensure that signs and symptoms, especially pain and swelling, are not increased.[758]

An example of a rehabilitation protocol for a postsurgical lateral meniscal repair is outlined in Box 20-1.

Posterior Cruciate Ligament Tear

Rupture of the PCL is a severe knee injury that can lead to delayed rehabilitation, instability, and chronic knee pathologies.[759] Because of its inherent strength, damage to the PCL usually only occurs with significant trauma such as a dashboard injury associated with a motor vehicle accident, or by a fall on the anterior aspect of the proximal end of the lower leg with a flexed knee, or hyperflexion or hyperextension of the knee.[760] High-energy mechanisms are thought to result in a higher portion of combined injuries, whereas lower-energy mechanisms are thought to result in a high proportion of isolated injuries.[761] T e prevalence of PCL rupture is unknown, perhaps because this injury often remains undiagnosed.[762] T e diagnosis of a PCL tear is generally made by combining information from the patient history, physical examination, medical tests, imaging techniques, and, potentially, arthroscopy.[763]

Subjective and objective findings for a PCL tear include the following:

- Reports of hearing a "pop."
- Pain in the posterior aspect of the knee joint that may be aggravated with kneeling. Minimal pain typically occurs with extension, but is typically increased past 90 degrees of flexion and the patient may lack 10–20 degrees of flexion.[764]
- Minimal swelling.
- Possible abrasion or contusion on the superior, anterior aspect of the tibia, suggesting the occurrence of a posteriorly directed force of the tibia on the femur.
- Instability may or may not be present, depending on the severity of the tear. If present, the patient may complain of "giving way."
- Positive special tests, such as the posterior drawer, posterior sag, and quadriceps active test (see "Special Tests"). Caution must be used with the interpretation of these tests as their diagnostic accuracy is largely unknown.[763]
- Variable neurovascular findings based on severity. Structures to be assessed include the posterior tibial artery and vein (palpation of the distal posterior tibialis and dorsal pedis pulses and the fibular (peroneal) nerve (motor and sensory distributions of the nerve).

It is important for the clinician to delineate between isolated and combined lesions as intervention recommendations between these groups are different.[764] Specifically, isolated injuries (grades I and II, where the posterior translation is < 10 mm) are generally treated conservatively, whereas combined injuries frequently necessitate a more aggressive intervention.[388]

Diagnostic studies may include radiographs, MRI, instrumented testing and stress radiographs. In acute cases, routine radiographs are essential to determine the absence or presence of associated fracture or an avulsion.

CLINICAL PEARL

MRI has been heralded as the gold standard for assessing PCL injuries.[765] Sensitivity and specificity for detection of PCL tears with MRI has been reported that 99%.[766]

Although it is not possible to predict which patient will have a favorable clinical result from conservative intervention, and which patient will worsen over time, it would appear that the prognosis for an injury that occurs at high velocities

Box 20-1 Rehabilitation Protocol for Postsurgical Lateral Meniscus Repair

Week 1

- Continuous passive motion (CPM): PROM 10–70 degrees (knee extension/flexion), 3 × 60 min/d
- No AROM exercises
- Partial weight bearing with crutches (20% of body weight)
- Knee brace locked in extension (for 4 weeks); wear brace day and night; remove brace for exercising and CPM
- Modalities to decrease swelling and pain: ice 6 × 10 min/d, transcutaneous electrical nerve stimulation (TENS) 2 × 20 min/d
- Patella mobilizations, low grade, 5 min/d
- Soft-tissue massage (posterolateral, suprapatellar), 15 min/d
- Isometric quadriceps contractions (in 20 degrees of flexion), 10 × 30 s/d
- Electrical muscle stimulation (EMS) for quadriceps (in 20 degrees of flexion): 30 contractions per day (4-s duration [85 Hz], 20-s rest time per day)
- Upper body ergometer aerobic program, 10 min/d
- Upper extremity and trunk strengthening program, 30 min/d

Week 2

- Continue with the above program
- Partial weight bearing with crutches (20% of body weight)
- PROM goal: 0–90 degrees
- AROM exercises for extension (in available range)
- No AROM for flexion
- Seated concentric quadriceps contractions, 60–0 degrees of flexion (against manual resistance, Theraband), 6 × 20 reps/d
- EMS for quadriceps (60 degrees of flexion), 30 contractions per day (4-s duration [85 Hz], 20-s rest time)
- Pool exercises (gait, balance, coordination), 20 min/d

Week 3

- Continue with the above program
- Partial weight bearing with crutches (50% of body weight)
- ROM goal: 0 degree, 120 degrees, discontinue CPM when goal reached
- Flexibility exercises for quadriceps (Thomas position), 6 × 30 s/d
- Bilateral proprioceptive exercises (knee flexion, 10–20 degrees), on different unstable surfaces, 6 × 1 min/d
- Bilateral balance exercises (Biodex Stability System), 6 × 30 s/d
- Isokinetics (speeds 30 degrees/s and 60 degrees/s) in limited ROM (40–90 degrees of flexion) for quadriceps, 3 × 20 reps/d
- Stationary bike for gentle ROM exercise (low resistance), 3 × 15 min/d

Week 4

- Continue with the above program
- Partial weight bearing with crutches (70% of body weight)
- ROM goal: 0–130 degrees
- Begin gentle AROM exercises for flexion
- Bilateral mini-squats (0–40 degrees), 6 × 20 reps/d
- Unilateral proprioceptive and balance training (knee flexion, 10–20 degrees), 6 × 20 s/d
- Isometric hamstring exercises (in 0, 20, 40, 60, and 80 degrees of flexion), 6 × 30 reps/d
- Simulated leg press on the CKC attachment (Biodex Systems), range 0–60 degrees, speed 90 degrees/s, 3 × 30 reps/d
- Deep-water running program (with wet vest), 20 min/d

Week 5

- Continue with the above program
- Full weight bearing for level gait (avoid stairs), discontinue the use of crutches
- ROM goal: ensure 0–130 degrees with active and passive exercises
- Discontinue knee brace, use of knee neoprene sleeve

(Continued)

Box 20-1 Rehabilitation Protocol for Postsurgical Lateral Meniscus Repair (Continued)

- Flexibility exercises: add stretching for hamstrings, gastrocnemius/soleus, iliotibial hand, hip flexors, adductors, 3 × 30 s for each muscle group
- Unilateral proprioceptive and balance training (knee flexion, 10–20 degrees), 6 × 30 s/d
- Isokinetics quadriceps (speeds, 30, 60, 90, 120, 150, and 180 degrees/s; range, 110–0 degrees), 6 × 10 reps (each speed)/d
- Hamstring exercises (0–90 degrees of flexion) with Theraband, 5 × 20 reps/d
- Stationary bike (increase resistance), 3 × 20 min/d

Week 6

- Continue with the above program
- Exercise passive flexion end of ROM (unloaded flexion), 6 × 10 min/d
- Bilateral semi-squats (0–60 degrees), 6 × 20 reps/d
- Bilateral reactive/quickness training, 10 × 30 s/d
- Agility training (lateral movements with Sport Cord), 3 × 15 min/d

Week 7

- Continue with the above program
- "Sit back on heels" exercise (loaded flexion), 12 × 1 min/d
- Stairs allowed
- Unilateral mini-squats (0–40 degrees), 6 × 20 reps/d
- Isokinetics quadriceps AND hamstring (speeds 180, 210, 240, 270, and 300 degrees/s; range, 110–0 degrees), 6 × 10 reps (each speed)/d
- Strengthening program on weight machines (leg press, leg curls), 1 × 30 min/d
- Endurance program on bike, 1 × 45 min/d

Week 8

- Continue with the above program
- PROM goal: symmetrical
- Progress unilateral mini-squats to semisquats
- Lunges program (front, lateral, diagonal), 3 × 25 each
- Stairmaster, 1 × 30 min/d

Week 9

- Continue with the above program
- Intensify strengthening (2 × 45 min/d) and endurance program (1 × 60 min/d)

Week 10

- Continue with the above program
- "Sit back on heels" goal: symmetrical
- Plyometrics program (bilateral vertical and horizontal jumping), 1 × 20 min/d
- Controlled return to sports

Week 11 to 14

- Continue with the above program
- If no problems, discontinue rehabilitation by end of week 12
- Intensify sport-specific ice training until complete integration in the team training

Data from Bizzini M, Gorelick M, Drobny T. Lateral meniscus repair in a professional ice hockey goaltender: A case report with a 5-year follow-up. J Orthop Sports Phys Ther. 2006;36:89–100.

and force levels is less favorable when compared with injury that occurred at low velocities and lower force levels.[767,768]

The focus of conservative intervention for isolated PCL injuries is to restore ROM and to strengthen the quadriceps and gastrocnemius while delaying hamstring strengthening (for approximately 6–8 weeks) and protecting the articular surfaces.

- Quadriceps strengthening is performed to help reduce posterior tibial translation.[769] Theoretically, with the distal end fixed, a concentric contraction of the gastrocnemius can glide the femoral condyles posteriorly thereby reducing posterior subluxation of the tibia on the femur.

- Hamstring strengthening is delayed following the injury to decrease the potential for PCL stress. Resisted OKC knee flexion exercises should be avoided. Instead, the hamstrings should be strengthened in a CKC environment to minimize any posterior shear stresses due to joint compression as well as substantially decreasing the angle of pull of the hamstrings on the posterior tibia.

A combination of OKCEs and CKCEs are initiated to promote dynamic stability of the knee.

Important exercises include squats, lunges, and CKC knee extensions. Heavy resistance OKC knee extension exercises through a range of 45–20 degrees of flexion are avoided to protect the PFJ.[248,270]

CLINICAL PEARL

Many isolated PCL injuries heal with conservative intervention, especially in light of the fact that many PCL-deficient patients do not experience functional instability.[764] However, the long-term follow-up studies of PCL injuries reveal a progressive development of pain and degeneration of the medial compartment of the tibiofemoral joint.[770]

Balance and proprioceptive exercises also are performed. For the symptomatic patient, the use of a PCL brace may be advantageous. In addition, for patients with medial compartment pain, a trial of a lateral heel wedge may be beneficial.

Plyometric exercises are introduced for appropriate patients such as athletes. Return to sports may occur in as little as 6–8 weeks, but on average takes 12–16 weeks, providing that there are no complicating factors. These complicating factors include significant varus or valgus alignment, or damage to additional tissues.

Surgical intervention of isolated PCL injuries is an area of continued controversy, and there is yet no clear consensus as to which techniques or graft designs are best. Complicating matters is that outcomes between the various surgical treatments are difficult to compare due to the wide range of injury patterns, differences in surgical and rehabilitation protocols. As the outcomes of conservative management are good or excellent in 50–80% of patients with isolated grade I or grade II PCL injuries, a trial period of rehabilitation as described above is typically recommended initially.[667,771]

The surgical management of patients who have PCL injuries combined with other ligament or capsular injuries is somewhat clearer and is recommended in the presence of pain and/or significant instability. As with postsurgical ACL protocols, a wide variety exists, a summary of which follows:

- Day 1–1 month: the goals during this phase are to control inflammation and promote healing, achieve full knee extension, knee flexion ROM to 90 degrees, and quadriceps strength ≥3/5. Exercises during this phase include quad sets, ankle pumps, supine straight leg raise, and hip abduction/adduction. Any added resistance is applied proximal to the knee.
- 1–3 months: the goals during this phase are to achieve knee flexion ROM equal to 125 degrees, and quadriceps strength ≥4/5. At approximately 8 weeks postoperatively, exercises can include stationary bike without toe clips, leg press from 0 to 90 degrees, CKC terminal knee extension, and balance and proprioceptive exercises.
- 3–9 months: the goals during this phase are to have no limitation with activities of daily living and a limited resumption of low impact recreational activities. The CKCEs are progressed.
- 9–12 months: During this phase steps should be taken to return to previous levels of physical function and athletic pursuits.

Medial Collateral Ligament

The injury incidence of the superficial MCL and other medial knee stabilizers (the deep MCL and the posterior oblique ligament) has been reported to be 0.24 per 1000 people in the United States in any given year, and to be twice as high in males (0.36) compared to females (0.18).[772] The majority of injuries occur in young athletes during sporting events, with the usual mechanism involving a valgus contact, tibial external rotation, or a combined valgus and external rotation force delivered to the knee. Although most complete grade III medial knee injuries heal, some do not, which can lead to continued instability. For these patients, a thorough understanding of the presenting history and a physical examination are important because these injuries can often be confused with PL corner injuries.[773]

Clinical diagnosis of medial knee injuries is primarily achieved using the application of a valgus stress in full extension and at 30 degrees of knee flexion (Fig. 20-25). In addition, an examination of the amount of AM tibial rotation is performed at 90 degrees of flexion, while the dial test (Fig. 20-33), performed at 30 degrees and 90 degrees of flexion, is important because it evaluates for rotational abnormalities.[773] Valgus stress radiographs are useful to objectively determine the amount of medial compartment gapping and to discern whether there is medial or lateral compartment gapping when a medial or PL corner knee injury cannot be differentiated, especially with a chronic injury.[773]

Since the majority of acute grade III medial knee injuries heal following a nonoperative rehabilitation program, an anatomic medial knee reconstruction with grafts may be indicated in severe midsubstance injuries or chronic medial knee injuries.[773] Rehabilitation principles for acute medial knee injuries involve controlling edema, regaining ROM, and avoiding any significant valgus stress on the healing ligaments.

Patellofemoral Instability

Patellar instability is characterized by dislocation or subluxation of the patella relative to the femoral trochlea, almost always in the lateral direction.[774] It was widely believed that patellar instability occurred primarily in adolescent females in part because of increased joint laxity and physiologic, pathologic variations in lower joint alignment, such as femoral anteversion, genu valgum, increased Q-angles, and external tibial torsion.[775] However, a study by Waterman et al.[776] did not substantiate an increased incidence in women. Once the instability and its direction have been established, the

anatomic cause of the instability is determined. Patella instability can be produced by the following:

- A small patella. A smaller patella decreases the stability of the patella during its tracking.[10,777,778]
- A shallow trochlear groove. The term dysplastic femoral trochlea implies a shallow intercondylar sulcus, especially at the lateral ridge, which often contributes to instability.[10,777,778] There is strong evidence that implicates the depth of the trochlear groove of the femur for abnormal patella malalignment relative to the femur.[779] Powers[779] compared the trochlear groove or sulcus angle, using pneumatic MRI, of 23 women with patellofemoral disorders, 12 of whom had no history of patellofemoral disorders, at various degrees of knee flexion (45, 56, 27, 18, 9, and 0 degrees). The study indicated that the trochlear groove depth correlated with patella kinetics. Trochlear groove shallowness was found to be predictive of lateral tilt at the angles studied between 27 and 0 degrees and lateral patella displacement at 9 and 0 degrees.[779] These findings suggest that the depth of the trochlear sulcus affects the orientation of the patella in the first 30 degrees of knee flexion for lateral tilt and the first 10 degrees for lateral glide.[780]
- An abnormal patellar position. The patella may lie too far proximally or distally relative to the trochlea, conditions called patella alta and patella baja (or patella infera), respectively.[237,781,782] Patella alta, as a separate entity, does not necessarily contribute to knee pain, but it can certainly contribute to lateral maltracking by causing the patella to enter into the patellar groove late in knee flexion. Patella baja occurs rarely in otherwise normal individuals. It is seen in achondroplastic dwarfs, who seldom have anterior knee pain, and as a postoperative complication of knee surgery.[360,783,784] Several radiographic methods for diagnosis of patella alta and baja have been reported in the literature.[782,785–787]
- A muscle imbalance between the VMO and VL.[128,141,485] These imbalances are discussed in "Biomechanics".
- Generalized ligamentous laxity or complex malalignments of the entire extremity (genu recurvatum).[194,304,788]

Instability is usually identified through the history, with the patient reporting either dislocation or subluxation episodes. A subluxation needs to be differentiated from "giving way," as this can be simply a reflex inhibition of the quadriceps secondary to pain. The direction of instability is usually lateral, with medial instability almost always secondary to iatrogenic causes.[302] On palpation, medial retinacular and distal patellar pole tenderness or distal quadriceps tenderness may be elicited.[340]

- Race. There is some evidence that Caucasians and African Americans may have increased rates of patellar dislocation when compared with other races.[776]
- Prior episodes. Patients with prior episodes of instability are seven times more likely to have a recurrence.[775] The number of prior episodes is important because patients who are first-time dislocators and infrequent subluxators should have a trial of conservative intervention or limited arthroscopic evaluation for documented osteochondral lesions,[194] whereas, recurrent instability is an indication for surgical intervention.[302]

Nonoperative treatment remains the gold standard of intervention after primary patellar dislocation without osteochondral fragments.[789]

Symptomatic Plica

The plica syndrome has been associated with anterior pain as well as clicking, catching, locking, or pseudolocking of the knee, and it may even mimic acute internal derangement of the knee.[113,366,790–795]

There is some controversy regarding the prevalence of the plica syndrome, with some reports suggesting that it does not exist.[796–798] Jackson and colleagues,[113,798] Dandy,[797] and others[108,110,237,366,799–802] have stated that although plicae may indeed cause symptoms, the syndrome is overdiagnosed, and many normal synovial plicae are removed. Conversely, other authors consider the plica syndrome to be a common cause of anterior pain in the knee that is often misdiagnosed and believe that a suprapatellar membrane is virtually never asymptomatic.[118,803,804] Sherman and Jackson[805] have proposed a set of criteria for the diagnosis of symptomatic synovial plica:

- History of the appropriate clinical symptoms.
- Failure of nonoperative intervention.
- Arthroscopic finding of a plica with an avascular fibrotic edge that impinges on the medial femoral condyle during flexion of the knee. This is often a diagnosis of exclusion and can only be confirmed at arthroscopy.
- No other abnormality in the knee that would explain the symptoms. It has also been suggested that a localized area of chondromalacia at the site of impingement by a plica on the femoral condyle is evidence that a plica is the cause of the symptoms.

Clinical Findings

The mediopatellar plica (also termed Lino's shelf), although the least common variety, is often the cause of problems if it becomes thickened, resulting in pain with palpation over the medial parapatellar area. The severity of symptoms is not proportional to the size or breadth of the synovial plica.[113] There also appears to be no correlation between the duration of symptoms and the presence of pathologic changes in the plica.[806]

A palpable band or snapping, especially over the medial femoral condyle, should be sought. In one study of plicae in the knee, clicking was reported in 64%, "giving way" in 59%, and pseudolocking in 45% of the patients.[366] A number of special tests exist for the detection of plical irritation (see "Special Tests").

Plicae are not visualized well on plain radiographs, but a double-contrast arthrogram may demonstrate a suprapatellar plica or an anterior plica.[801,807–811] A skyline radiograph may demonstrate a synovial shelf.[791,812,813]

The conservative intervention for plica syndrome involves stretching of the quadriceps, hamstrings, and gastrocnemius as well as isometric strengthening, cryotherapy, ultrasound, patellar bracing, anti-inflammatory medication, and an altered sports-training schedule.[110,790,814–817] In an uncontrolled

study,[818] this type of intervention resulted in an improvement in 40% of patients over a 1-year period.

Injection of the synovial plicae with corticosteroids and a local anesthetic in another uncontrolled study[819] was reported to have an excellent result in 73% of patients.

When patients are truly symptomatic, or when conservative measures have failed, surgical excision is usually curative.

PREFERRED PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH LOCALIZED INFLAMMATION

Tendinopathy

Patellar and Quadriceps

Patellar tendinopathy (jumper's knee) and quadriceps tendinopathy are overuse conditions that are frequently associated with eccentric overloading during deceleration activities (e.g., repeated jumping and landing, downhill running). T e association of patellar tendinopathy with jumping was first described by Maurizio,[820] but the term jumper's knee originated from Blazina et al.[821] Some authors feel that the term patellar tendinopathy is a misnomer because the patellar "tendon," which connects two bones, is, in fact, a ligament.[822,823]

T e high stresses placed on these areas during CKC functioning place them at high risk for overuse injuries. Overuse is simply a mismatch between stress on a given structure and the ability of that structure to dissipate the forces, resulting in inflammatory changes.[824]

T e diagnosis of tendinopathy is based on a detailed history and careful palpation of the tendon in both flexion and extension. Pain on palpation near the patellar insertion is present in both patellar and quadriceps tendinopathy. T ese are usually self-limiting conditions that respond to rest, stretching, eccentric strengthening,[495,825,826] bracing, and other conservative techniques. When treating overuse injuries, it is essential that the clinician limit both the chronic inflammation and degeneration by working on both sides of the problem: tissue strength should be maximized through proper training, and adequate healing time must be allowed before returning to full participation.[824]

Several protocols have been advocated for the conservative intervention of patellar tendinopathy. Stanish et al.[826] proposed the following strengthening program of eccentric exercise for chronic patellar tendinopathy.

A 5-minute warm-up period consisting of a series of three to five static stretches held for 15–30 seconds each is performed. Next, the patient, from a standing position, flexes the knees, abruptly drops to a squatting position, and then recoils to the standing position. T e velocity of the drop is increased until the patient is able to perform it as quickly as possible without pain. At this point, sandbags are added to the patient's shoulders to increase the load on the tendon. Apart from some minor discomfort during the exercises and some postexercise muscle soreness, the procedures should be performed without pain.[826]

Reid[827] proposed a protocol based on the severity of the lesion. Grade I lesions, which are characterized by no undue functional impairment and pain only after the activity, are addressed with an adequate warm-up before training and ice massage after training. With grade II to III strains, activity modification, localized heating of the area, a detailed flexibility assessment, and an evaluation of athletic techniques are recommended. In addition, a concentric–eccentric program for the anterior tibialis muscle group is prescribed, which progresses into a purely eccentric program as the pain decreases.[828]

T e patient is positioned in supine with the foot in full plantar flexion. T e clinician applies overpressure on the posterior aspect of the foot, placing the foot into further plantar flexion and stretching the anterior tibialis. T e patient is asked to perform a concentric contraction into full dorsiflexion, which is resisted by the clinician. An eccentric contraction is then performed by the patient by returning the foot to its plantar flexed position as the clinician resists the motion during full dorsiflexion to full plantar flexion. T is maneuver is repeated to the point of fatigue of the anterior tibialis.[828] As soon as possible, the eccentric loading program is added.

It is not clear why a program initially directed at the anterior tibialis muscle group should be therapeutic for the infrapatellar tendon and ligament, but it is theorized that the program may stretch the infrapatellar ligament, change the quadriceps-to-foreleg strength ratio or alter the biomechanics of take-off and landing.[827]

Surgical intervention is usually required only if significant tendonosis develops and is successful in the majority of patients.[829]

Iliotibial Band Friction Syndrome

ITBFS occurs in 5–40% of runners and is the leading cause of lateral knee pain and the second leading cause of overall knee pain in this population.[830] ITBFS is the most common overuse syndrome of the knee, being particularly common in long-distance runners (20–40 miles/week). In addition, those runners who train on hilly terrain, graded slopes, or road cambers are also at risk, especially if their runs include downhill running,[831,832] which positions the knee in significantly less flexion than normal at initial contact.

As its name suggests, ITBFS is a repetitive stress injury that results from friction of the ITB as it slides over the prominent lateral femoral condyle at approximately 20 to 30 degrees of knee flexion where the distal ITB is believed to move over the lateral femoral epicondyle.[833] T e friction has been found to occur at the posterior edge of the band, which is felt to be tighter against the lateral femoral condyle than the anterior fibers.[832,833] T e friction causes a gradual development of a reddish-brown bursal thickening at the lateral femoral condyle. T us, although most cases of ITBFS have been reported in distance runners, anyone engaging in activity that requires repetitive knee flexion and extension, such as downhill skiing, circuit training, weight lifting, and jumping sports, is prone to developing this pathology.[521] ITBFS is also common in cyclists.[834–836] T is is thought to be due to the pedaling stroke, which causes the ITB to be pulled anteriorly on

the down-stroke and posteriorly on the upstroke. Extrinsic factors include excessive bike seat height or cleat position on the pedal. If the cleats are excessively internally rotated on the pedal, the tibia also internally rotates, resulting in a valgus force on the knee and increased tension of the ITB.

A study of six cadavers by Muhle et al.[837] found that in four of six individuals, some fibers of the ITB remained in contact with the lateral femoral condyle during extension. With further flexion, the ITB moves posteriorly and contacts the lateral femoral epicondyle and LCL, indicating a phase during knee flexion during which an impingement of the band occurs. In runners, this impingement phase occurs predominantly during the early stance phase, very soon after initial contact.[521] In general, the faster the speed of running, the less the time spent in the impingement zone, because the knee-flexion angle at initial contact increases with speed of running.[838–840]

In addition to those factors already mentioned, development of ITBFS also occurs with imbalances in flexibility and strength, shoe wear, running kinematics, and training volume. Adaptive shortening of the lateral thigh structures and hip abductor weakness have both been reported to be factors.[841] In addition, excessive motions of the hip and knee in the frontal and transverse planes during running are often cited as important contributing factors.[842] Given the anatomy of the ITB with its proximal attachment to the pelvis through both the tensor fasciae latae and gluteal muscles, and its distal insertion including the lateral femoral epicondyles and the Gerdy tubercle, greater hip and knee adduction, as well as greater hip and knee rotation, may increase the tensile strain in the ITB.[843]

Subjectively, the patient reports pain with the repetitive motions of the knee. T ere is rarely a history of trauma. Although walking on level surfaces does not generally reproduce symptoms, especially if a stiff-legged gait is used,[160,832] climbing or descending stairs often aggravates the pain.[844] Patients do not usually complain of pain during sprinting, squatting, or during such stop-and-go activities as tennis, racquetball, or squash.[832] T e progression of symptoms is often associated with changes in training surfaces, increased mileage, or training on crowned roads. T e lateral knee pain is described as diffuse and hard to localize.

Objectively, there is localized tenderness to palpation at the lateral femoral condyle or Gerdy tubercle on the anterolateral portion of the proximal tibia. T e resisted tests are likely to be negative for pain. T e special tests for the ITB (Ober test, Noble compression test, and creak test) should be positive for pain, or crepitus, or both, especially at 30 degrees of WB knee flexion. T ere may also be associated biomechanical changes. In addition to an adaptively shortened ITB, the following findings have all been associated with ITB friction problems, although they have yet to be substantiated: cavus foot (calcaneal varus) structure,[845] leg-length difference (with the syndrome developing on the shorter side),[846,847] fatigue,[848] internal tibial torsion (increased lateral retinaculum tension), anatomically prominent lateral femoral epicondyle, and genu varum.[849]

A study by Fredericson et al.[841]found that long-distance runners with ITBFS have weaker hip abduction strength in the involved leg compared with the uninvolved leg and symptoms improved with a successful return of hip abductor strength. To control coronal plane movement during stance phase, the gluteus medius and TFL must exert a continuous hip abductor movement. Fatigued runners or those with weak gluteus medius muscles are prone to increased thigh adduction and internal rotation at midstance. T is, in turn, leads to an increased valgus vector at the knee and increased tension on the ITB, making it more prone to impingement.[841]

Conservative intervention for ITBFS consists of activity modification to reduce the irritating stress (decreasing mileage, changing the bike seat position, and changing the training surfaces), using new running shoes,[850] heat or ice applications, strengthening of the hip abductors, and stretching of the ITB.[212] Surgical intervention, consisting of a resection of the posterior half of the ITB at the level that passes over the lateral femoral condyle, is reserved for the most recalcitrant cases.[836]

Bursitis

Several types of bursitis are differentiated:

- Superf cial and deep infrapatellar bursitis. Inflammation of these bursae usually results from mechanical irritation during such activities as kneeling ("nun's knee") or direct trauma.
- Prepatellar bursitis ("housemaid's knee"). Inflammation of this bursa is seen in patients who experience recurrent minor trauma of the anterior knee. T ose whose occupations require long periods of kneeling are particularly at risk. Diagnosis is straightforward, with pain and possibly swelling present on palpation of the prepatellar bursa.
- Superf cial pes anserinus bursitis. T is condition can involve any of the bursae lying between the various tendons of the superficial pes anserinus or a bursa between the MCL and the superficial pes anserinus. Inflammation of these bursae is common in novice swimmers and long-distance runners. Clinical findings may include medial knee pain just distal to the joint line, and an externally rotated tibia, compared with the uninvolved side.
- MCL bursitis.[557] MCL bursitis was first described by Brantigan and Voshell[851] as inflammation of the bursae deep to the MCL.[851–853] Because of the proximity of this bursa to the medial meniscus or medial meniscotibial ligament, this condition is often misdiagnosed. Patients describe pain along the medial joint line, confirmed on physical examination by a tender palpable mass that can be exacerbated by placing the knee under a valgus load. Because of the proximity of the semimembranosus tendon to the bursa, internal and external rotation can also impinge on the bursa and cause pain.[851] Imaging is not essential, but an MRI scan may show the inflamed bursa.[276]

T e intervention for bursitis includes the removal of the irritation. T is may involve the stretching of adaptively shortened structures or joint mobilizations to help correct alignment.

Sindig–Larson–Johansson Syndrome and Osgood–Schlatter Disease

T is condition is an apophysitis of the tibial tubercle (Osgood–Schlatter disease) and inferior pole of the patella (Sinding–Larsen–Johanssen syndrome) that occurs in skeletally immature individuals, especially those involved in sports requiring repetitive-loaded knee flexion.

Osgood–Schlatter disease presents between the ages of 8 and 13 years in females and 10 and 15 years in males, who are affected about three times as often.[827] In 25–33% of the cases, there is bilateral involvement.[854] T e condition is the result of a retrograde ossification of the tibial tubercle, which produces an apophysitis. Although usually self-limiting, it can progress to an osteonecrosis.

Sinding–Larsen–Johanssen syndrome usually occurs prior to the growth spurt. Fragmentation of the tibial tubercle or irregular calcification of the inferior patellar pole may be seen on radiographs. Pain is usually reported with use of the knee in activities such as athletics, cycling, or resisted knee extension. T e involved area is tender and usually prominent on physical examination.

T e intervention for these conditions is usually symptomatic, including short courses of anti-inflammatory medications, a focus on hamstring flexibility, and moderate-intensity quadriceps strengthening. T e traditional approach of activity limitations is no longer considered necessary. Rarely, individuals will require excision of symptomatic ossicles or degenerated tendons for persistent symptoms at skeletal maturity. More persistent cases may require immobilization for 6–8 weeks.[827]

Quadriceps Contusion

Quadriceps contusions, resulting from a direct blow, can be very disabling.[855] T e term charley horse is synonymous with a contusion of the quadriceps muscle. T ese contusions are quite common and can vary in their degree of discomfort. T ey are usually because of a direct blow to the anterior thigh, with the VL and intermedius being the most frequently involved. Contusions of the anterior portion of the muscle are usually more serious than those involving the lateral portion of the muscle because of the differences in muscle mass present in the two areas.

T e patient usually describes a specific mechanism and complains of a dull aching pain in the thigh. Clinical findings include

- palpable tenderness over the anterior lateral aspect of the thigh;
- variable swelling; extreme swelling should alert the clinician to the possibility of an injury to major vessels;
- the pain increased with knee flexion, which is sometimes accompanied by spasm;
- a palpable hematoma on occasion.

As elsewhere in the body, contusions are graded according to severity. A grade I contusion produces only mild discomfort, with no swelling and no detrimental effect on gait. T e patient with a grade II contusion may or may not have a normal gait cycle. Grade III contusions in this muscle are very rare due to the lack of muscle belly tissue.

Quadriceps contusions can also be graded according to functional loss[856]:

- Grade I. In a mild contusion, the patient has localized tenderness with no alteration of gait. Knee motion can be performed without pain up to at least 90 degrees of flexion.
- Grade II. In a moderate contusion, there is local swelling and a tender muscle mass. Knee flexion motion is restricted to less than 90 degrees, and an antalgic gait is present. T e patient is unable to climb stairs or arise from a chair without considerable discomfort.
- Grade III. In a severe contusion, the patient cannot bend their knee beyond approximately 45 degrees. T e patient is unable to walk unaided. Marked tenderness and swelling are present.

T ese are frustrating injuries for the clinician and the patient because there are often few clinical and radiographic findings to establish the diagnosis, resulting in a diagnosis made by way of exclusion. MRI may be helpful in the acute phase, but this remains a diagnosis that is largely based on the history.

Conservative intervention involves a gradual progression of ROM and strengthening exercises. If the intervention for these contusions occurs too early or is too aggressive, myositis ossificans can develop. Myositis ossificans is a pathologic bone formation resulting from muscle tissue damage, bleeding, and damage to the periosteum of the femur, and producing ectopic bone formation.[857,858]

T e intervention includes ice with 24-hour compression applied immediately, which should be continued until all of the signs and symptoms are absent. Gentle pain-free quadriceps-stretching exercises are begun on the first day, progressing to resistive exercises as tolerated, usually on the second day. If an abnormal gait is present, the patient may be issued crutches until the normal gait returns.

Patients with a grade I contusion can continue with normal activities as tolerated. A patient with a grade II contusion may require 3–21 days for rehabilitation. Grade III contusions may require 3 weeks to 3 months to fully heal.

Turf Knee or Wrestler's Knee

Turf knee, or wrestler's knee, is an injury to the soft tissue overlying the knee. It is caused by a shearing mechanism within the subcutaneous tissues. Swelling and tenderness are present, but the swelling is present in the extra-articular tissues and should be differentiated from a true joint effusion. A joint effusion is characterized by a ballotable patella, and the intraarticular fluid is mobile and can be pushed to and from the suprapatellar pouch. With turf knee, these signs are absent, but there is boggy swelling in the soft tissue, and a sense of subcutaneous fluid is present on palpation. T is injury usually responds well to rest and avoidance of the aggravating trauma.

Hoffa (Fat Pad) Syndrome

T e infrapatellar fat pad may be a cause of anterior knee pain. T is syndrome was first described by Hoffa[859] in 1904. It is thought to represent hypertrophy and inflammation of the infra-patellar fat pad secondary to impingement between the femoral condyles and tibial plateau during knee extension.

Direct trauma and overuse have also been attributed as causes. Irritation also can be produced by a posterior tilt of the inferior pole of the patella.

Symptoms include anterior knee pain that is inferior to the pole of the patella. Pain is exacerbated by knee extension, particularly hyperextension, but not by knee flexion.[340] Inspection may reveal inferior patellar edema and associated tenderness of the fat pad when palpated through the tendon. Direct palpation of the fat pad on either side of the patellar tendon as the knee is brought from flexion into a full extension is painful if the fat pad is inflamed. A diagnostic test termed the bounce test (eliciting pain with passive knee hyperextension), is sometimes useful.[276] One must be careful to look for other causes of inflammation, such as OA, before concluding that the fat pad is the primary source of pain.[302] Plain radiographs are invariably negative, but abnormalities of the fat pad can be noted on MRI.[860]

Conservative intervention includes rest, ice, anti-inflammatory medications, and iontophoresis or phonophoresis. Local corticosteroid injections into the fat pad are preferred by some physicians because they can be both diagnostic and therapeutic.

Biomechanical interventions include addressing the causes of hyperextension through orthotic interventions, such as heel lifts or taping the superior pole posteriorly and holding the patella in a superior glide with tape.

In recalcitrant cases, surgical resection of portions of the fat pad is indicated.

Medial Retinaculitis

Medial retinaculitis is a rare condition seen almost exclusively in runners. It probably represents a fatigue tear in the medial capsular insertion into the patella. A positive bone scan in the medial edge of the patella confirms this diagnosis.

Baker Cyst

Usually a Baker cyst is asymptomatic, but in the presence of a synovial effusion, the cyst can swell up with fluid and become painful. On occasion, the cyst can become so large that it protrudes through the soft tissues, just proximal to the popliteal fossa, between the heads of the gastrocnemius. Ruptures of the cyst can occur, and these can mimic the symptoms of a tear of the gastrocnemius.

Clinical findings with the larger cysts include pain with active and passive knee flexion and extension, with WB, and pain and an increased prominence of the swelling with resisted knee flexion.

T e conservative intervention for this condition normally involves treating the articular disorder that caused the cyst to swell. T e medical management includes aspiration or surgical resection.

Popliteus Tendinopathy

Popliteus tendinopathy is common in runners who use canted surfaces, which produce oblique lateral rotary stresses to the knee, or who run downhill frequently. T e condition typically manifests as point tenderness in the lateral aspect of the knee corresponding to the popliteus insertion site, which is exacerbated with eccentric loading.

Popliteus tendinopathy can be diagnosed by having the patient sit so that the leg is in the figure-4 position, with the lateral aspect of the ankle resting on the contralateral knee.

Intervention involves a modification in the training regimen, ultrasound, and transverse friction massage.

Breaststroker Knee

T is condition of pain and tenderness localized on the medial aspect of the knee is often associated with performance of the whip-kick, the kick used with breaststroke.[94] T e forceful whipping together of the lower legs often forces the lower leg into slight abduction at the knee, with subsequent irritation and inflammation to the MCL of the knee.

In a study of breaststroke kinematics,[861] it was found that angles of hip abduction of less than 37 degrees, or greater than 42 degrees at the initiation of the kick, resulted in a dramatic increase in the incidence of knee pain.[94]

PREFERRED PRACTICE PATTERN 4G: IMPAIRED JOINT MOBILITY, MUSCLE PERFORMANCE, RANGE OF MOTION ASSOCIATED WITH FRACTURE

Tendon Ruptures or Fractures

Quadriceps and patellar tendon ruptures, and patellar fractures, usually result from eccentric overload of the extensor mechanism or direct trauma. T ese are usually easy to diagnose, because the patient is unable to actively extend the knee, and there is a palpable defect at the site of injury. Radiographs will confirm fractures or avulsions. In skeletally immature individuals, fractures involving the proximal tibial epiphysis can occur. T ese are usually evident on radiographs and often require surgical intervention.

INTEGRATION OF PREFERRED PATTERNS 4F AND 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND RANGE OF MOTION SECONDARY TO COMPLEX REGIONAL PAIN SYNDROME (REFLEX SYMPATHETIC DYSTROPHY), MYOFASCIAL PAIN SYNDROMES (REFERRED PAIN SYNDROMES), PERIPHERAL NERVE ENTRAPMENT

Peripheral Nerve Entrapment

Compression Neuropathy of the Saphenous Nerve[597]

Saphenous nerve palsy is an impingement of the large cutaneous branch of the femoral nerve by the fascia of its three

bordering muscles (anterolaterally by the vastus medialis, posterolaterally by the adductor longus, and medially by the sartorius) as it exits the adductor canal.[852,862–864] Occasionally, branches of the femoral vessels also may impinge on the nerve. The onset can be insidious or secondary to trauma or surgery about the knee.

Entrapment of the saphenous nerve often results in marked pain at the medial aspect of the knee. Patients describe a burning sensation in the nerve's sensory distribution, which typically worsens at night and is exacerbated by lower limb activity. The pain can be confused with an internal derangement of the knee or an anserine bursitis.

Physical examination reveals a Tinel sign at the adductor canal. Often there is associated local tenderness. Sensory changes may be seen within the sensory distribution of the nerve. There is no motor weakness. Confirmation of a saphenous lesion can be made using resisted flexion of the knee or resisted adduction of the thigh, which should increase the pain, or pressure over the saphenous opening, in the subsartorial fascia, producing a radiation of the pain. Active flexion of the knee beyond 60 degrees can also reproduce the pain.

EMG and nerve conduction studies can help eliminate L3 and L4 radiculopathies and aid in the diagnosis.[862] Diagnostic peripheral nerve blocks with lidocaine also may be performed. Mild-to-moderate cases can be treated with rest, anti-inflammatory medications, ice, ultrasound, and TENS.[852,864,865] Second-line interventions include therapeutic nerve blocks with phenol.[863] Cases refractory to these interventions can be managed with surgical release of fascial bands and neurectomy.[864]

Compression Neuropathy of Superficial Fibular (Peroneal) Nerve

This nerve can be entrapped as a result of fibrosis following a direct blow,[866,867] or surgery. Symptoms typically include pain over the lateral distal aspect of the leg and ankle, mimicking symptoms of a disk herniation, with irritation of the L5 nerve root. However, differentiation can be made with percussion or pressure over the nerve at its point of exit, which will cause reproduction of the symptoms in this syndrome.[868]

Myofascial Pain Dysfunction: Vastus Medialis

This muscle refers pain deep to the patella, and patients typically complain of knee joint stiffness and loud cracking noises as the patella suddenly releases during knee flexion.[869] Dysfunction of the vastus medialis, which counters the lateral pull of the other three quadriceps muscles and ensures proper patellar tracking, can lead to patellofemoral dysfunction and pain. Structural deformities, such as valgus deviation of the knee or overpronation of the foot, put additional strain on this muscle and perpetuate trigger point activity.[869]

Complex Regional Pain Syndrome (Reflex Sympathetic Dystrophy)

This condition is characterized by intractable knee pain of considerable duration. The patient may appear severely disabled, often using crutches, and may appear anxious and depressed. The presence of cyanosis or mottling indicates autonomic dysfunction. There also may be a noticeable difference in temperature between the involved area and the contralateral limb. In late cases, trophic changes of the skin occur. In addition, wasting of the quadriceps and stiffness of the joint may be evident.

Early diagnosis is the key to a successful intervention. The intervention should include a comprehensive team approach involving the physician and physical therapist. The most important rule is to avoid excessive pain.[870] Complete rest to the involved region, particularly immobilization in a cast, is harmful.[871,872]

It is important to not reinjure the region or aggravate the problem with aggressive physical rehabilitation.[872] Thus, the progression should occur slowly and gently.

- Exercises are prescribed for strengthening, active assistive ROM, and AROM. WB exercises and active stress loading exercises also should be incorporated.
- Sensory threshold techniques, including fluidotherapy, vibration desensitization, TENS, contrast baths, and desensitization using light and heavy pressure of various textures over the sensitive area, should be used.
- Affected joints should be rested and elevated to counteract the vascular stasis, but the joint also should be mobilized gently several times per day.[871]

THERAPEUTIC TECHNIQUES

Techniques to Increase Joint Mobility

A number of techniques can be used to increase joint mobility.

Joint Mobilizations

The mobilizations described in this section should always be complimented with exercises or automobilization techniques performed at home by the patient.

Patellofemoral Mobilizations

Numerous studies in the literature recommend using patellar mobilizations as one of the components of a physical therapy intervention for patellofemoral disorders.[198,873] These mobilizations are advocated to be performed in a variety of directions to increase the mobility of the patella, presumably to improve tracking. These include superior mobilizations, inferior mobilizations, and medial and lateral glides. However, from an evidence-based perspective, there is not one randomized study supporting the efficacy of patellofemoral mobilizations in the treatment of patellofemoral disorders at present.

The mobilizations for the tibiofemoral joint are identical to the techniques used to assess the joint, which are described in the passive physiologic articular mobility tests of the examination.

Distraction of the Tibiofemoral Joint

A variety of techniques can be used to apply a long-axis traction force to the tibiofemoral joint. Joint distraction is used

for pain control and general mobility. Distraction at this joint tends to occur when moving into flexion. Using the resting position of the joint as a starting point, and the tibia rotated into either neutral, external rotation, or internal rotation, different ranges of flexion can be used.

Posterior Glide of the Tibia on the Femur

This technique is used to increase the joint glide associated with flexion of the tibiofemoral joint, with the emphasis of the mobilization technique varying according to the ROM being treated. For example, in the midranges of flexion, the posterior glide of the tibia is applied along the plane of the joint, whereas in the last few degrees of flexion, the posterior glide is applied with the congruent rotation of internal rotation of the tibia. Active mobilization can also be employed by positioning the patient's foot and leg into internal rotation, and asking the patient to pull isometrically with the hamstrings.

Anterior Glide of the Tibia on the Femur

This technique is used to increase the joint glide associated with extension of the tibiofemoral joint. If the clinician is attempting to regain the last 10–30 degrees of extension, the emphasis is placed on positioning the tibia in external rotation.

Proximal Tibiofibular Joint

The mobilizations for this joint are identical to the techniques used to assess the joint, which are described in the passive physiologic articular mobility tests of the examination. Myofascial restrictions of this joint present with the fibular head in an anterior or posterior position, and in the absence of adaptive shortening, the passive mobility tests will be normal. The intervention should be aimed at the cause of the muscle imbalance, but if direct treatment is attempted, active mobilization (muscle energy) techniques are used.

- To increase the posterior movement, the patient is asked to contract the hamstrings. The biceps femoris is attached to the fibular head and will help draw the fibular posteriorly.
- To increase the anterior glide, the patient is asked to contract the anterior tibialis, whose attachment will pull the fibula anteriorly.

Pericapsular hypomobility restrictions also present with the fibular head positioned anteriorly or posteriorly. The passive mobility test demonstrates reduced motion with a capsular end-feel. Treatment is by anterolateral (foot in plantar flexion) or posteromedial (foot in dorsiflexion) capsular stretches.

High-Velocity Correction for a Posterior Fibular Head

The patient is placed in the supine position, with the clinician standing beside the table, opposite the dysfunction. The clinician grasps the patient's foot and ankle on the side of the dysfunction with the nonthrusting hand and flexes the patient's hip and knee to 90 degrees. The clinician first places the index finger of his or her thrusting hand into the patient's popliteal crease, monitoring the dysfunctional fibular head. Next, the clinician locks the patient's foot on the side of the dysfunction in his or her armpit. The clinician then exerts a rapid downward thrust on the distal tibia and fibula while simultaneously pulling the fibular head anteriorly with his or her index finger.

FIGURE 20-74 Towel hyperextensions.

AUTOMOBILIZATIONS

To Increase Extension

- Towel hyperextensions. A towel of sufficient height to elevate the calf and thigh off the table is placed under the heel (Fig. 20-74). A weight can be added to the tibia or femur to assist in regaining hyperextension at the knee (Fig. 20-75).
- Prone hangs (Fig. 20-76) VIDEO
- Quadriceps setting. These exercises are done repeatedly during the day and can also be performed during the towel extension exercise.
- Standing extension (Fig. 20-77) with foot placed on a stool or chair.

FIGURE 20-75 Towel hyperextensions with weight.

FIGURE 20-76 Prone hangs.

FIGURE 20-77 Standing extension.

FIGURE 20-78 Seated heel slides with passive overpressure.

FIGURE 20-79 Passive knee flexion with towel roll behind knee.

To Increase Flexion

- Wall slides in supine with the sole of the foot on the wall are performed until 90 degrees of flexion is obtained, and then seated heel slides with passive overpressure are initiated (Fig. 20-78).
- The patient is placed in the supine or sitting position. A rolled-up towel/pillow of sufficient size is placed behind the knee so that with the knee actively flexed, the towel/pillow can be held in place and act as a fulcrum. Using one or both hands, the patient grasps the anterior aspect of the lower leg (Fig. 20-79). By gently pushing the lower leg posteriorly, flexion of the knee can be increased.

Techniques to Increase Soft-Tissue Extensibility

Increasing soft-tissue extensibility is the hallmark of the functional knee rehabilitation protocol and includes stretching of the ITB, hamstring muscles, quadriceps, hip flexors, and Achilles tendon[196,340] (Table 20-21). The stretching techniques for the ITB, hamstring muscles, quadriceps, and hip flexors are described in Chapter 19. The technique for the Achilles tendon is described in Chapter 21.

Patients with marked internal rotation of the hip may require stretching of the anterior hip structures to increase the available external rotation and to help the gluteal muscles work in the inner range.[500]

TABLE 20-21 Muscle Stretching: Positions of Maximal Elongation and Stretch

Muscle	Maximal Elongation	Stretch
Gastrocnemius	Subtalar joint neutral, knee extension	Ankle dorsiflexion
Soleus	Subtalar joint neutral, knee flexion	Ankle dorsiflexion
Medial hamstrings	Hip external rotation, abduction, and flexion	Knee extension
Lateral hamstrings	Hip internal rotation and flexion	Knee extension
Rectus femoris	Hip extension	Knee flexion
Tensor fascia lata	Knee flexion, hip extension and external rotation	Hip adduction
Iliotibial band	Hip extension, neutral hip rotation, slight knee flexion	Hip adduction

CASE STUDY

LEFT ANTERIOR KNEE PAIN

HISTORY

History of Current Condition

A 30-year-old woman presented with a 2-month history of progressive anterior left-knee pain.[550] The pain had started insidiously 3 months after she began playing field hockey. She denied any traumatic inciting mechanism. The pain was increased with hyperflexion and weight-bearing activities, abated with rest, but seemed aggravated with prolonged sitting. The patient also noted difficulty achieving full knee extension and had intermittent swelling and stiffness. Previous trials of oral anti-inflammatories had only mildly improved her pain.

History of Current Condition

No previous history of knee surgery or injury.

Past Medical/Surgical History

Unremarkable.

Medications

None.

Other Tests and Measures

Radiographs were negative for loose bodies, tumors, and fracture.

Social Habits (Past and Present)

Nonsmoker and drinker; active lifestyle.

Social History

Single; living alone.

Family History

No relevant history of knee problems in family.

Growth and Development

Normal development; right-handed.

Living Environment

Two-storey house.

Occupational/Employment/School

Full-time laborer; high-school education.

Functional Status/Activity Level

The patient denied any locking of her left knee, although there had been occasions when she felt the knee gave way because of pain. Pain increases with stair negotiation, particularly ascending stairs, and with prolonged sitting.

Health Status (Self-report)

The patient reported being in generally good health, but pain interferes with tasks at home and at work.

Questions

1. What structure(s) do you suspect to be at fault in this patient and require a specific examination?
2. What might the history of pain with prolonged sitting and stair negotiation tell the clinician?
3. What other activities do you suspect would increase the patient's symptoms? Why?
4. To help rule out the various causes of anterior knee pain, what other questions can you ask?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?

CASE STUDY

LATeRAL Kn e e PAIn WITh RUn n In G

HISTORY

History of Current Condition

A 22-year-old male runner complained of lateral right-knee pain that radiated from the lateral aspect of the knee, up the lateral thigh, and down to the proximal aspect of the lateral tibia. The pain was aggravated with running, especially on hills, and had begun about 6 weeks ago when he began training for a triathlon. The patient reported no pain with walking. The patient saw his physician, who prescribed a course of NSAIDs and recommended physical therapy.

History of Current Condition

No previous history of lower extremity pain.

Medical/Surgical History

Unremarkable.

Medications

Ibuprofen, 800 mg daily.

Functional Status/Activity Level

Pain was interfering with training for a triathlon. The patient also experienced pain with stair climbing.

Health Status (Self-report)

The patient reported being in generally good health.

Questions

1. What structure(s) could be at fault with complaints of lateral knee pain aggravated with running?
2. What might the history of a gradual onset of pain related to a change in training tell the clinician?
3. Why do you think the patient's symptoms are worsened with running on hills but not affected with walking?
4. What additional questions would you ask to help rule out referred pain from the lumbar spine?
5. What is your working hypothesis at this stage? List the various diagnoses that could present with these signs and symptoms, and the tests you would use to rule out each one.
6. Does this presentation/history warrant a scan? Why or why not?

CHAPTER 21

Lower Leg, Ankle, and Foot

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the joints, ligaments, muscles, and blood and nerve supply that comprise the ankle and foot complex.
2. Describe the biomechanics of the ankle and foot complex, including the open- and close-packed positions, normal and abnormal joint end-feels, kinesiology, and the effects of open- and closed-chain activities.
3. Outline the purpose and components of the tests and measures of the ankle and foot complex.
4. Perform a detailed examination of the ankle and foot complex, including palpation of the articular and soft-tissue structures, range-of-motion (ROM) testing, passive articular mobility tests, and stability tests for the ankle and foot complex.
5. Discuss the significance of the key findings from the tests and measures.
6. Evaluate the total examination data to establish a physical therapy diagnosis.
7. Describe the significance of muscle imbalance in terms of functional muscle performance and the deleterious effects on the lower kinetic chain.
8. Develop self-reliant examination and intervention strategies.
9. Describe the intervention strategies based on clinical findings and established goals.
10. Apply manual techniques to the ankle and foot complex, using the correct grade, direction, and duration.
11. Incorporate appropriate therapeutic exercises into the intervention progression.
12. Evaluate intervention effectiveness in order to progress or modify the intervention.
13. Plan an effective home program and instruct the patient in same.

OVERVIEW

T e ankle and foot is a complex structure of 28 bones, also known as tarsals, (including two sesamoid bones) and 27 articulations (including 20 synovial joints), interconnected by more than 100 ligaments and muscles.

T e foot and ankle are uniquely differentiated to provide enough mobility to adapt to different surfaces and attenuate shock, yet maintain sufficient stability for effective locomotion.[1] In order to perform these diverse functions, the foot has undergone a number of evolutionary adaptations. First, the foot has become plantigrade, which allows most of the sole to be a weight-bearing surface. Second, the great toe has come to lie in a position with the other toes and, because of the relative immobility of the first metatarsal at the metatarsophalangeal (MTP) joint, is now relatively nonprehensile. T ird, the metatarsals and phalanges have progressively shrunk and become small in comparison to the hypertrophied tarsus. Last, the medial side of the foot has become larger and stronger than that of any other primate.

Unfortunately, when the requirements for foot and ankle mobility and stability are exceeded, structural breakdown occurs. Increasing the potential for breakdown is the fact that the ankle joint sustains the greatest load per surface area of any joint of the body.[2] Peak vertical forces reach 120% of body weight during walking, and they approach 275% while running.[3] T e joints and ligaments of the ankle and foot complex act as stabilizers against these forces and constantly adapt during weight-bearing activities, especially on uneven surfaces. It is estimated that an average 180-lb man absorbs 76.2 tons on each foot while walking 1 mile and that the same man absorbs 121.5 tons per foot while running 1 mile.[4] Approximately 60% of this weight-bearing load is carried out by the hindfoot,[5] and 28% by the metatarsal heads.[6] Although the ankle and foot complex normally adapts well to the stresses of everyday life, sudden or unanticipated stresses to this region have the potential to produce dysfunction.

Anatomically and biomechanically, the foot can be subdivided into the hindfoot, sometimes referred to as the rear foot (tibia, talus, and calcaneus), the midfoot (the navicular, cuboid, and the three cuneiforms), and the forefoot (the 14 bones of the toes, the five metatarsals, and the medial and lateral sesamoids) (Table 21-1 and Fig. 21-1). T e seven tarsal bones occupy the proximal half of the foot (see Fig. 21-1).

TABLE 21-1 The Joints of the Foot and Ankle: Their Open- and Close-Packed Positions and Capsular Patterns

Joints of the Hindfoot	Open-Packed Position	Close-Packed Position	Capsular Pattern
Tibiofibular joint	Plantarflexion	Maximum dorsiflexion	Pain on stress
Talocrural joint	10 degrees of plantarflexion and midway between inversion and eversion	Maximum dorsiflexion	Plantarflexion and dorsiflexion
Subtalar joint	Midway between the extremes of ROM	Supination	Varus and valgus
Joints of the Midfoot			
Midtarsal joints	Midway between the extremes of ROM	Supination	Dorsiflexion, plantarflexion, adduction, and internal rotation
Joints of the Forefoot			
Tarsometatarsal joints	Midway between the extremes of ROM	Supination	None
Metatarsophalangeal joints	10 degrees of extension	Full extension	Great toe: extension and flexion of second to fifth toes: variable
Interphalangeal joints	Slight flexion	Full extension	Flexion and extension

ANATOMY

The ankle and foot complex is a sophisticated musculoskeletal arrangement designed to facilitate numerous and various weight-bearing and non–weight-bearing functions.[7] Although described separately, the joints of the lower leg, ankle, and foot act as functional units and not in isolation. The joints of the foot and ankle, their open- and close-packed positions, and capsular patterns are outlined in Table 21-1. The shapes of the articulating surfaces of the leg and foot are outlined in Table 21-2. An appreciation of the shapes of the articulating surfaces is important when examining the joint glides and when performing joint mobilizations. Most of the stability of the foot and ankle is provided by a vast array of ligaments (Table 21-3).

DISTAL TIBIOFIBULAR JOINT

The distal tibiofibular joint (Fig. 21-1) is classified as a syndesmosis, except for approximately 1 mm of the inferior portion, which is covered in hyaline cartilage. The joint consists of a concave tibial surface and a convex or plane surface on the medial distal end of the fibula. The tibia is the second longest bone of the skeleton and is a major weight-bearing bone. There is an elongation into the joint by the synovium of the talocrural joint, the fibers of which are oriented inferiorly and laterally. The fibula serves as a site for muscular and ligamentous attachment, providing stability for the talus at the talocrural joint. A minor amount of fibular elevation and rotation is available at this joint. Sprains of this joint, which are called syndesmotic sprains or high-ankle sprains, typically occur in positions of dorsiflexion with eversion.[1]

As at the proximal tibiofibular joint (see Chapter 20), support for this joint is provided primarily by ligaments. The joint is stabilized by four ligaments, collectively known as the syndesmotic ligaments. These include the inferior interosseous ligament, the anterior inferior tibiofibular ligament, the posterior inferior tibiofibular ligament, and the inferior transverse ligament. Of these ligaments, the inferior interosseous ligament is the primary stabilizer.

HINDFOOT

The joints of the hindfoot are the talocrural (ankle) joint, and the subtalar (talocalcaneal) joint. The proximal row of tarsals comprises the talus (astragalus) (see Fig. 21-1), and calcaneus (or calcis). The function of the hindfoot is as follows:

- to influence the function and movement of the midfoot and forefoot;
- to convert the transverse rotations of the lower extremity into sagittal, transverse, and frontal plane movements.[8]

CLINICAL PEARL

Hindfoot/rear foot varus is an inwardly angled hindfoot position in the frontal plane.
Hindfoot/rear foot valgus is outwardly angled hindfoot position in the frontal plane.

TABLE 21-2 Shapes of the Articulating Surfaces of the Leg and Foot

Joint	Proximal Bone and Shape of Its Joint Surface	Distal Bone and Shape of Its Joint Surface
Inferior tibiofibular	Tibia—concave	Fibula—convex
Talocrural	Tibia—concave in anterior–posterior direction and concave–convex–concave in mediolateral direction	Fibula—convex in anterior–posterior direction and convex–concave–convex in mediolateral direction
Talocalcaneal	Talus—posterior facet biconcave, middle facet biconvex, and anterior facet convex	Calcaneus—posterior facet biconvex, middle facet biconcave, and anterior facet concave
Talonavicular	Talus—biconvex	Navicular—biconcave
Calcaneocuboid	Calcaneus—convex in mediolateral direction and concave in superior–inferior direction (saddle shaped)	Cuboid—concave in mediolateral direction and convex in superior–inferior direction (saddle shaped)
Cuboideonavicular	Navicular—planar	Cuboid—planar
Cuneonavicular	Navicular—slightly convex	Cuneiforms—slight concave
Intercuneiform	Cuneiforms (medial and middle)—planar	Cuneiforms (middle and lateral)—planar
Cuneocuboid	Lateral cuneiform—planar	Cuboid—planar
Tarsometatarsal	Cuneiforms and cuboid—planar to slightly convex	Bases of metatarsals—planar to slightly concave
Metatarsophalangeal	Metatarsals—biconvex	Proximal phalanges—biconcave
Interphalangeal	Proximal phalanges—convex in superior–inferior and concave in medial–lateral direction	Middle phalanges—concave in superior–inferior and convex in medial–lateral direction

MIDFOOT

The joints of the midfoot include the midtarsal (transverse) joint and the tarsometatarsal joints. The midtarsal joint complex consists of the talonavicular and calcaneocuboid joints. The tarsometatarsal joints include the articulations between the cuneiforms, cuboid, and metatarsal bases. The distal tarsal row contains, medial to lateral, the medial, intermediate, and lateral cuneiforms and the cuboid, which is roughly in parallel with the proximal row and which forms a transverse arch, posteriorly (dorsally) convex. Medially, the navicular is positioned between the talus and the cuneiforms (see Fig. 21-1). Laterally, the cuboid is positioned between the calcaneus and the lateral cuneiform and the fourth and fifth metatarsals (see Fig. 21-1). The cuneiforms articulate intimately with the bases of the second and third rays forming a midfoot lever.[9] The function of the midfoot is to transmit motions from the hindfoot to the forefoot and to promote stability.[8]

CLINICAL PEARL

The transverse tarsal joint complex, or Chopart's joint, consists of the calcaneocuboid joint and talonavicular joint and connects the hindfoot to the midfoot. The midtarsal joint facilitates adduction and abduction of the forefoot.[7] Ligamentous support for the calcaneocuboid joint includes the long plantar ligament.

The tarsometatarsal, or Lisfranc's joint complex, connects the midfoot and the forefoot.[7] The plantar calcaneonavicular, or spring ligament, provides ligamentous support for the talonavicular joint.

FOREFOOT

The joints of the forefoot include the tarsometatarsal joints, the intermetatarsal joints, the MTP joints, and the interphalangeal (IP) joints. The function of the forefoot is to adapt to the terrain, adjusting to uneven surfaces. The first metatarsal is the shortest and the strongest (see Fig. 21-1), whereas the second is the longest and the least mobile, serving as the anatomic touchstone for abduction and adduction of the foot.[10] The second and third rays, which are functionally rigid because of their associated osseous and ligamentous configuration, act as the "I-beam" or longitudinal strut of the foot.[11] The fourth and fifth rays have the most mobility. The phalanges of the foot, although similar in number and distribution to those in the hand, are shorter and broader than their counterparts.

CLINICAL PEARL

Forefoot varus is an inwardly angled forefoot in the frontal plane.
Forefoot valgus is an outwardly angled forefoot in the frontal plane.
Forefoot adductus is an inwardly angled forefoot in the transverse plane.
Forefoot abductus is an outwardly angled forefoot in the transverse plane.

THE TALOCRURAL (ANKLE) JOINT

The talocrural (tibiotalar) joint is the synovial articulation between the articulating facets of the talus and the tibiofibular

TABLE 21-3 Ankle and Foot Joints and Associated Ligaments

Joint	Associated Ligament	Fiber Direction	Motions Limited
Distal tibiofibular	Anterior tibiofibular	Distolateral	Distal and posterior glide of fibula
	Posterior tibiofibular	Distolateral	Distal and anterior glide of fibula
	Interosseous	Distolateral	Separation of tibia and fibula
Ankle	Deltoid (medial collateral)		
	Superficial		
	Tibionavicular	Plantar–anterior	Lateral translation and external rotation of the talus
	Calcaneotibial	Plantar, plantar–posterior	Eversion (abduction of talus, calcaneus and navicular)
	Posterior talotibial	Plantar–posterior	Dorsiflexion, lateral translation and external rotation of the talus
	Deep		
	Anterior talotibial	Anterior	Abduction of the talus when in plantarflexion or eversion
	Lateral or fibular collateral		
	Anterior talofibular	Anterior–medial	Inversion and plantarflexion Anterior displacement of the talus Internal rotation of the talus
	Calcaneofibular	Posterior distal and medial	Inversion and dorsiflexion
	Posterior talofibular	Horizontal	Dorsiflexion Posterior displacement of foot Inversion
Subtalar	Lateral (anterior) talocalcaneal	Distal anterolateral	Joint separation during inversion and dorsiflexion
	Medial (posterior) talocalcaneal	Distal	Anterior translation of talus and inversion
	Cervical ligament	Distal–posterior–lateral	Inversion
	Interosseous	Distal and lateral	Joint separation
Main ligamentous support of longitudinal arches	Long plantar	Anterior, slightly medial	Eversion
	Short plantar	Anterior	Eversion
	Plantar calcaneonavicular	Dorsal–anterior–medial	Eversion
	Plantar aponeurosis	Anterior	Eversion
Midtarsal or transverse	Bifurcated		Joint separation
	Medial band	Longitudinal	Plantarflexion
	Lateral band	Horizontal	Inversion
	Dorsal talonavicular	Longitudinal	Plantarflexion of talus on navicular
	Dorsal calcaneocuboid	Longitudinal	Inversion, plantarflexion
Intertarsal	Dorsal and plantar ligaments		Joint motion in direction causing ligament tautness
	Interosseous ligaments connecting cuneiforms, cuboid, and navicular		Flattening of the transverse or longitudinal arch
Tarsometatarsal	Dorsal, plantar, and interosseous		Joint separation
Intermetatarsal	Dorsal, plantar, and interosseous		Joint separation
	Deep transverse metatarsal		Joint separation Flattening of the transverse arch
Metatarsophalangeal	Fibrous capsule		
	Dorsal, thin—separated from extensor tendons by bursae		Flexion
	Plantar—inseparable from deep surface of plantar and collateral ligaments		Extension
	Collateral		Flexion, abduction, or adduction in flexion
Interphalangeal	Collateral		Flexion, abduction, or adduction in flexion
	Plantar		Extension

mortise. The talus serves as the link between the foot and the leg through the ankle joint and functions to distribute the body weight posteriorly toward the heel and anteriorly to the midfoot. The talus is divided into an anterior head and a posterior neck and body:

- Body. The superior dome-shaped surface of the body articulates with the tibia. The body is convex in the anteroposterior (A-P) direction and slightly concave in the mediolateral (M-L) and superior directions. The shape of this articulating surface can be compared with that of a cone, with the base of the cone facing laterally and the apex medially. Since the superior aspect of the body of the talus is wedge shaped with the wider portion anterior, no varus/valgus movement is possible when the ankle is positioned in maximum dorsiflexion, unless the mortise or the tibiofibular ligaments are compromised.
- Neck. The neck of the talus is a narrow region between the head and the body of the talus, and it is medially inclined. Its rough surfaces serve as attachments for ligaments. Inferior to the neck of the talus is the sulcus tali, which, when the talus and the calcaneus are articulated, roofs the sinus tarsi (a cylindrical cavity located between the talus and calcaneus on the lateral aspect of the foot that separates the anterior and posterior aspects of the subtalar joint—see later) and is occupied by the talocalcaneal interosseous and cervical ligaments.
- Head. The plantar surface of the head has three articular areas separated by smooth ridges. The most posterior and largest of the articular areas is oval, slightly convex, and rests on a shelf-like medial calcanean projection called the sustentaculum tali. The other two articulating facets connect the talus with the navicular and the plantar calcaneonavicular ligament.

The medial malleolus extends distally to approximately one-third of the height of the talus, whereas the lateral malleolus, which is positioned slightly posterior to the medial malleolus, extends distally to approximately two-thirds the height of the talus. Thus, the axis of rotation is inclined distally by 10 degrees and rotated posteriorly by 6 degrees, referencing the lateral side of the joint.[1]

The fibrous capsule of the ankle joint is relatively thin on its anterior and posterior aspects. It is lined with synovial membrane and reinforced by the collateral ligaments (see later).

CLINICAL PEARL

No tendons, with the exception of a small slip from the posterior tibialis, attach to the talus. However, the talus serves as the attachment for many ligaments.

The talus receives its blood supply from the branches of the anterior and posterior tibial arteries and is very susceptible to aseptic necrosis, particularly with proximal fractures.[12]

Talocrural Ligaments

The most important ligaments of the talocrural joint can be divided into two main groups: lateral collaterals and medial (deltoid) collaterals.

Lateral Collaterals

The lateral collateral ligament complex consists of three separate bands, which function together as the static stabilizers of the lateral ankle. Each of the lateral ligaments has a role in stabilizing the ankle and/or subtalar joint, depending on the position of the foot. As such, these ligaments are commonly involved in ankle sprains.[13–17]

Anterior Talofibular Ligament. The fibers of this thickening of the anterior capsule course laterally from the talus in the transverse plane and superiorly between the sagittal and frontal planes to attach on the anterior distal tip of the lateral malleolus (Fig. 21-2).[18]

The anterior talofibular ligament (ATFL) is an extracapsular structure of the talocrural joint and is approximately 2–5-mm thick and 10–12-mm long.[19] The primary function of the ATFL is to resist anterior displacement of the talus relative to the ankle mortise, talocrural internal rotation and plantarflexion.[18,20] When the ankle is positioned in plantarflexion, the ATFL is usually the first ankle ligament to be torn in an inversion injury.[19] The accessory functions of the ATFL include providing resistance against anterior talar displacement from the mortise and resistance against internal rotation of the talus within the mortise.[21]

CLINICAL PEARL

The ATFL requires the lowest maximal load to produce failure of the lateral ligaments, although it has the highest strain to failure of that group.[22]

Calcaneofibular Ligament. The calcaneofibular ligament (CFL) (see Fig. 21-2), an extraarticular structure covered by the fibularis (peroneal) tendons, is larger and stronger than the ATFL. It travels at 10–40 degrees from the tip of the lateral malleolus to the lateral side of the calcaneus, paralleling the horizontal axis of the subtalar joint. The fibers of this ligament span across both the talocrural and subtalar joints, which have markedly different axes of rotation. Thus, its attachment is designed so that it does not restrict motion in either joint, whether they move independently or simultaneously.[23–25] Although tension within the ligament increases with dorsiflexion, the CFL resists ankle inversion and calcaneal adduction relative to the fibula throughout the full range of ankle motion. However, as the ankle joint passes from dorsiflexion to plantarflexion, the CFL is less able to resist talar tilt to inversion, but it is still able to resist the varus loading with the foot in a plantigrade position, although the ATFL is better suited to resist this tilt.[23] If the ankle is in neutral, the CFL may be injured along with the ATFL or alone.[26] However, due to its orientation and function, injury to this ligament may have a more profound functional effect on the ankle complex than isolated injuries to the ATFL.[27]

Posterior Talofibular Ligament. The posterior talofibular ligament (PTFL) (see Fig. 21-2) which is intracapsular but extrasynovial, runs from the posterior medial portion of the fibula to the lateral tubercle aspect of the talus. The orientation of the ligament is relatively horizontal. Its attachment on the talus involves nearly the entire nonarticular portion of the posterior talus to the groove for the flexor hallucis longus (FHL)

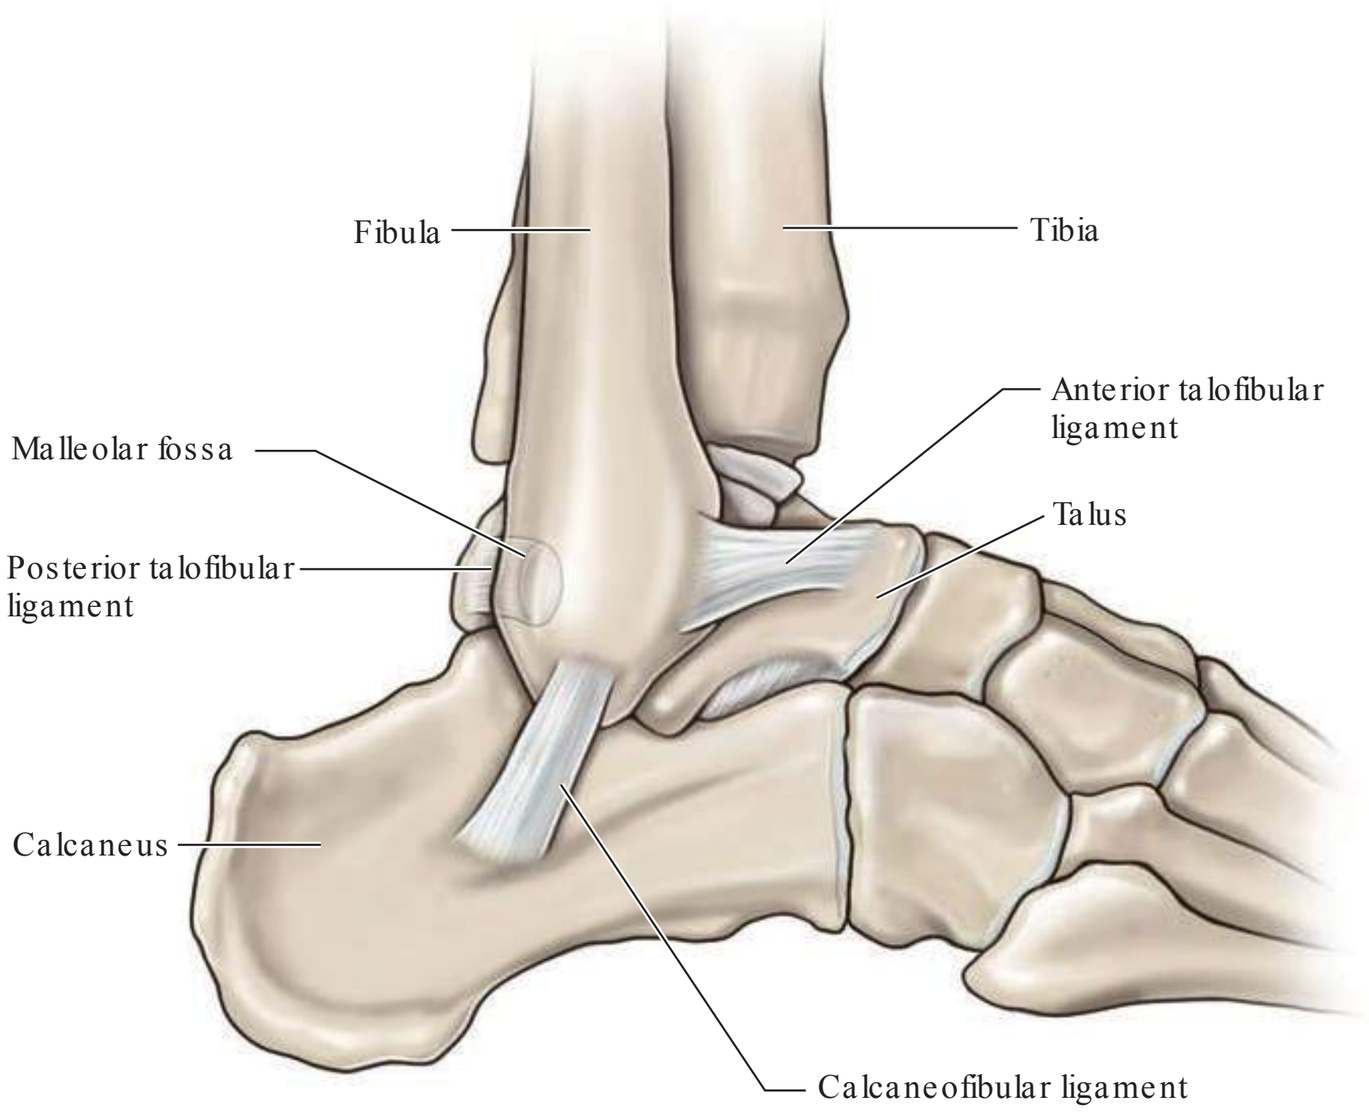

FIGURE 21-2 Lateral ligaments. (Reproduced, with permission, from Chapter 37. Leg. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

tendon, and anteriorly to the digital fossa of the fibula, which transmits the vessels that supply the talus and the fibula.[28] The PTFL is the strongest of the lateral ligament complex,[19] and serves to indirectly aid posterolateral talofibular stability during dorsiflexion due to its anatomic location, where it can act as a true collateral ligament and prevent talar tilt into inversion (abduction of the talus).[23] Along with the CFL, ATFL, and medial collateral ligaments, the PTFL assists to couple movements between the lower extremity and the foot.[23] The PTFL is rarely injured in a typical ankle sprain before the CFL and ATFL, but movements that involve extreme ankle dorsiflexion, foot external rotation, along with limb internal rotation may cause injury to this ligament. More commonly, the PTFL is involved in syndesmotic (high ankle) sprains.

Lateral Talocalcaneal Interosseous

The lateral talocalcaneal interosseous (LTCIL) ligament is sometimes included in this group as it does play a role in lateral ankle and subtalar stability[23,29] (see "Talocalcaneal Ligaments" section).

CLINICAL PEARL

In dorsiflexion, the PTFL is maximally stressed, and the CFL is taut, whereas the ATFL is loose. Conversely, in plantarflexion, the ATFL is taut, and the CFL and PTFL become loose.[30–33]

Besides maintaining lateral ankle stability, the lateral ankle ligaments play a significant role in maintaining rotational ankle stability.[23] Significant compromise to the ATFL and/or CFL leads to a measurable increase in inversion without any tilting of the talus or subtalar gapping.[23] A loss of ATFL function permits an increase in external rotation of the leg and unlocks the subtalar joint, allowing further inversion, which may lead to symptomatic instability.[23]

Medial Collaterals. Collectively, the medial collateral ligaments form a triangular-shaped ligamentous structure known as the deltoid ligament of the ankle (Fig. 21-3). Wide variations have been noted in the anatomic description of the deltoid ligament of the ankle but is generally agreed that it consists of both superficial and deep fibers. The superficial fibers consist of the following:

- *Tibionavicular fibers* (see Fig. 21-3). These fibers extend from the medial malleolus to the tuberosity of the navicular and serve to resist lateral translation and external rotation of the talus.
- Posterior tibiotalar *fibers* (see Fig. 21-3). These fibers travel in a posterolateral direction from the medial malleolus to the medial side of the talus and medial tuberosity of the talus. These fibers resist ankle dorsiflexion and lateral translation and external rotation of the talus.
- *Tibiocalcaneal fibers* (see Fig. 21-3). These thin fibers extend from the medial malleolus to the sustentaculum tali. The fibers are oriented in such a way that they resist abduction of the talus, calcaneus and navicular when the foot and ankle are positioned in plantarflexion and eversion.[34] The tibiocalcaneal ligament is usually the first ruptured with an eversion injury.[35]

The deep fibers consist of the following:

- Anterior tibiotalar *fibers* (see Fig. 21-3). The fibers of this strong ligament extend from the tip of the medial malleolus to the anterior aspect of the medial surface of the talus. These fibers are oriented in such a way that they

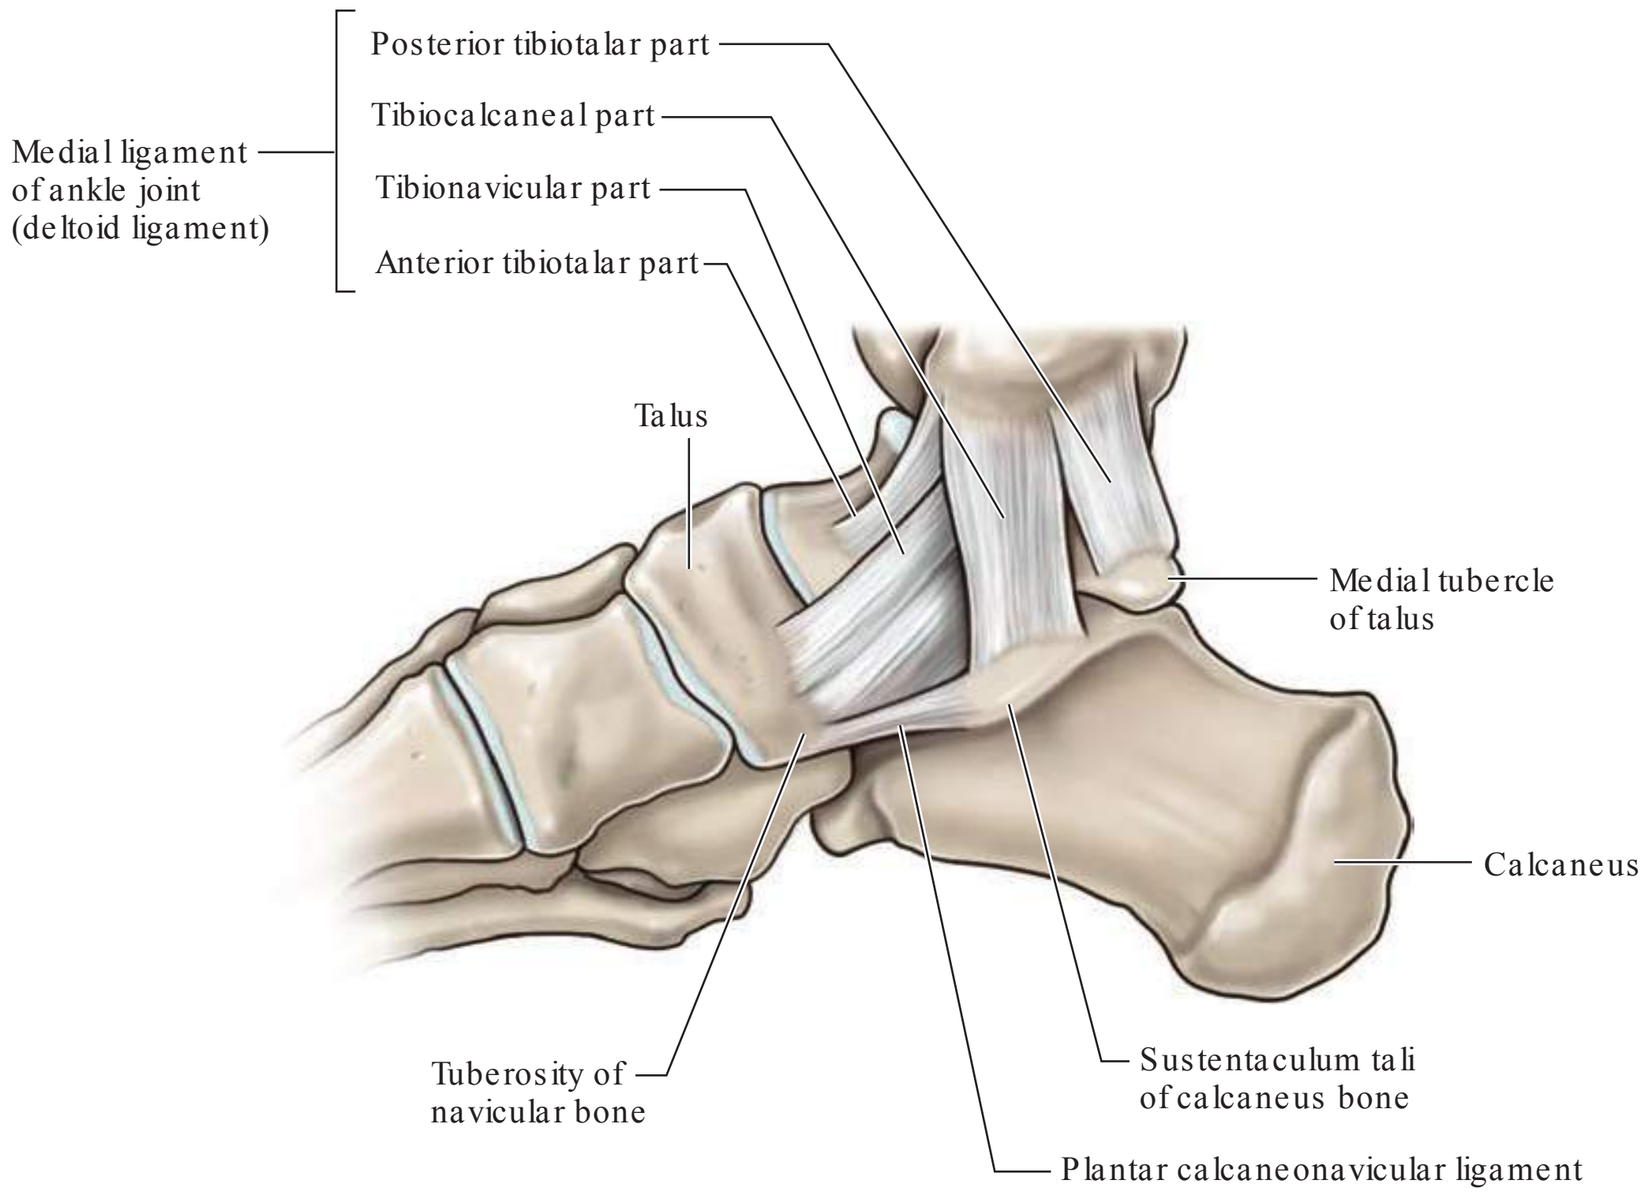

FIGURE 21-3 Medial ligaments. (Reproduced, with permission, from Chapter 37. Leg. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

resist abduction of the talus when it is in plantarflexion and eversion. Such is the strength of these fibers that an injury to this ligament rarely occurs with an eversion sprain but is often associated with an avulsion fracture in more traumatic injuries.

The medial collateral ligaments are most likely to be damaged by a mechanism of hyper eversion (valgus loading).[1] Although the calcaneotibial ligament is very thin and supports only negligible forces before failing, the talotibial ligaments are very strong.[36,37] Rasmussen et al.[38,39] found that the superficial fibers of the deltoid ligament of the ankle specifically limited talar abduction or negative talar tilt and that the deep layers of the deltoid ligament of the ankle ruptured with external rotation of the leg, without the superficial portion being involved.

CLINICAL PEARL

The strength of the ankle ligaments from weakest to strongest is the ATFL, PTFL, CFL, and deltoid complex.[40]

SUBTALAR (TALOCALCANEAL) JOINT

The subtalar joint, which is the articulation between the distal talus and proximal calcaneus, is a major articulation of the hindfoot and plays a significant role in foot function. The articulation consists of two separate, modified ovoid surfaces with their own joint cavities. The two anterior and posterior articulations are connected by an interosseous membrane.

- The anterior joint consists of two to three concave facets on the superior aspect of the calcaneus and a convex facet on the inferior aspect of the talus. Typically there is an anterior, medial, and posterior articular facet on the calcaneus. The anterior and medial facets sometimes form a single articular surface resulting in two rather than three articular facets.[26] The anterior component is situated more medial than the posterior, giving the plane of the joint an average 42 degrees (± 9 degrees) superior from the transverse foot plane and 23 degrees (± 11 degrees) medial from the sagittal foot plane.[41]
- The posterior joint consists of a cone-shaped facet on the superior aspect of the calcaneus and a concave facet on the inferior aspect of the talus.[26]

This relationship, which is thought to set up a complex screw-like movement that occurs during subtalar joint motion, ensures that the anterior and posterior aspects can move in opposite directions to each other during functional movements (while the anterior aspect is moving medially, the posterior aspect is moving laterally). From a clinical perspective, it may be important to impart gliding that essentially spins the calcaneus around the oblique axis.[26]

CLINICAL PEARL

The sinus tarsi, a funnel-shaped canal, separates the anterior subtalar joint and posterior subtalar joint. It is located distal and slightly anterior to the lateral malleolus on the lateral side of the foot and is bordered by the neck of the

talus and anterosuperior aspect of the calcaneus. The canal opens medially, posterior to the sustentaculum tali of the calcaneus and contains blood vessels, nerves, fat and a ligamentous complex, including

- medial, intermediate and lateral roots of the inferior extensor retinaculum.
- lateral cervical ligament.
- medial talocalcaneal interosseous ligament (ligament of the sinus tarsi).

The calcaneus, the largest tarsal bone and the most frequently fractured, projects further posteriorly than the tibia and fibula. It serves as a weight-bearing bone and as a short lever for muscles of the calf, which are attached to its posterior surface. The skin and fat over the distal-inferior area of the calcaneus are specialized for friction and shock absorption.[42]

CLINICAL PEARL

The skin on the sole of the foot is thicker than anywhere else in the body. Located beneath the skin in the heel area is a fat pad, which is designed to handle compressive loads beyond what other fat pads in the body will tolerate. This fat pad comprises a honeycombed pattern of subcutaneous fat globules in fibroelastic septae 13–21 mm thick, which abuts the calcaneus.[43] The septae closest to the calcaneus are aligned concentrically, in a pattern that opposes a concentrically aligned reversed pattern closest to the skin. These opposing patterns create a torsion effect that resists compression, thereby providing a cushion for initial contact by the heel and allowing the skin to resist forces up to five times the body weight while running.[43] However, after the age of 40 years, the thickness of the subcutaneous fat decreases, with a resultant loss of shock absorbency.[44] This can be counteracted by using a heel cup/counter, which confines the overall volume of the fat pad around the calcaneus.

The retrocalcaneal bursa lies anterior to the posterosuperior calcaneal tuberosity of the calcaneus. It lubricates the Achilles tendon anteriorly, as well as the superior aspect of the calcaneus.[45] The superior or proximal surface of the calcaneus is divisible into thirds.

- The posterior third. This is a roughened surface that is concavoconvex in extension, the convexity transverse. It supports fibroadipose tissue between the calcaneal tendon and the ankle joint. Distal to the posterior articular facet is a rough depression that narrows into a groove on the medial side—the sulcus calcanei—which completes the sinus tarsi with the talus.
- The middle third. This surface carries the posterior talar facet and is oval and convex anteroposteriorly.
- The anterior third. This surface is only partly articular.

Subtalar (Talocalcaneal) Ligaments

A number of ligaments provide support to the subtalar joint, although some confusion exists in the descriptions and nomenclature of these ligaments.[46]

Medial Talocalcaneal

The medial talocalcaneal ligament extends from the medial tubercle of the talus to the posterior aspect of the sustentaculum tali and the area of the calcaneus just posterior to the sustentaculum tali. It functions to stabilize against anterior translation of the talus (especially in the initial contact phase of the gait cycle) by producing passive eversion of the talus. This results in a close packing of the lateral foot and fibula. Damage to this ligament, which typically occurs with inversion sprains and rotational compression fractures of the calcaneus, can permit excessive anterior motion of the talus. This excessive motion may result in posterior tibialis tendinopathy[47] and on occasion, Achilles' tendinopathy.[48]

Lateral Talocalcaneal

The fibers of the lateral talocalcaneal ligament (LTCL) are parallel to and blend in with the posterior fibers of the CFL. Unlike the ATFL, CFL, and PTFL, the LTCL does not cross the ankle joint. Instead, the LTCL crosses the posterior subtalar joint and is considered weaker and smaller than the CFL.[29] The lateral aspect of the subtalar joint is further stabilized by the interosseous talocalcaneal ligament (see next).[28] This is highly innervated structure is typically injured with a dorsiflexion and inversion mechanism.[49] The LTCL serves to limit supination at the subtalar joint. A combined injury of the ATFL and the interosseous talocalcaneal ligament can induce anterolateral rotary instability of the ankle joint.[50]

Interosseous Talocalcaneal

The interosseous talocalcaneal ligament lies in the spaces running inferior and superior between the talus and the calcaneus. The fibers of these ligaments, which run obliquely between the talus and calcaneus, separate the subtalar joint into posterior and anterior chambers.[50] Some have described an anterior band (sometimes referred to as the cervical ligament) and posterior band. The talocalcaneal interosseous and cervical ligaments are often collectively referred to as the interosseous ligaments.[28] In relation to the sinus tarsi, the anterior band is located more laterally than the posterior band.[23] The interosseous talocalcaneal ligament functions as a stabilizer of the subtalar joint keeping the joint surfaces of the talus and calcaneus from separating throughout the entire range of motion (ROM) via a screw-like rotation.[26] Severing the interosseous talocalcaneal ligament results in the following[51]:

- increased range of the subtalar joint motion especially toward supination
- instability of the subtalar joint
- a disconnect between the calcaneus and talus resulting in marked motion between the tibia and calcaneus.

Posterior Talocalcaneal

This ligament is previously described under the talocrural ligaments.

Calcaneofibular

The CFL serves to limit supination at the subtalar joint.

TRANSVERSE TARSAL JOINT COMPLEX

The transverse tarsal joint complex, which consists of the talonavicular and calcaneocuboid articulations, is also known as the Chopart's joint.

Talonavicular

The talonavicular joint is classified as a synovial pivot joint.

The joint is actually formed by components of the talus, navicular, calcaneus, and plantar calcaneonavicular (spring) ligament. The convex anterior head of the talus fits into the concavity of the posterior navicular and the anterior component of the subtalar joint and rests on the posterior (dorsal) surface of the spring ligament. The joint capsule is only well developed posteriorly, where it forms the anterior part of the interosseous ligament. Although the plantar calcaneonavicular or spring ligament does not articulate with the talus, it prevents the talar head from plantarflexing (dorsiflexion of the navicular relative to the talus), and also limits the medial longitudinal arch from lowering.[52] The talonavicular joint moves three times more than the calcaneocuboid joint, with movement between the navicular and the cuboid being negligible.[53]

Calcaneocuboid

The calcaneocuboid joint is classified as a plane synovial joint.

The anterior surface of the calcaneus, which articulates with the reciprocally shaped posterior surface of the cuboid, is relatively convex in an oblique horizontal direction and relatively concave in an oblique vertical direction.[54] The cuboid, most lateral in the distal tarsal row, is located between the calcaneus proximally and the fourth and fifth metatarsals distally. To the posterior (dorsal) surface are attached posterior (dorsal) calcaneocuboid, cubonavicular, cuneocuboid, and cubometatarsal ligaments, and to the proximal edge of the plantar ridge, deep fibers of the long plantar ligament. To the projecting proximal–medial part of the plantar surface are attached a slip of the tendon of tibialis posterior and flexor hallucis brevis (FHB). To the rough part of the medial cuboidal surface are attached the interosseous, cuneocuboid, and cubonavicular ligaments, and proximally the medial calcaneocuboid ligament, which is the lateral limb of the bifurcated ligament.[28] The capsule is thickened posteriorly (dorsally) to form the posterior (dorsal) calcaneocuboid ligament. The joint has a large plantar phalanx to provide additional support during weight bearing.

A number of ligaments help provide support to this region. The spring ligament (plantar calcaneonavicular Fig. 21-3) connects the navicular bone to the sustentaculum tali on the calcaneus. The ligaments of the calcaneocuboid joint include the long plantar ligament and a portion of the bifurcate ligament posterior (dorsally).

- The long and strong plantar ligament attaches to the plantar surface of the calcaneus, the tuberosity on the plantar surface of the cuboid bone, and to the bases of the second, third, and fourth (and possibly fifth) metatarsals.[28] The plantar ligament functions to provide indirect plantar support to the joint, by limiting the amount of flattening of the lateral longitudinal arch of the foot. Together with the groove in the cuboid bone, it forms a tunnel for the passage of the fibularis (peroneus) longus tendon across the plantar surface of the foot.[28] The perpendicular arrangement of the long and short plantar ligaments may compress the calcaneocuboid joint increasing its stability.[26] During inversion, the cuboid inverts approximately twice as much of the calcaneus.[53]
- The bifurcate ligament functions to support the medial and lateral aspects of the foot when weight bearing in a plantarflexed position (twisted).

The plantar calcaneocuboid ligament, sometimes referred to as the short plantar ligament, is a relatively broad and strong strap-like structure that extends from the area of the anterior tubercle of the calcaneus to the adjacent plantar surface of the cuboid bone. It provides plantar support to the joint and possibly helps to limit flattening of the lateral longitudinal arch.

TARSOMETATARSAL JOINT

The tarsometatarsal (Lisfranc's) joint includes the articulations between the cuneonavicular joint, intercuneiform joints, the cuneocuboid joint, the cubometatarsal joint, the cubonavicular, and the intermetatarsal joints.

CUNEONAVICULAR

The cuneonavicular joint is classified as a plane synovial, joint. The navicular presents a convex surface to the concave surface of the combined cuneiforms. The wedge-like cuneiform bones articulate with the navicular proximally and with the bases of the first to third metatarsals distally (see Fig. 21-1). The medial cuneiform is the largest and the intermediate, the smallest. In the intermediate and lateral cuneiforms, the posterior (dorsal) surface is the base of the wedge, but in the medial, the wedge is reversed, a prime factor in shaping the transverse arch. The wedge shape of these bones also provides a cavity for the neurovascular and musculotendinous structures of the foot. The proximal surface of all three cuneiforms form a concavity for the convex surface of the navicular. In the intermediate and lateral cuneiforms, the posterior (dorsal) surface is the base of the wedge, but in the medial, the wedge is reversed, which assists in the formation of the transverse arch. The medial cuneiform is the largest, the intermediate the smallest. The ligament of Lisfranc's, also referred to as the cuneometatarsal interosseous ligament, runs between the medial cuneiform and second metatarsal base. Disruption of this ligament can lead to a dislocation of the medial aspect of the foot, as the first metatarsal and medial cuneiform separate from the second metatarsal and intermediate cuneiform. This ligament is often involved in low and high energy injuries to the midfoot.[55] The joint cavity and capsule of the cuneonavicular joint is continuous with that of the intercuneiform and cuneocuboid joints, and the synovium is continuous with that of these joints, the second and third cuneometatarsal joints, and the intermetatarsal joints of each base except the fifth.

INTERCUNEIFORM AND CUNEOCUBOID JOINTS

T ese joints (see Fig. 21-1) are classified as plane synovial joints. T e joint capsule and synovium is contiguous between all of these joints and with that of the cuneonavicular joint. Dysfunctions in the cuneocuboid joint result from a collapse of the plantar supporting structures or from direct trauma. Such dysfunctions may result in the cuboid subluxing in a plantar direction (medial border of cuboid moves inferiorly). At the intercuneiform joints, the third cuneiform may sublux on the second cuneiform.

CUBOMETATARSAL

Laterally, the cuboid bone articulates with the fourth and fifth metatarsals distally, and with the calcaneus proximally. When considered alone, the cubometatarsal joint is classified as a plane synovial joint. When the cubometatarsal joints are considered together, they form a modified sellar joint. T e joint capsule and synovium of the fourth and fifth cubometatarsal joints are separated from the other tarsometatarsal joints by an interosseous ligament.

CUBONAVICULAR

T e cubonavicular joint (see Fig. 21-1) is classified as a syndesmosis or a plane synovial joint. If the joint is synovial, the capsule and synovium is continuous with the cuneonavicular joint.

INTERMETATARSAL

T e intermetatarsal joints (see Fig. 21-1) are classified as plane synovial joints. If the joint is synovial, the capsule and synovium is continuous with the cuneonavicular joint. Motion at these joints is confined to posterior (dorsal)/anterior (plantar) gliding, producing a fanning and folding motion of the foot. Proximally, the five metatarsals articulate with the tarsals and with themselves through broad concavities.[10]

Available movements at the tarsometatarsal joint complex are a pronation twist and a supination twist, which mainly occur in closed kinetic chain at the end range of hindfoot and ankle movements. For example, in extreme closed kinetic chain plantarflexion, such as when standing on tip toes, the tarsometatarsal joints provide a compensatory pronation twist to prevent an excessively inverted position of the metatarsal heads and allow the forefoot to remain in contact with the ground.[1] Conversely, during extreme closed kinetic chain dorsiflexion, such as at the end ROM during a squat, the tarsometatarsal joints provide a compensatory supination twist to prevent excessive eversion of the metatarsal heads, so the forefoot can remain in contact with the ground.[1]

METATARSOPHALANGEAL

T e MTP joints (see Fig. 21-1) are classified as condyloid synovial joints. T e capsule and synovium in each of these joints are confined to its own joint and posteriorly (dorsally) is thin, whereas plantarly (anteriorly), it is blended with the plantar and collateral ligaments. T e rotation that occurs in the early stages of development of the limbs results in the thumb being the most lateral digit in the hand, whereas the hallux (great toe) is the most medial digit in the foot.[56] T e concave bases of the proximal phalanges (see Fig. 21-1) articulate with the convex heads of the metatarsals. T e first MTP joint, with its more extensive articular surface on the anterior (plantar) aspect of the metatarsal than on the posterior (dorsal), allows for a greater freedom of motion,[56] and its anterior (plantar) surface forms two grooves for articulation with the hallucal sesamoids (see next section). T e fifth metatarsal has a lateral styloid process at its base, which serves as the insertion site for the tendon of the fibularis (peroneus) brevis. T e styloid area is often avulsed during acute inversion injuries of the foot.[10] T ree types of forefoot are recognized based on the length of the metatarsal bones, although it is unclear whether these various types affect foot function in any way.[56]

- Index plus. T is type is characterized by the first metatarsal being longer than the second, with the other three of progressively decreasing lengths, so that 1 > 2 > 3 > 4 > 5.
- Index plus–minus. In this type, the first metatarsal is of the same length as the second, with the others progressively diminishing in length, so that 1 = 2 > 3 > 4 > 5.
- Index minus. With this type, the second metatarsal is longer than the first and third metatarsals. T e fourth and fifth metatarsals are progressively shorter than the third, so that 1 < 2 > 3 > 4 > 5.

Stability of the MTP joints is primarily provided by a musculocapsular ligamentous complex anteriorly (plantarly), and medially and laterally by the medial and lateral collateral ligaments, respectively.

First MTP Joint

T e first MTP joint is the articulation between the head of the first metatarsal and the proximal phalanx. Although there is some anatomic variation from patient to patient, the first MTP joint is typically a cam-shaped, bicondylar-hinged joint that has 2 degrees of freedom.[57] T e first MTP joint has little inherent stability because the proximal phalanx has a fairly shallow cavity in which the metatarsal head articulates. T e joint is stabilized posteriorly (dorsally) by the capsule and expansion of the extensor hallucis tendon. Fan-shaped medial and lateral collateral ligaments provide valgus and varus stability, respectively. T e plantar surface of the capsule is reinforced by a fibrocartilaginous plate, called the plantar accessory ligament. In addition, the MTP joint is dynamically stabilized by the short flexor complex (FHB and the two sesamoids embedded in the FHB tendons), the adductor hallucis, and the abductor hallucis tendons.

CLINICAL PEARL

The sesamoids are contained within the tendon of the FHB and serve to increase the lever arm for flexion of the MTP joint, analogous to the function of the patella in knee extension.[58]

The sesamoids are connected distally to the base of the proximal phalanx by extensions of the FHB called the plantar plate. Typically, the sesamoids are anterior (plantar) to the medial and lateral condyles of the metatarsal pad. The sesamoids are separated on the anterior (plantar) aspect of the first metatarsal head by a cresta, which helps to stabilize the sesamoids, and are connected to one another by the intersesamoidal ligament. The abductor hallucis inserts into the medial sesamoid, and the adductor hallucis inserts into the lateral sesamoid. The FHL (Fig. 21-4) pierces the two heads of the FHB muscle to run just anterior (plantar) to the intersesamoidal ligament. In normal gait, the capsuloligamentous complex of the first MTP joint must withstand 40–60% of body weight, but in athletic activity, this can reach as much as eight times body weight.[59–65] While there are many conditions that can affect first-ray function, the most prevalent include progressive first MTP joint degeneration, hallux abducto-valgus (HAV), hallucal sesamoid syndrome, flexor hallucal longus tendinopathies, turf toe, metatarsalgia, and interdigital neuroma.[11]

INTERPHALANGEAL

The IP joints are classified as condyloid synovial joints. The hallux has two phalanges, whereas each of the remaining toes have three (see Fig. 21-1). The IP joints are classified as simple, synovial, modified sellar joints. The saddle-shaped articular fossa of the head of the proximal phalanx articulates with the base of the intermediate phalanx. This in turn receives the smaller and flatter distal phalanx.

ACCESSORY OSSICLE

An accessory ossicle (accessory bone) is an anomalous bone that fails to unite during developmental ossification. Common locations include the fibular malleolus, tibial malleolus, navicular, and talus.

The accessory navicular is the most common accessory bone in the foot.[66] It occurs on the medial, anterior (plantar) border of the navicular, at the site of the tibialis posterior tendon insertion.[67] The incidence in the general population has been reported to be 4–14%[67,68] The posterior aspect of the talus often exhibits a separate ossification center, appearing at 8–10 years of age in girls and 11–13 years of age in boys. Fusion usually occurs 1 year after its appearance.[69,70] When fusion does not occur, an os trigonum is formed (see Chapter 5).

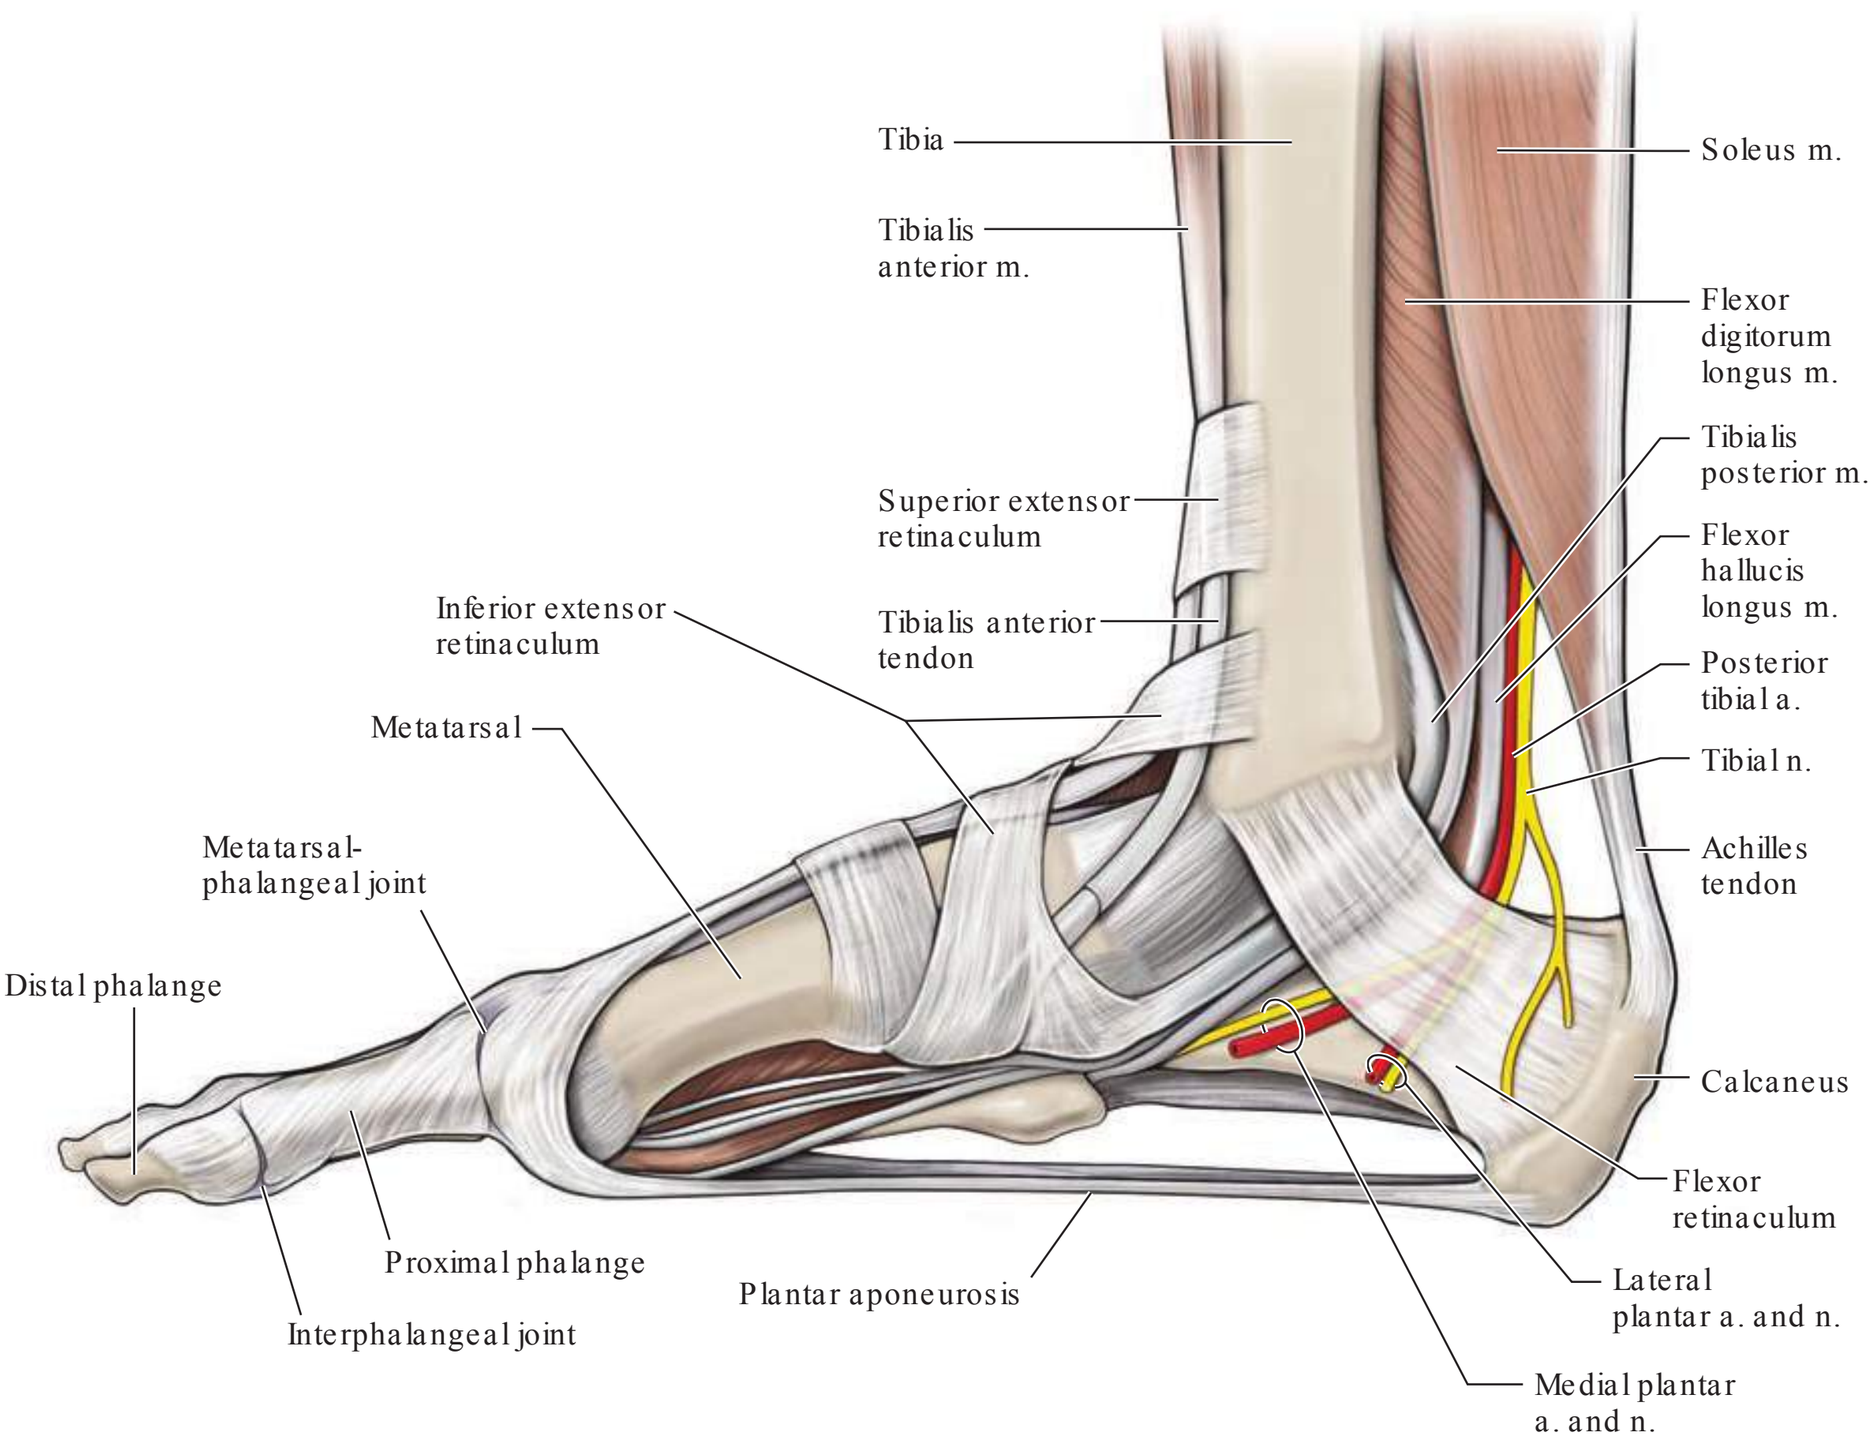

FIGURE 21-4 Medial aspect of the ankle and foot. (Reproduced, with permission, from Chapter 38. Foot. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

CLINICAL PEARL

An accessory bone can be differentiated from a fracture radiographically, as an accessory bone will have rounded edges where a fracture will have sharp edges.[63]

PLANTAR FASCIA/PLANTAR APONEUROSIS

The terms plantar *fascia* and plantar aponeurosis (Fig. 21-4) are often used interchangeably, although strictly speaking only the central part of the plantar fascia is extensively aponeurotic.[71] The plantar fascia is the investing fascial layer of the anterior (plantar) aspect of the foot that originates from the os calcis and inserts through a complex network to the anterior (plantar) forefoot. It is a tough, fibrous layer, composed histologically of both collagen and elastic fibers. The plantar fascia is often regarded as being analogous to the palmar fascia of the hand. However, unlike the fascial layer of the palm, which is generally thin, the plantar fascia is a thick structure, and not only serves a supportive and protective role, but is also intricately involved with the weight-bearing function of the foot.[71] The load to failure of the plantar fascia is estimated in the range of 1,000 N.[72]

The plantar fascia is divided into three major areas: a central portion and medial and lateral sections, each oriented longitudinally on the anterior (plantar) surface of the foot.[33]

- Central portion. The central portion is the major portion of the plantar fascia both anatomically and functionally.[71] This portion is the thickest and the strongest and is narrowest proximally where it attaches to the medial process of the calcaneal tuberosity, proximal to the flexor digitorum brevis (FDB). This attachment site is often involved in a condition called plantar heel pain (see "Intervention Strategies" section); however, pain can occur anywhere in the structure. From its insertion, the central portion of the fascia fans out and becomes thinner distally. Its fibers are longitudinally oriented and adhere to the underlying FDB muscle.[71] The central portion envelops the FDB muscle on both sides, forming the medial and lateral intermuscular septums, which anchor the plantar fascia to the deep plantar pedis.[71] At the midshaft of the second to fifth MTP joints, the body of the central portion branches into five superficial longitudinal tracts.[71] All five superficial longitudinal tracts terminate by inserting into, and blending with, the overlying subcutaneous tissues and skin. Due to the anatomical connections of the central portion, dorsiflexion of the toe slides the plantar pads distally, placing tension on the plantar aponeurosis. The central portion of the fascia primarily functions as a dynamic stabilizer of the medial longitudinal arch during weight-bearing activities.
- Lateral and medial portions. The smaller and thinner lateral and medial portions are thin and cover the undersurface of the abductor digiti minimi and abductor hallucis muscles, respectively.

With standing and weight bearing, the plantar fascia plays a major role in the support of the weight of the body, by virtue of its attachments across the medial longitudinal arch. During the different phases of gait, the plantar fascia assumes different biomechanical functions, which have been described as a windlass mechanism or a truss mechanism:

- Windlass. The windlass effect on the plantar fascia helps to reconstitute the medial longitudinal arch and generates a more rigid foot for propulsion during the toe-off portion of the gait cycle.[73] The plantar fascia, which serves as the cable of the windlass mechanism, wraps around the head of the metatarsal, which serves as the cylinder of the windlass, and raises the medial longitudinal arch to attach to the medial tubercle of the calcaneus.[74]
- Truss. In the truss system of the foot, the triangular unit is the medial longitudinal arch with the ankle joint functioning as the apex of the triangle, the calcaneus and talus are the posterior struts, and the first ray is the anterior strut. The plantar fascia stabilizes the two rigid struts inferiorly by limiting the ability of the struts to spread apart.

During the initial contact, and during the first half of the stance phase of the gait cycle (see Chapter 6) with the toes in neutral, the plantar fascia relaxes, flattening the arch. This allows the foot to accommodate to irregularities in the walking surface and to absorb shock.[73] As the foot proceeds from midstance to terminal stance, the foot pressure migrates anteriorly and the toes dorsiflex and, through its attachments to the toes via the plantar plate, the plantar fascia tightens. The tension in the plantar fascia is directly related to dorsiflexion of the MTP of the toes.[75] The plantar fascia is pulled over the metatarsal heads, causing the metatarsal heads to be depressed and the longitudinal arch to rise.[71] During the swing phase of gait, the plantar fascia is under little tension and appears to serve no important functional role.

RETINACULA

The extensor and fibular (peroneal) retinacula contribute to ankle and hindfoot stability primarily due to their anatomical orientation. There are four important ankle retinacula, which function to tether the leg tendons as they cross the ankle to enter the foot (Fig. 21-4).[10]

- Inferior extensor retinaculum. The inferior extensor retinaculum runs from the tip of the lateral malleolus to insert on the lateral calcaneus and sinus tarsi. It also blends with the inferior fibular retinaculum and may improve evertor muscle function.[76] It consists of two parts: superior and inferior. The superior part functions to contain the tendons of the extensor digitorum longus (EDL), extensor hallucis longus (EHL), tibialis anterior, and fibularis (peroneus) tertius. The Y-shaped inferior part consists of an upper and a lower band, which prevent "bow-stringing" of the posterior (dorsal) tendons.
- Superior *fi*bular (peroneal) retinaculum. The superior fibular retinaculum, which courses from the lateral malleolus to the calcaneus, parallel with the posterior fibers of the CFL,[50] firmly tethers the fibularis

(peroneus) longus and brevis tendons behind the fibular malleolus.

- Flexor retinaculum. The flexor retinaculum provides a firm support structure for the flexor digitorum longus (FDL), FHL, tibialis posterior, and the neurovascular bundle.

EXTRINSIC MUSCLES OF THE LEG AND FOOT

Twenty-three muscles are involved with motion at the foot and ankle, 12 of which originate on the tibia or fibula, and 11 on the foot itself. For simplicity sake, the muscles of the leg and foot are divided into extrinsic muscles (those that originate at the tibia or fibula), and intrinsic (those that originate from the foot itself) muscles. The extrinsic muscles of the foot (Table 21-4) are further subdivided based on location into anterior, posterior superficial, posterior deep, and lateral compartments.

Anterior Compartment

This compartment contains the dorsiflexors (extensors) of the foot. These include the tibialis anterior, fibularis tertius, EDL, and EHL (see Fig. 21-5).

CLINICAL PEARL

Clinically, the loss of the ankle dorsiflexors is a common problem as a result of an isolated L4 nerve root compromise. The common sign of this weakness is a "foot slap" during gait which is evident by an accelerated plantarflexion of the ankle immediately following initial contact.[26]

The tibialis anterior muscle attachment, which is distal to the ankle joint on the plantar surface of the medial cuneiform and first metatarsal, indicates a role of this muscle at the subtalar joint and talonavicular joints.[77] In addition to dorsiflexion of the foot, the tibialis anterior can produce a supination moment as its pull is medial to the subtalar joint, although its moment arm for supination is one-fifth the moment arm of the tibialis posterior muscle.[77] The moment arm of the tibialis anterior muscle at the talonavicular joint is not well described but it is assumed to be a powerful dorsiflexor, and therefore, may play a role in forefoot control.[26] The EDL balances the inversion component of the tibialis anterior to keep dorsiflexion in the sagittal plane, making it an open kinetic chain foot evertor. In addition, it powerfully extends the proximal phalanges of the four lateral toes and extends the middle and distal phalanges less intensely.[78]

TABLE 21-4 Extrinsic Muscle Attachments and Innervation

Muscle	Proximal	Distal	Innervation
Gastrocnemius	Medial and lateral condyle of femur	Posterior surface of calcaneus through Achilles tendon	Tibial S2 (S1)
Plantaris	Lateral supracondylar line of femur	Posterior surface of calcaneus through Achilles tendon	Tibial S2 (S1)
Soleus	Head of fibula, proximal third of shaft, soleal line and midshaft of posterior tibia	Posterior surface of calcaneus through Achilles tendon	Tibial S2 (S1)
Tibialis anterior	Distal to lateral tibial condyle, proximal half of lateral tibial shaft, and interosseous membrane	First cuneiform bone, medial and plantar surfaces, and base of first metatarsal	Deep fibular (peroneal) L4 (L5)
Tibialis posterior	Posterior surface of tibia, proximal two-thirds posterior of fibula, and interosseous membrane	Tuberosity of navicular bone and tendinous expansion to other tarsals and metatarsals	Tibial L4 and L5
Fibularis (peroneus) longus	Lateral condyle of tibia, head, and proximal two-thirds of fibula	Base of first metatarsal and first cuneiform, lateral side	Superficial fibular (peroneal) L5 and S1 (S2)
Fibularis (peroneus) brevis	Distal two-thirds of lateral fibular shaft	Tuberosity of fifth metatarsal	Superficial fibular (peroneal) L5 and S1 (S2)
Fibularis (peroneus) tertius	Lateral slip from extensor digitorum longus	Tuberosity of fifth metatarsal	Deep fibular (peroneal) L5 and S1
Flexor hallucis longus	Posterior distal two-thirds fibula	Base of distal phalanx of great toe	Tibial S2 (S3)
Flexor digitorum longus	Middle three-fifths of posterior tibia	Base of distal phalanx of lateral four toes	Tibial S2 (S3)
Extensor hallucis longus	Middle half of anterior shaft of fibula	Base of distal phalanx of great toe	Deep fibular (peroneal) L5 and S1
Extensor digitorum longus	Lateral condyle of tibia proximal anterior surface of shaft of fibula	One tendon to each lateral four toes, to middle phalanx, and extending to distal phalanges	Deep fibular (peroneal) L5 and S1

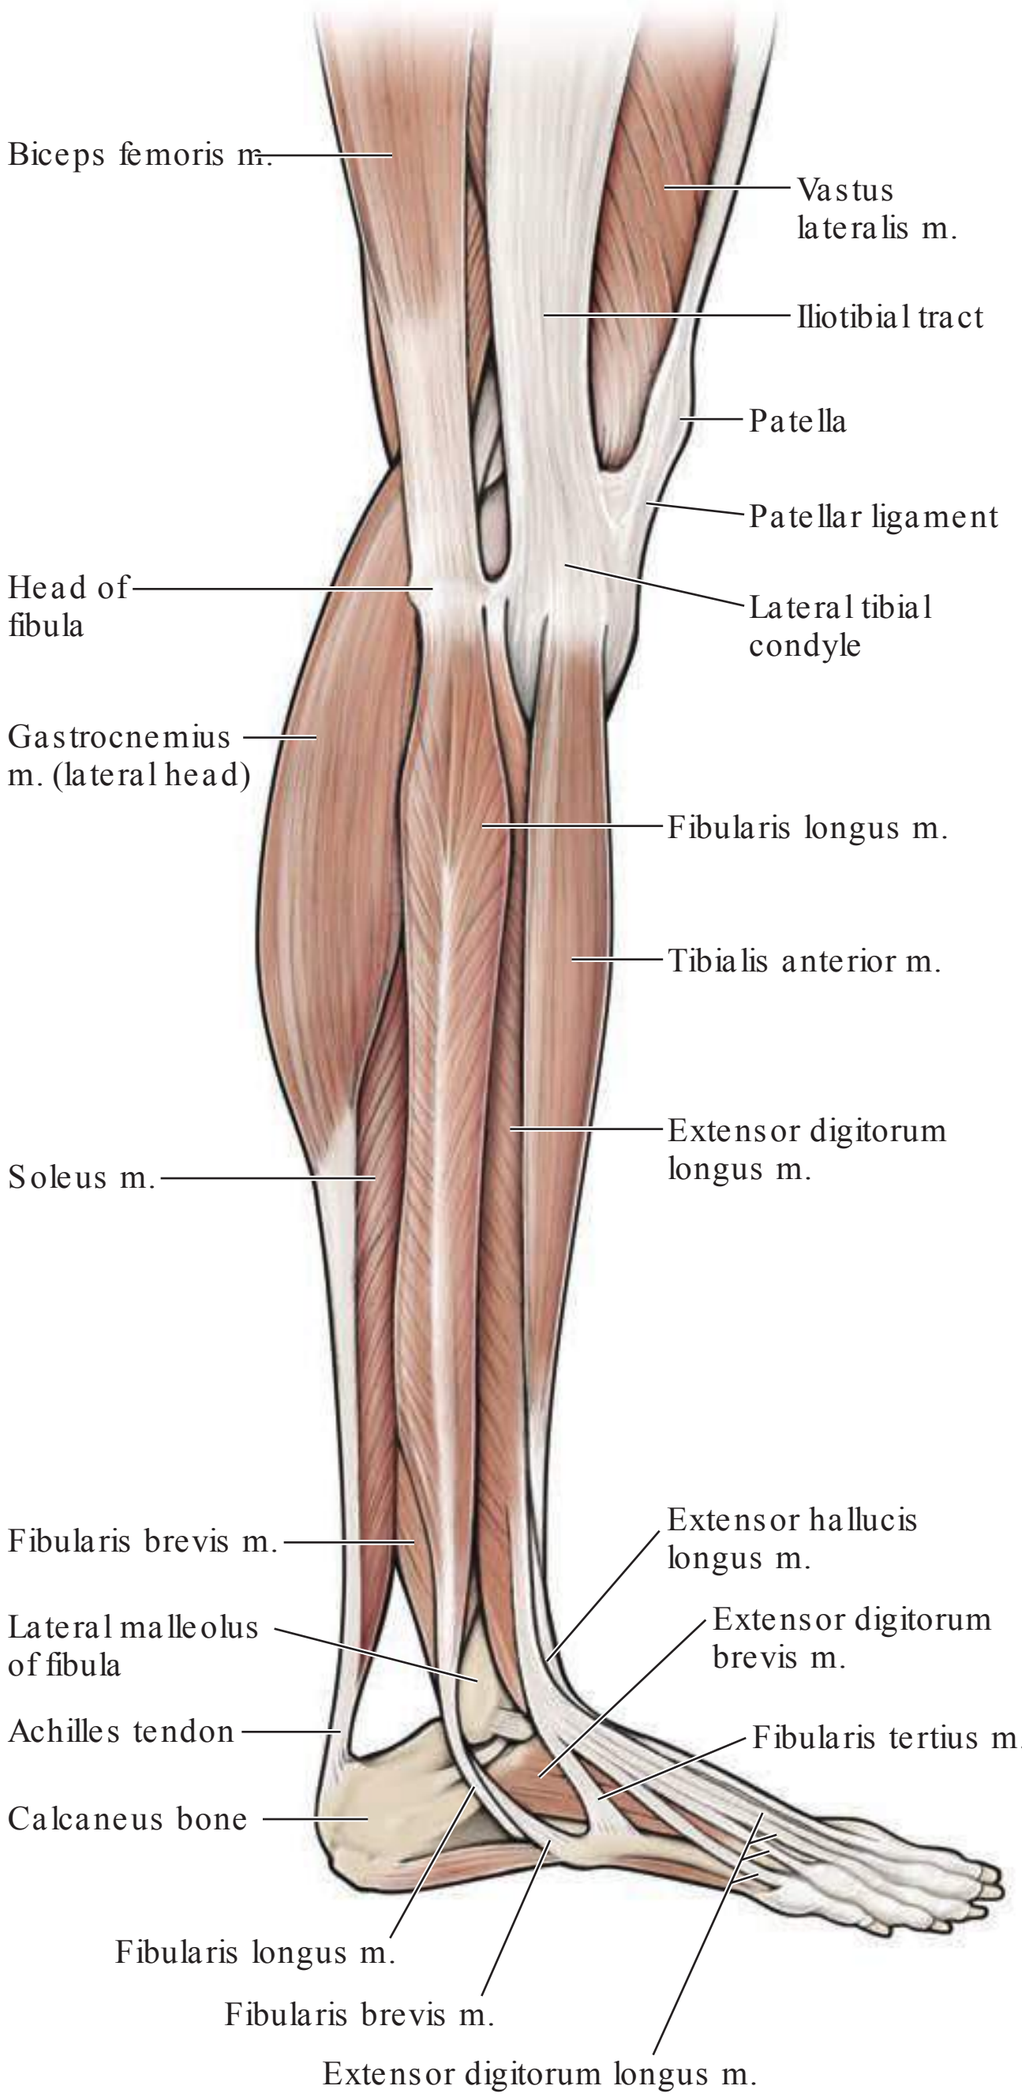

FIGURE 21-5 Lateral aspect of foot and ankle. (Reproduced, with permission, from Chapter 37. Leg. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

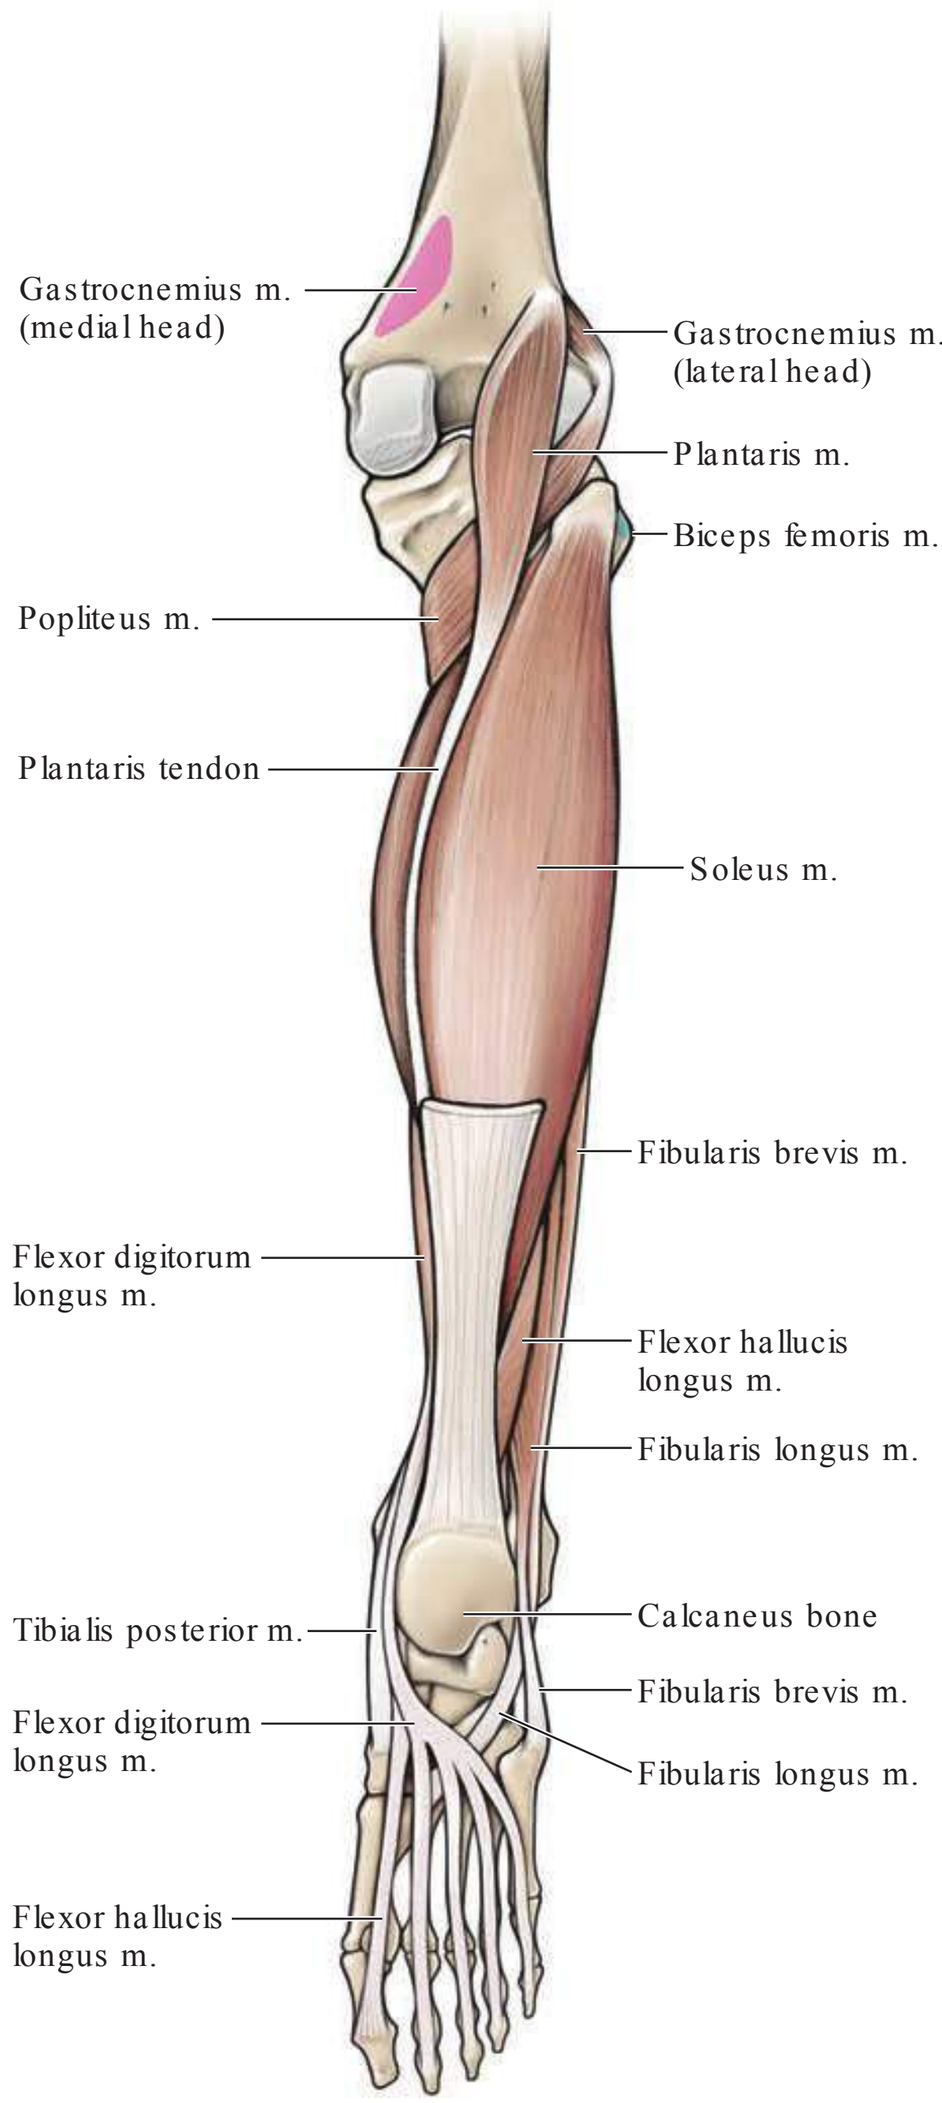

FIGURE 21-6 Posterior superficial muscles. (Reproduced, with permission, from Chapter 37. Leg. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

The EHL functions to strongly extend the proximal phalanx of the great toe. In order to perform this function, the first dorsal interosseous muscle must synergistically fixate the proximal phalanx.[78]

Posterior Superficial Compartment

This compartment, located posterior to the interosseous membrane, contains the calf muscles that plantarflex the foot. These include the gastrocnemius, soleus (see Fig. 21-5), and the plantaris muscle (Fig. 21-6). All three muscles converge to attach on to the Achilles tendon, which then inserts into the calcaneus.

Triceps Surae

The triceps surae comprises the two heads of the gastrocnemius, which arise from the posterior aspects of the distal femur, and the soleus, which arises from the tibia and fibula, which combine to form the Achilles tendon.[79] The medial head of the gastrocnemius is by far the largest component and, according to electromyographic (EMG) studies, is the most active of the two while running.[80,81] The soleus (Fig. 21-5), because it does not cross the knee joint, is subject to early disuse atrophy with undertraining and/or immobilization.[80] Instead, the soleus muscle crosses only the ankle, specifically the talocrural joint and the talocalcaneal joint.[78] It is enclosed between two layers of thick fascia, the aponeurosis

of the Achilles tendon superficially, and a second layer deep to the soleus.[82] Unusual in human muscle (most human skeletal muscle is estimated to be an even mix of slow and fast twitch fiber types), the soleus muscle is approximately 70% slow twitch fiber type which would suggest the soleus is resistant to fatigue.[26,83,84] In contrast, the gastrocnemius is approximately 54% fast twitch fiber type,[84] which is more typical of human muscle.[26] The gastrocnemius functions in closed kinetic chain activities to assist the other plantarflexors in controlling the forward sagittal plane rotation of the leg over the fixed foot during ambulation while also stabilizing the knee.[78] By virtue of the calcaneocuboid joint, a plantarflexor moment is extended through the lateral two metatarsals.[78] The large cross-sectional area of the soleus and gastrocnemius muscles, coupled with a large moment arm, make the triceps surae muscle capable of producing significant joint moments and powers of the ankle.[26]

The fibers from the gastrocnemius and soleus interweave and twist as they descend. There is an area of high stress 2–6 cm above the distal tendon insertion.[85] A region of relative avascularity exists in the same area,[86] which correlates well with the site of some Achilles tendon injuries, including complete spontaneous rupture.[80,87,88] The plantaris muscle has its own tendon and contributes no fibers to the Achilles tendon.[89]

CLINICAL PEARL

The gastrocnemius is the dominant plantarflexor when vigorous force is needed, and even though it is intimately attached to the soleus, neither contribute to propulsion during slow pace steady-state gait.[90]

Achilles Tendon

The Achilles tendon is the thickest, strongest tendon in the body.[79] As the Achilles tendon comes from the posterior calf muscles, it courses distally to attach approximately three-quarters of an inch below the superior portion of the os calcis, on the medial aspect of the calcaneus. As the tendon fibers spiral 90 degrees instead of vertically, there is an increased potential for elongation and energy production.[91] In fact, the tendon can stretch up to 4% before microscopic damage occurs; macroscopic rupture occurs at strain levels greater than 8%.[92] Two bursae occur at the point of insertion of the Achilles tendon into the calcaneus. The retrocalcaneal bursa lies deep into the tendon, adjacent to the calcaneus. The superficial bursa of the tendo achillis lies superficial to the distal portion of the tendon, between the tendon itself and the subcutaneous tissues but is not visible unless it is pathologically inflamed. Deeper to the Achilles tendon is the pre-Achilles fat pad, a triangular area of adipose tissue, also known as Kager's triangle. Further anterior to this fat pad are the deep flexor tendons of the calf, predominantly the FHL, which overlies the posterior tibia and the talus.

There is no synovial sheath surrounding the Achilles tendon. The peritendon covers the endotendon and is composed of a thin sheath, called the epitenon, and another fine outer sheath, the peritenon, composed of fatty areola tissue, which fills the interstices of the fascial compartment in which the tendon is situated.[93] The peritenon is able to stretch 2–3 cm with tendon movement, which allows the Achilles tendon to glide smoothly.[94] The plantarflexion moment arm of the Achilles tendon is approximately 4 cm and varies little across the full range of plantarflexion and dorsiflexion.[95] This moment arm suggests a significant mechanical advantage in plantarflexing the calcaneus.[26]

Deep Posterior Compartment

This compartment contains the flexors of the foot. These muscles course behind the medial malleolus. They include the tibialis posterior, FDL, and FHL (see Fig. 21-7). This group is thought to play a major role in supinating the subtalar joint.[26]

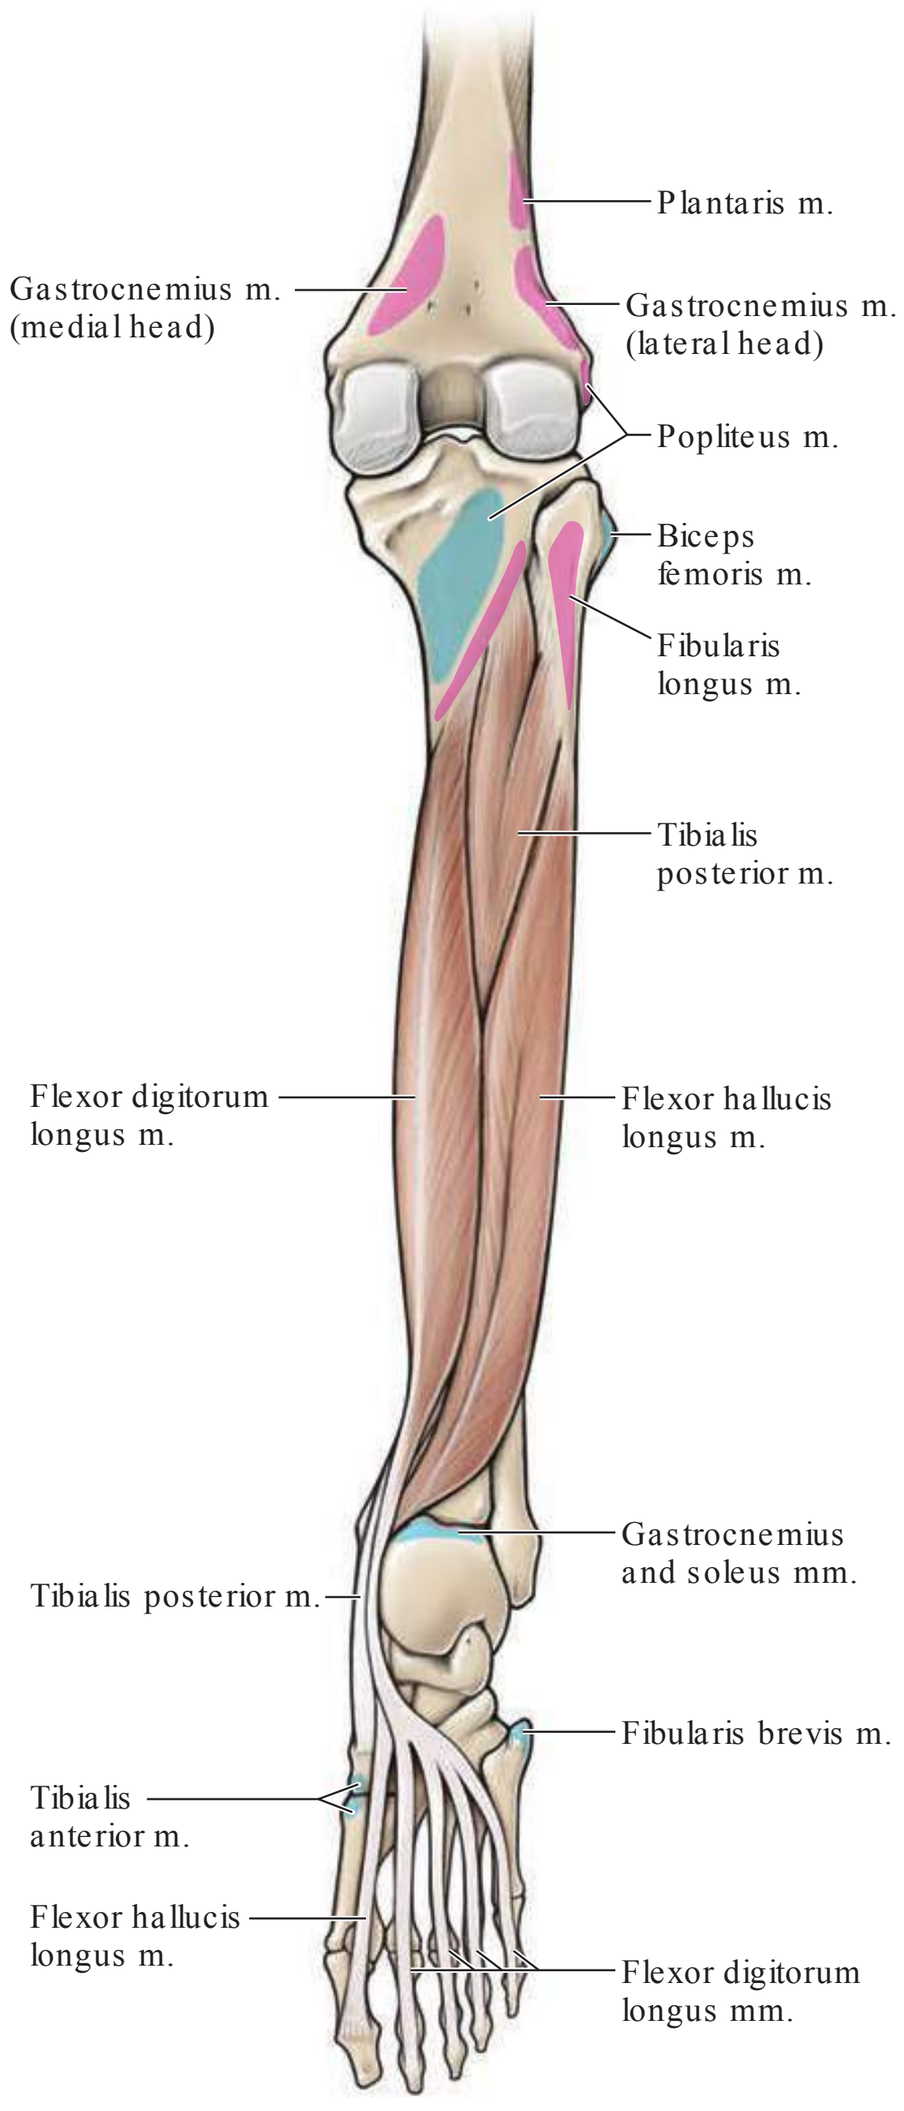

FIGURE 21-7 Posterior Deep muscle compartment. (Reproduced, with permission, from Chapter 37. Leg. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

The tibialis posterior muscle is arguably one of the most important determinants of optimal foot and ankle function as it is a key stabilizer of the leg, ankle, and foot. It originates from the posterior lateral surface of the tibia, medial two thirds of the posterior fibular, interosseous membrane, intermuscular septa, and fascia. The myotendinous junction appears in the distal one-third of the leg from which it courses posterior to the medial malleolus in a separate fibro-osseous groove and is held in place by the lancinate ligament (flexor retinaculum).[96] The tendon of the tibialis posterior then courses posterior to the medial malleolus, thereby passing posterior to the axis of the talocalcaneal (tibiotalar) joint and medial to the subtalar joint. As the tendon nears its insertion on the navicular tuberosity, it divides into three slips[96]:

- Anterior. The anterior slip is the largest of the three, is in direct continuation with the proximal tendon, and inserts on the navicular tuberosity.
- Middle. The middle slip continues distally as a tarsometatarsal extension and inserts on the plantar aspects of the intermediate and lateral cuneiforms, and the bases of metatarsals 2, 3, and 4. The middle slip also attaches on the plantar cuboid, covering the fibular canal through which the fibularis longus courses. The middle slip also serves as an origin for the Y-shaped FHB.
- Posterior. The posterior slip is recurrent and arises from the main tendon. It is oriented posteriorly and laterally, and inserts on the anterior portion of the sustentaculum tali.

CLINICAL PEARL

The tibialis posterior tendon is unique in the fact that it lacks a complete mesotenon and must receive its vascular supply through other channels, namely the posterior tibial artery, and the periosteum.[97]

The tibialis posterior is innervated by the tibial nerve, arising from the fifth lumbar and first sacral nerve roots.

CLINICAL PEARL

In the open kinetic chain, the tibialis posterior functions to invert the subtalar and ankle joints, adduct the forefoot, and plantarflex the foot and ankle. As the tendon is located farthest medially from the axis of the subtalar joint, it creates a moment arm that allows the tendon to have a great degree of inversion force.[96]

The primary function of the tibialis posterior muscle is to invert, adduct, and plantarflex the foot. It also provides support to the medial longitudinal arch.[98] The tibialis posterior muscle at the subtalar joint has a moment arm that is 2.5–5 times larger than the other deep compartment muscles, which would tend to suggest that it is the dominant supinator of the subtalar joint.[99] Because of the significant mechanical advantage, the tibialis posterior muscle has the potential to both strictly control hindfoot movement and influence the medial longitudinal arch by inverting the subtalar joint.[26]

The primary antagonist of the tibialis posterior muscle is the fibularis brevis muscle, although the former is more than two times stronger.[96]

The FDL originates from the posterior surface of the body of the tibia, medial to the tibial origin of the tibialis posterior. The tendon then passes behind the medial malleolus in a groove together with the tibialis posterior, but separated from the latter by a fibrous septum. It then travels superficial to the deltoid ligament of the ankle in an anterolateral direction into the sole of the foot, where it crosses inferior to the tendon of the FHL. It finally divides into four tendons, which insert into the bases of the last phalanges of the second, third, fourth, and fifth toes, as they each pass through an opening in the corresponding tendon of the FDB opposite the base of the first phalanx. The FDL functions to flex the phalanges of the lateral four toes and assists with plantarflexion of the foot.

CLINICAL PEARL

The FHL and FDL tendons cross each other at a point called the Master Knot of Henry (approximately one thumb breadth lateral to the navicular tuberosity), a fibrous slip that envelops the FHL and FDL tendons. The Master Knot of Henry has several intertendinous connections and is often a source of pain[100]

The FHL tendon courses distally from the posterior border of the fibula and interosseous membrane before traveling through a retinacular structure posterior to the ankle and subtalar joints. It continues between the medial and lateral tubercles of the talus to the sustentaculum tali. Distal to the sustentaculum tali, the FHL crossed dorsal to the FDL to the intersesamoidal ligament through a fibro-osseous tunnel, ultimately inserting on the distal phalanx of the hallux. The FHL flexes the great toe and also assists with plantarflexion of the foot.[100]

CLINICAL PEARL

The deep posterior compartment muscles likely interact with the foot intrinsic muscles to control the raising and lowering of the medial longitudinal arch and plantarflex the forefoot and toes.[26]

Lateral Compartment

The lateral compartment of the lower leg is innervated by the superficial fibular nerve (L4–S1). This compartment contains the fibularis (peroneus) longus and brevis (see Fig. 21-5). The fibular (peroneal) tendons lie behind the lateral malleolus in a fibro-osseous tunnel formed by a groove in the fibula and the superficial fibular (peroneal) retinaculum. The fibular (peroneal) retinaculum and the posterior CFL form the posterior wall of this tunnel. Distal to the lateral malleolus, the fibularis longus tendon sheath bifurcates around the fibular tubercle and through the inferior fibularis retinaculum. The os paronychium which is ossified in approximately 20% of individuals is located within the substance of the fibularis

(peroneus) longus tendon at the level of the calcaneocuboid joint.[101] The fibularis (peroneus) longus tendon, which forms a sling around the lateral and plantar aspects of the cuboid before inserting on the plantar aspect of the lateral first metatarsal base and medial cuneiform assist with calcaneocuboid joint stabilization.[102] The fibularis (peroneal) muscles serve as both plantarflexors and evertors of the foot, although the fibularis (peroneus) longus produces about 1/10 the plantarflexor force and the gastrocnemius, and the fibularis brevis exerts half of the fibularis (peroneus) longus.[103–105] The fibularis (peroneus) brevis also abducts the forefoot in the transverse plane, thereby serving as a support for the medial longitudinal arch.[106] The fibularis muscles are known to pronate the subtalar joint. The fibularis (peroneus) longus muscle is also a plantarflexor of the first metatarsal through its attachment to the base of the first metatarsal and medial cuneiform bones. The fibularis (peroneus) longus is counterbalanced by the tibialis posterior to stabilize the midtarsal joint.[11]

CLINICAL PEARL

The fibularis (peroneal) muscles have an important role in the rehabilitation of lateral ankle injuries because of the moment arms of these muscles toward pronation at the subtalar joint.[26]

INTRINSIC MUSCLES OF THE FOOT

Beneath the plantar aponeurosis–plantar fascia are the four muscular layers of the intrinsic muscles of the anterior (plantar) foot (Table 21-5), as well as the plantar ligaments of the rear- and midfoot. The intrinsic muscles provide support to the foot during propulsion.[107] Specifically, these muscles are synergists for proximal interphalangeal (PIP) joint flexion (second-fifth digits), MTP joint flexion (first-fifth digits), and adduction and abduction of the MTP joints.[26] In addition, this muscle group also plays an important function in arch support and propulsion during walking and running.[108] The foot intrinsic muscles are typically described based on their anatomical position using a series of layers.

First Layer

The first layer is the most anterior and superficial (plantar) and consists of the following:

- Abductor hallucis (Fig. 21-8). This muscle arises from the medial process of the calcaneal tuberosity and inserts on the medial side of the base of the proximal phalanx of the great toe. It functions to flex and/or abduct the proximal phalanx of the great toe (depending on its variable anatomical insertion),[109] and also helps to control pronation at the midtarsal joint.[107]
- Abductor digiti minimi (see Fig. 21-8). This muscle arises from the lateral process of the calcaneal tuberosity as well as the plantar aponeurosis and inserts into the lateral side of the base of the proximal phalanx of the little toe.
- Flexor digitorum brevis (see Fig. 21-8). This muscle arises from the medial process of the calcaneal tuberosity, lateral to the abductor hallucis and deep into the central portion of the plantar fascia, and inserts into the middle phalanx of the lateral four toes. It functions to flex only the middle phalanx of the lateral four toes.

Second Layer

- Flexor digitorum accessorius (quadratus plantae; Fig. 21-8). This muscle arises from the calcaneal tuberosity via two heads. The medial head arises from the medial surface of the calcaneus and the medial border of the long plantar ligament, whereas the lateral head arises from the lateral border of the anterior (plantar) surface of the calcaneus and the lateral border of the long plantar ligament. The muscle terminates in tendinous slips, joining the long flexor tendons to the second, third, fourth, and occasionally fifth toes.
- Lumbricals. There are four lumbricals (see Fig. 21-8), all of which arise from the tendon of the FDL. The first arises from the medial side of the tendon of the second toe, the second from adjacent sides of the tendons for the second and third toes, the third from adjacent sides of the tendons for the third and fourth toes, and the fourth from adjacent sides of tendons for the fourth and fifth toes. They insert with the tendons of the EDL and interossei into the bases of the terminal phalanges of the four lateral toes. The function of the lumbricals is to flex the MTP joint and extend the PIP joint.

Third Layer

- Flexor hallucis brevis (Fig. 21-8). This muscle arises from the medial part of the anterior (plantar) surface of the cuboid bone, the adjacent portion of the lateral cuneiform, and the posterior tibialis tendon and inserts on the medial and lateral side of the proximal phalanx of the great toe.
- Flexor digiti minimi (see Fig. 21-8). This muscle arises from the sheath of the fibularis (peroneus) longus, the base of the fifth metatarsal bone, and inserts into the lateral side of the base of the proximal phalanx of the little toe.
- Adductor hallucis (see Fig. 21-8). This muscle arises via two heads: an oblique and a transverse head. The oblique head arises from the bases of the second, third, and fourth metatarsal bones and the sheath of the fibularis (peroneus) longus. The transverse head arises from the joint capsules of the second, third, fourth, and fifth MTP heads and the deep transverse metatarsal ligament. The adductor hallucis inserts on the lateral side of the base of the proximal phalanx of the great toe.

Fourth Layer

- Posterior (dorsal) interossei. The four posterior (dorsal) interossei are bipennate, and they arise from adjacent sides of the metatarsal bones. The first inserts into the

TABLE 21-5 Intrinsic Muscles of the Foot

Muscle	Proximal	Distal	Innervation
Extensor digitorum brevis	Distal superior surface of calcaneus	Posterior (dorsal) surface of second through fourth toes and base of proximal phalanx	Deep fibular (peroneal) S1 and S2
Flexor hallucis brevis	Plantar surface of cuboid and third cuneiform bones	Base of proximal phalanx of great toe	Medial plantar S3 (S2)
Flexor digitorum brevis	Tuberosity of calcaneus	One tendon slip into base of middle phalanx of each of the lateral four toes	Medial and lateral plantar S3 (S2)
Extensor hallucis brevis	Distal superior and lateral surfaces of calcaneus	Posterior (dorsal) surface of proximal phalanx	Deep fibular (peroneal) S1 and S2
Abductor hallucis	Tuberosity of calcaneus and plantar aponeurosis	Base of proximal phalanx and medial side	Medial plantar L5 and
Adductor hallucis	Base of second, third, and fourth metatarsals and deep plantar ligaments	Proximal phalanx of first digit lateral side	Medial and lateral plantar S1 and S2
Lumbricals	Medial and adjacent sides of flexor digitorum longus tendon to each lateral digit	Medial side of proximal phalanx and extensor hood	Medial and lateral plantar L5, S1, and S2 (L4)
Plantar interossei			
First	Base and medial side of third metatarsal	Base of proximal phalanx and extensor hood of third digit	
Second	Base and medial side of fourth metatarsal	Base of proximal phalanx and extensor hood of fourth digit	Medial and lateral plantar S1 and S2
Third	Base and medial side of fifth metatarsal	Base of proximal phalanx and extensor hood of fifth digit	
Posterior (dorsal) interossei			
First	First and second metatarsal bones	Proximal phalanx and extensor hood of second digit medially	
Second	Second and third metatarsal bones	Proximal phalanx and extensor hood of second digit laterally	Medial and lateral plantar S1 and S2
Third	Third and fourth metatarsal bones	Proximal phalanx and extensor hood of third digit laterally	
Fourth	Fourth and fifth metatarsal bones	Proximal phalanx and extensor hood of fourth digit laterally	
Abductor digiti minimi	Lateral side of fifth metatarsal bone	Proximal phalanx of fifth digit	Lateral plantar S1 and S2

medial side of the proximal phalanx of the second toe. The second inserts into the lateral side of the proximal phalanx of the second toe. The third inserts into the lateral side of the proximal phalanx of the third toe, and the fourth inserts into the lateral side of the proximal phalanx of the fourth toe. The posterior (dorsal) interossei function to abduct the second, third, and fourth toes from an axis through the second metatarsal ray.

- Anterior (plantar) interossei (Fig. 21-8). The three anterior (plantar) interossei are unipennate and arise from the bases and medial sides of the third, fourth, and fifth metatarsal bones. They insert into the medial sides of the bases of the proximal phalanges of the third, fourth, and fifth toes. The anterior (plantar) interossei function to adduct the lateral three toes.

POSTERIOR (DORSAL) INTRINSIC MUSCLE

The posterior (dorsal) intrinsic muscles of the foot are the extensor hallucis brevis (EHB) and extensor digitorum brevis (EDB). The EHB inserts into the base of the proximal phalanx of the great toe, whereas the EDB inserts into the base of the second, third, and fourth proximal phalanges. Both of these

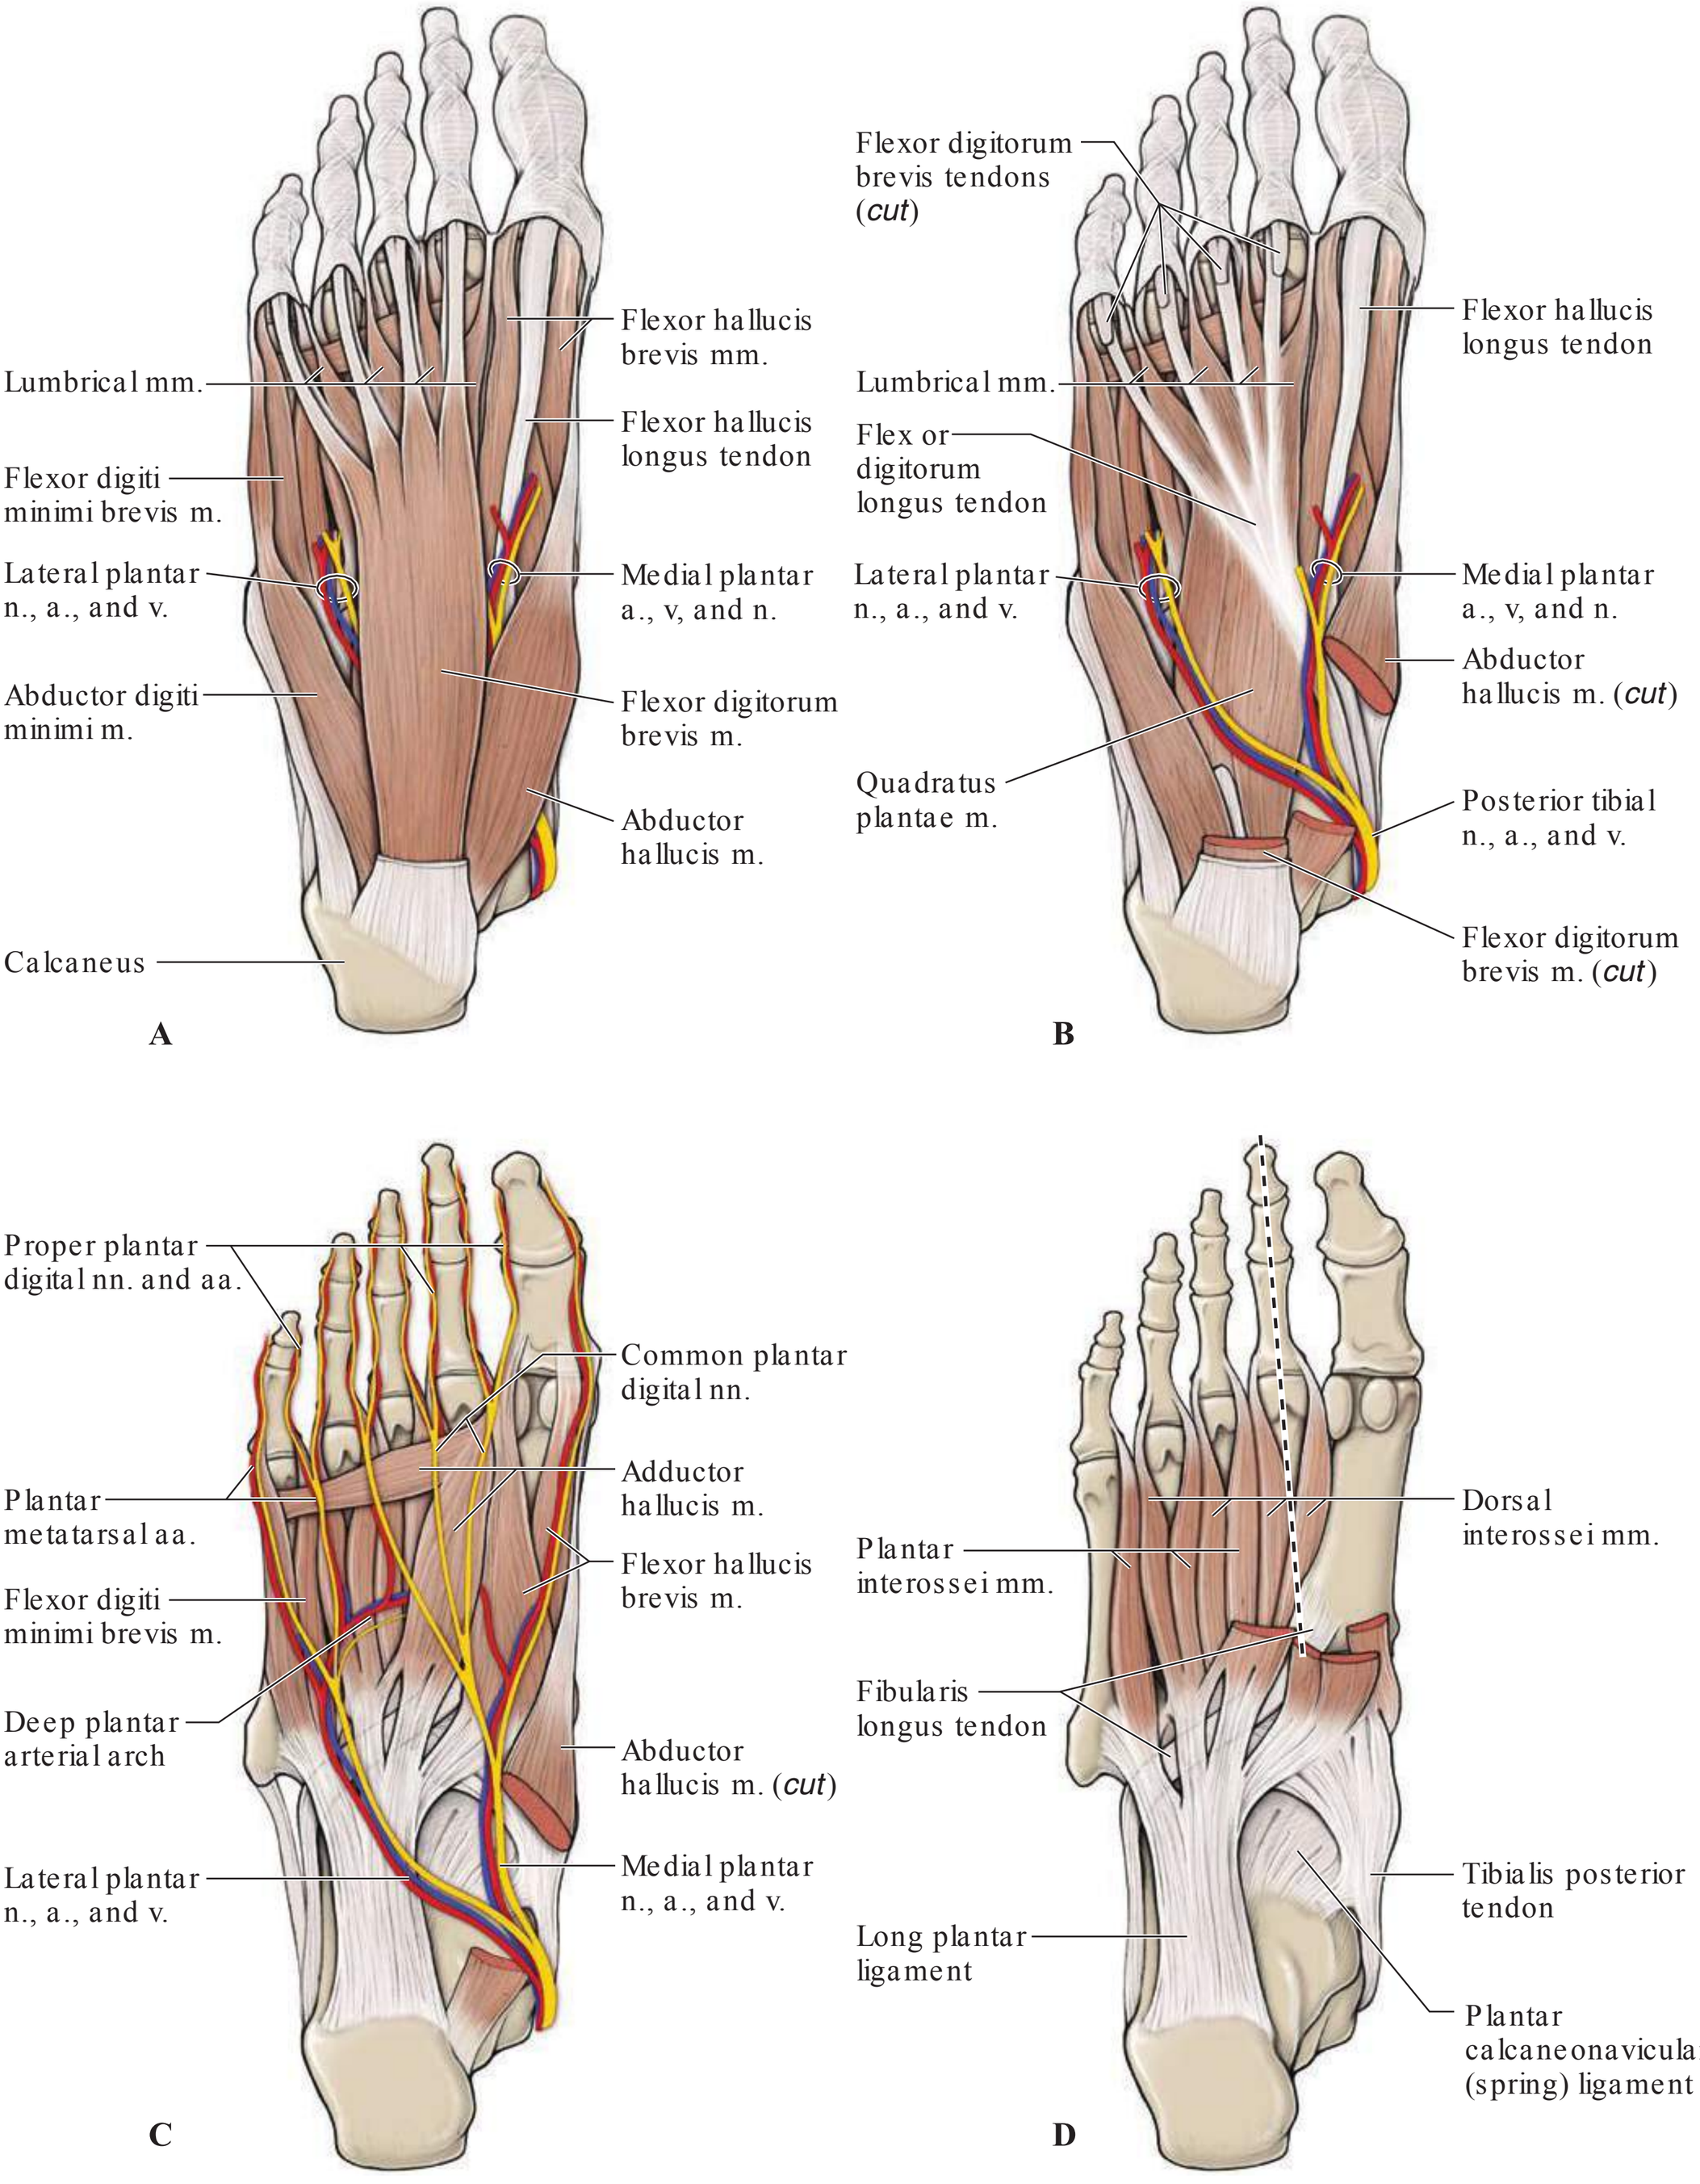

FIGURE 21-8 Intrinsic Muscles of the Foot. (Reproduced, with permission, from Chapter 38. Foot. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

muscles are innervated by the lateral terminal branch of the deep fibular (peroneal) nerve.

ARCHES OF THE FOOT

The arches of the foot support the foot by three mechanisms[110]:

- The osseous relationship of the tarsal and metatarsal bones.
- Ligamentous support from the plantar aponeurosis and anterior (plantar) ligaments.
- Muscle support.[111] There are three main arches: the medial longitudinal, the lateral longitudinal, and the transverse arches.

The Medial Longitudinal Arch

The medial longitudinal arch plays an important role in foot function during weight-bearing activities. The arch comprises the calcaneus, talus, navicular, three cuneiforms, and the three medial metatarsals (including the two sesamoids). Although some of the integrity of the arch depends on the bony architecture, support is also provided by the ligaments and muscles, including the anterior (plantar) calcaneonavicular (spring) ligament, the plantar fascia, the tibialis posterior, FDL, FHL, and fibularis (peroneus) longus.[106,112,113] The soleus and gastrocnemius muscle group has also been noted to have an effect on the arch and can flatten it with adaptive shortening.[106] Not only is the arch a major source of frontal plane motion of the foot, but it also is a major load-bearing structure.[114] Analysis of the medial longitudinal arch has long been used by clinicians to make determinations about foot abnormalities, with a high arch indicating a supinated foot and a low or collapsed arch being associated with a pronated or flatfoot, respectively.[115] Biomechanical models have suggested that damage to the plantar fascia results in lowering of the medial longitudinal arch and increased load on associated ligaments.[26,116] In addition, studies have found a higher incidence of stress fractures, plantar heel pain, metatarsalgia, and lower extremity injuries, including knee strains and iliotibial band syndrome, in individuals with high arches, compared with those who have low arches.[117–119] This is difference has always been attributed to the decreased shock-absorbing ability of the higher-arched foot,[120] although one study reported that arch height does not affect shock absorption.[121]

The role of muscle in controlling the medial longitudinal arches of the foot is controversial. A number of studies have shown that the foot intrinsic and extrinsic muscles, including the tibialis posterior and the Achilles tendon, are very active during gait and standing.[122–124] However, muscle control alone is insufficient to balance the forces experienced during high demand tasks, so it is likely that a combination of passive and active mechanisms underlie control of the medial longitudinal arch.[26]

The Lateral Longitudinal Arch

The lateral longitudinal arch, which is more stable and less mobile than the medial longitudinal arch, consists of the calcaneus, cuboid, and fourth and fifth metatarsals. The superior and deep longitudinal plantar ligament supports the calcaneocuboid and cubometatarsal joints, together with the fibularis (peroneus) brevis, longus, and tertius, and the abductor digiti minimi and FDB muscles.[125]

The Transverse Arch

The transverse arch forms the convexity of the posterior aspect of the foot and consists of metatarsal heads one through five, including the sesamoids (arch I); cuneiforms one through three and the cuboid (arch II); and the navicular and cuboid (arch III). The adductor hallucis, fibularis (peroneus) longus, posterior tibialis, and anterior tibialis all add dynamic support to this arch.

NAIL PLATE

The nail plate is composed of keratinized squamous cells, bordered by proximal and lateral nail folds.[126] The hyponychium lies between the distal portion of the nail bed and the distal nail fold and marks the transition to normal toe epidermis.[126] Fingernail plates grow on average at a rate of 3 mm per month, and toenail plates grow at one-half to one-third that rate.[126]

NEUROLOGY

The saphenous nerve, the largest cutaneous branch of the femoral nerve, provides cutaneous distribution to the medial aspect of the foot. Branches of the sciatic nerve provide the sensory and motor innervation of the foot and leg (see Chapter 3). The branches are the common fibular (peroneal) and tibial nerves. The common fibular (peroneal) nerve, in turn, divides into the superficial fibular (peroneal) and deep fibular (peroneal) nerves (Fig. 21-9). The tibial nerve divides into the sural, medial calcaneal, medial anterior (plantar), and lateral anterior (plantar) nerves.[126]

VASCULAR SUPPLY

Two branches of the popliteal artery (see Chapter 20), the anterior tibial artery and the posterior tibial artery, form the main blood supply to the foot (Fig. 21-9).

Anterior Tibial Artery

The anterior tibial artery supplies the anterior compartment of the leg and enters the posterior aspect of the foot under the superior and inferior retinacula as the posterior (dorsal) pedis artery. The posterior (dorsal) pedis artery gives rise to the arcuate artery and the first posterior (dorsal) and anterior (plantar) metatarsal artery, which serve the posterior aspect of the foot and the digits.

Posterior Tibial Artery

The posterior tibial artery, which supplies the posterior and lateral compartments and 75% of the blood to the foot, enters

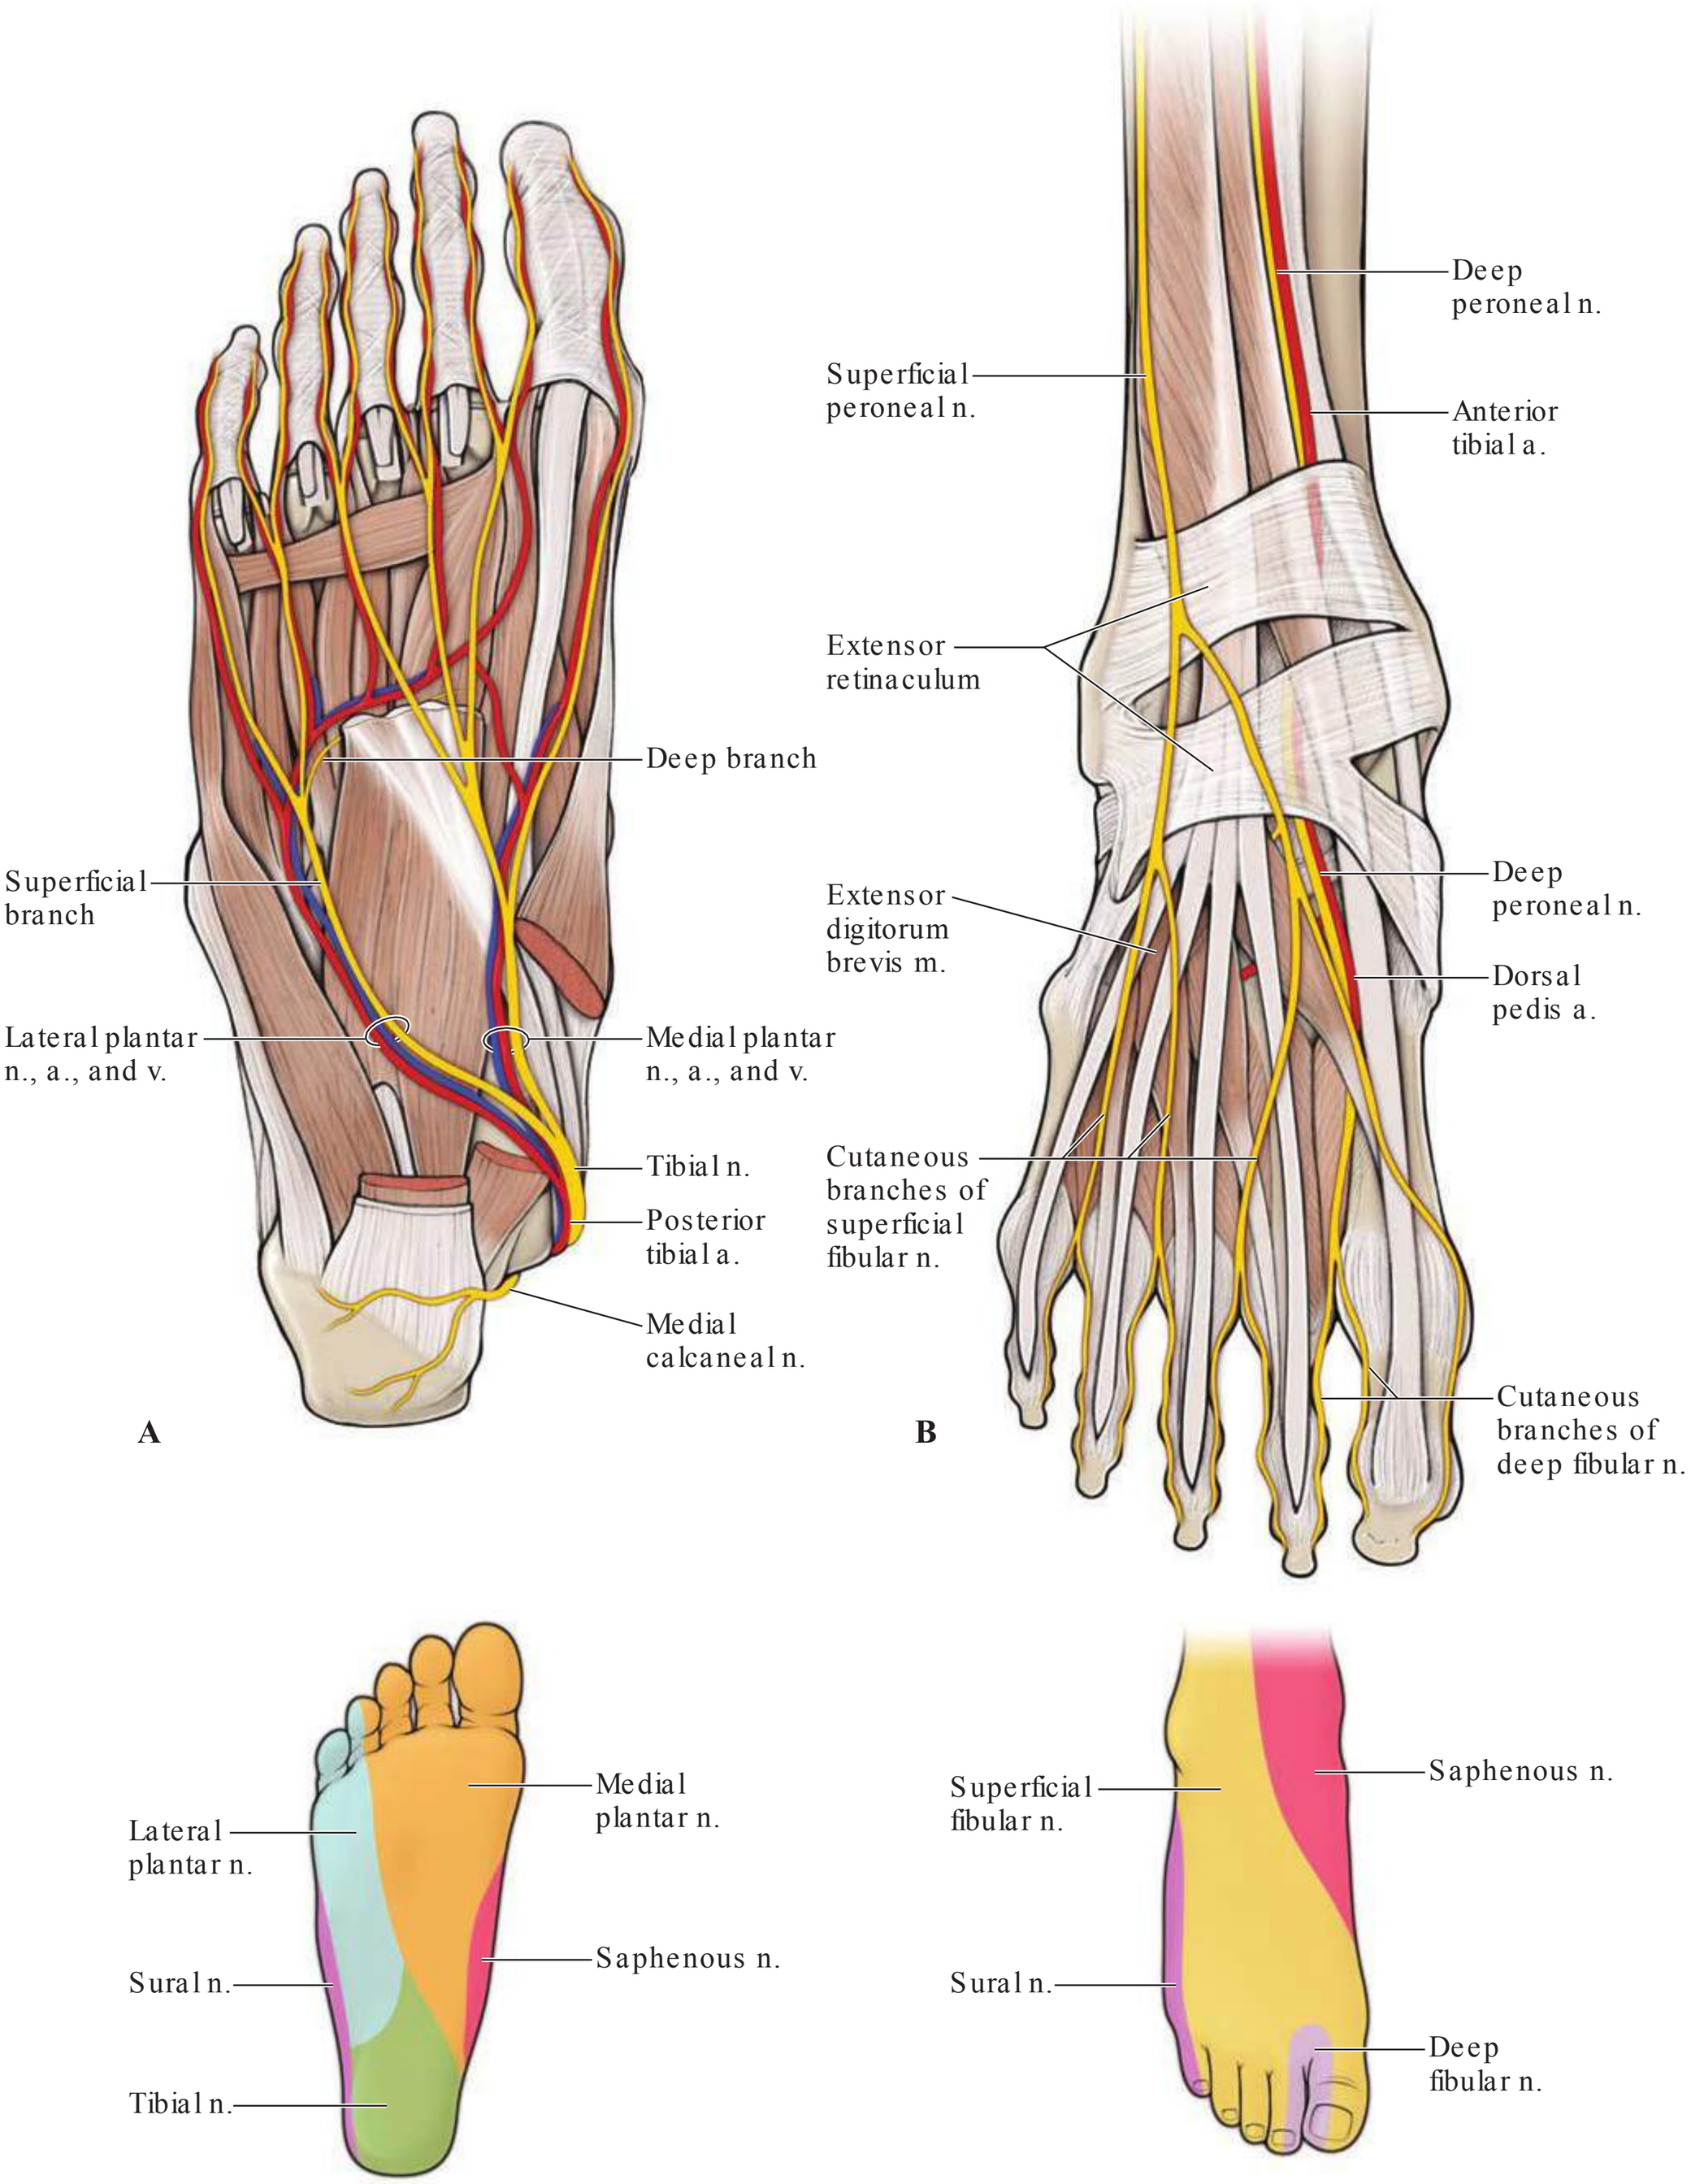

FIGURE 21-9 Neurovascular supply of the ankle and foot. (Reproduced, with permission, from Chapter 38. Foot. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

the foot after traveling around the medial malleoli. At this point, the artery divides into the medial and lateral anterior (plantar) arteries, which serve the anterior (plantar) aspect of the foot. A main branch of the posterior tibial artery, the fibular (peroneal) artery, supplies the lateral compartment as well as many hindfoot structures.

BIOMECHANICS

Terminology

Motions of the leg, foot, and ankle consist of single- and multiplane movements. The single-plane motions include the following:

- **The frontal plane motions of inversion and eversion.** Eversion is a frontal plane motion of the talonavicular joint about an anteroposterior axis, in which the medial aspect of the sole of the foot moves in an anterior (plantar) direction (Fig. 21-10). Inversion is a frontal plane motion of the foot about an A-P axis, in which the lateral aspect of the sole of the foot moves in an anterior (plantar) direction (Fig. 21-10).
- **The sagittal plane motions of dorsiflexion and plantarflexion.** These movements at the subtalar, talonavicular and forefoot joints occur in the sagittal plane about an M-L axis.[127] Plantarflexion is a movement of the foot downward toward the ground, and dorsiflexion is a movement of the foot upward toward the tibia.
- **The horizontal plane motions of adduction and abduction.** These motions of the talonavicular joint and forefoot occur in the transverse plane about a superoinferior axis. Abduction moves the forefoot laterally, whereas adduction moves the forefoot medially.

The axes of rotation of each component joint of the ankle–foot complex provides for movement in all three cardinal planes, a phenomenon called triplanar movement—a movement about an obliquely oriented axis through all three body planes.[1] Triplanar motions occur at the talocrural, subtalar, and transverse tarsal joints and at the first and fifth rays.[128] Pronation and supination are examples of triplanar motions. The three body plane motions in pronation are abduction in the transverse plane, dorsiflexion in the sagittal plane, and eversion in the frontal plane (Fig. 21-11).[128] The three body plane motions in supination are adduction in the transverse plane, plantarflexion in the sagittal plane, and inversion in the frontal plane (Fig. 21-12).[128] In pronation, the forefoot is rotated in such a manner so that the big toe moves downward, and little toe moves upward, whereas in supination, the reverse occurs.

CLINICAL PEARL

Terms that describe movement of the foot and ankle typically end in the suffix "-ion" whereas terms ending in the suffixes "-ed," "-us," and "-um" commonly refer to positions of the foot and ankle.[1] For example, "forefoot adduction" is the movement of the forefoot toward the midline about a superoinferior axis of rotation, while "forefoot adductus" is the static position of the foot in an adducted position.

Distal Tibiofibular Joint

Although the two tibiofibular joints (proximal and distal) are described as individual articulations, they function as a pair. The movements that occur at these joints are primarily a result of the ankle's influence.

- Supination of the foot produces a distal and posterior glide of the head of the fibula.
- Pronation produces a proximal and anterior glide with an external rotation of the fibula.
- Plantarflexion of the foot produces a distal glide with a slight medial rotation of the fibula.
- Dorsiflexion of the ankle yields a proximal glide. The fibula rotates externally around its longitudinal axis.

During these movements, however, it is the tibia that performs the greatest amount of movement, as it rotates around the fibula. This is probably a consequence of more body weight falling through the larger bone. During ipsilateral rotation, both the tibia and the fibula rotate laterally, but in relative terms, the tibia moves more laterally than the fibula, causing a relative anterior and superior glide of the fibular head on the tibia at the superior joint. During contralateral rotation, the tibia rotates more medially, producing a relative posterior and inferior fibular glide at the joint.

The ligaments of the distal tibiofibular joint are more commonly injured than the ATFL.[129] Injuries to the ankle syndesmosis most often occur as a result of forced external rotation of the foot or during internal rotation of the tibia on a planted foot.[21] Hyperdorsiflexion may also be a contributing mechanism.[130]

The capsular pattern of this joint is likely pain with weight-bearing dorsiflexion of the ankle, as this produces the greatest ligamentous tension (Table 21-1). For the same reason, the close-packed position is considered as weight-bearing dorsiflexion of the ankle.

CLINICAL PEARL

Because of the interaction between the proximal and distal tibiofibular joints with the knee and the ankle function, the clinician should always assess the functional mobility of both these complexes when treating one or the other.

An abnormal position of the fibula (anterior or posterior relative to the tibia) at the distal tibiofibular joint has been reported to contribute to abnormal muscle function in patients after an ankle sprain.[131,132]

Talocrural Joint

The talocrural, or tibiotalar, joint is classified as a synovial hinge or modified sellar joint. There is general agreement that motion between the tibia and the foot is a complex combination of talocrural and subtalar joint motion, which is limited by the shape of the articulations and soft-tissue interaction. Stability for this joint in weight bearing is provided by the articular surfaces, while in nonweight bearing, the ligaments appear to provide the majority of stability.[23]

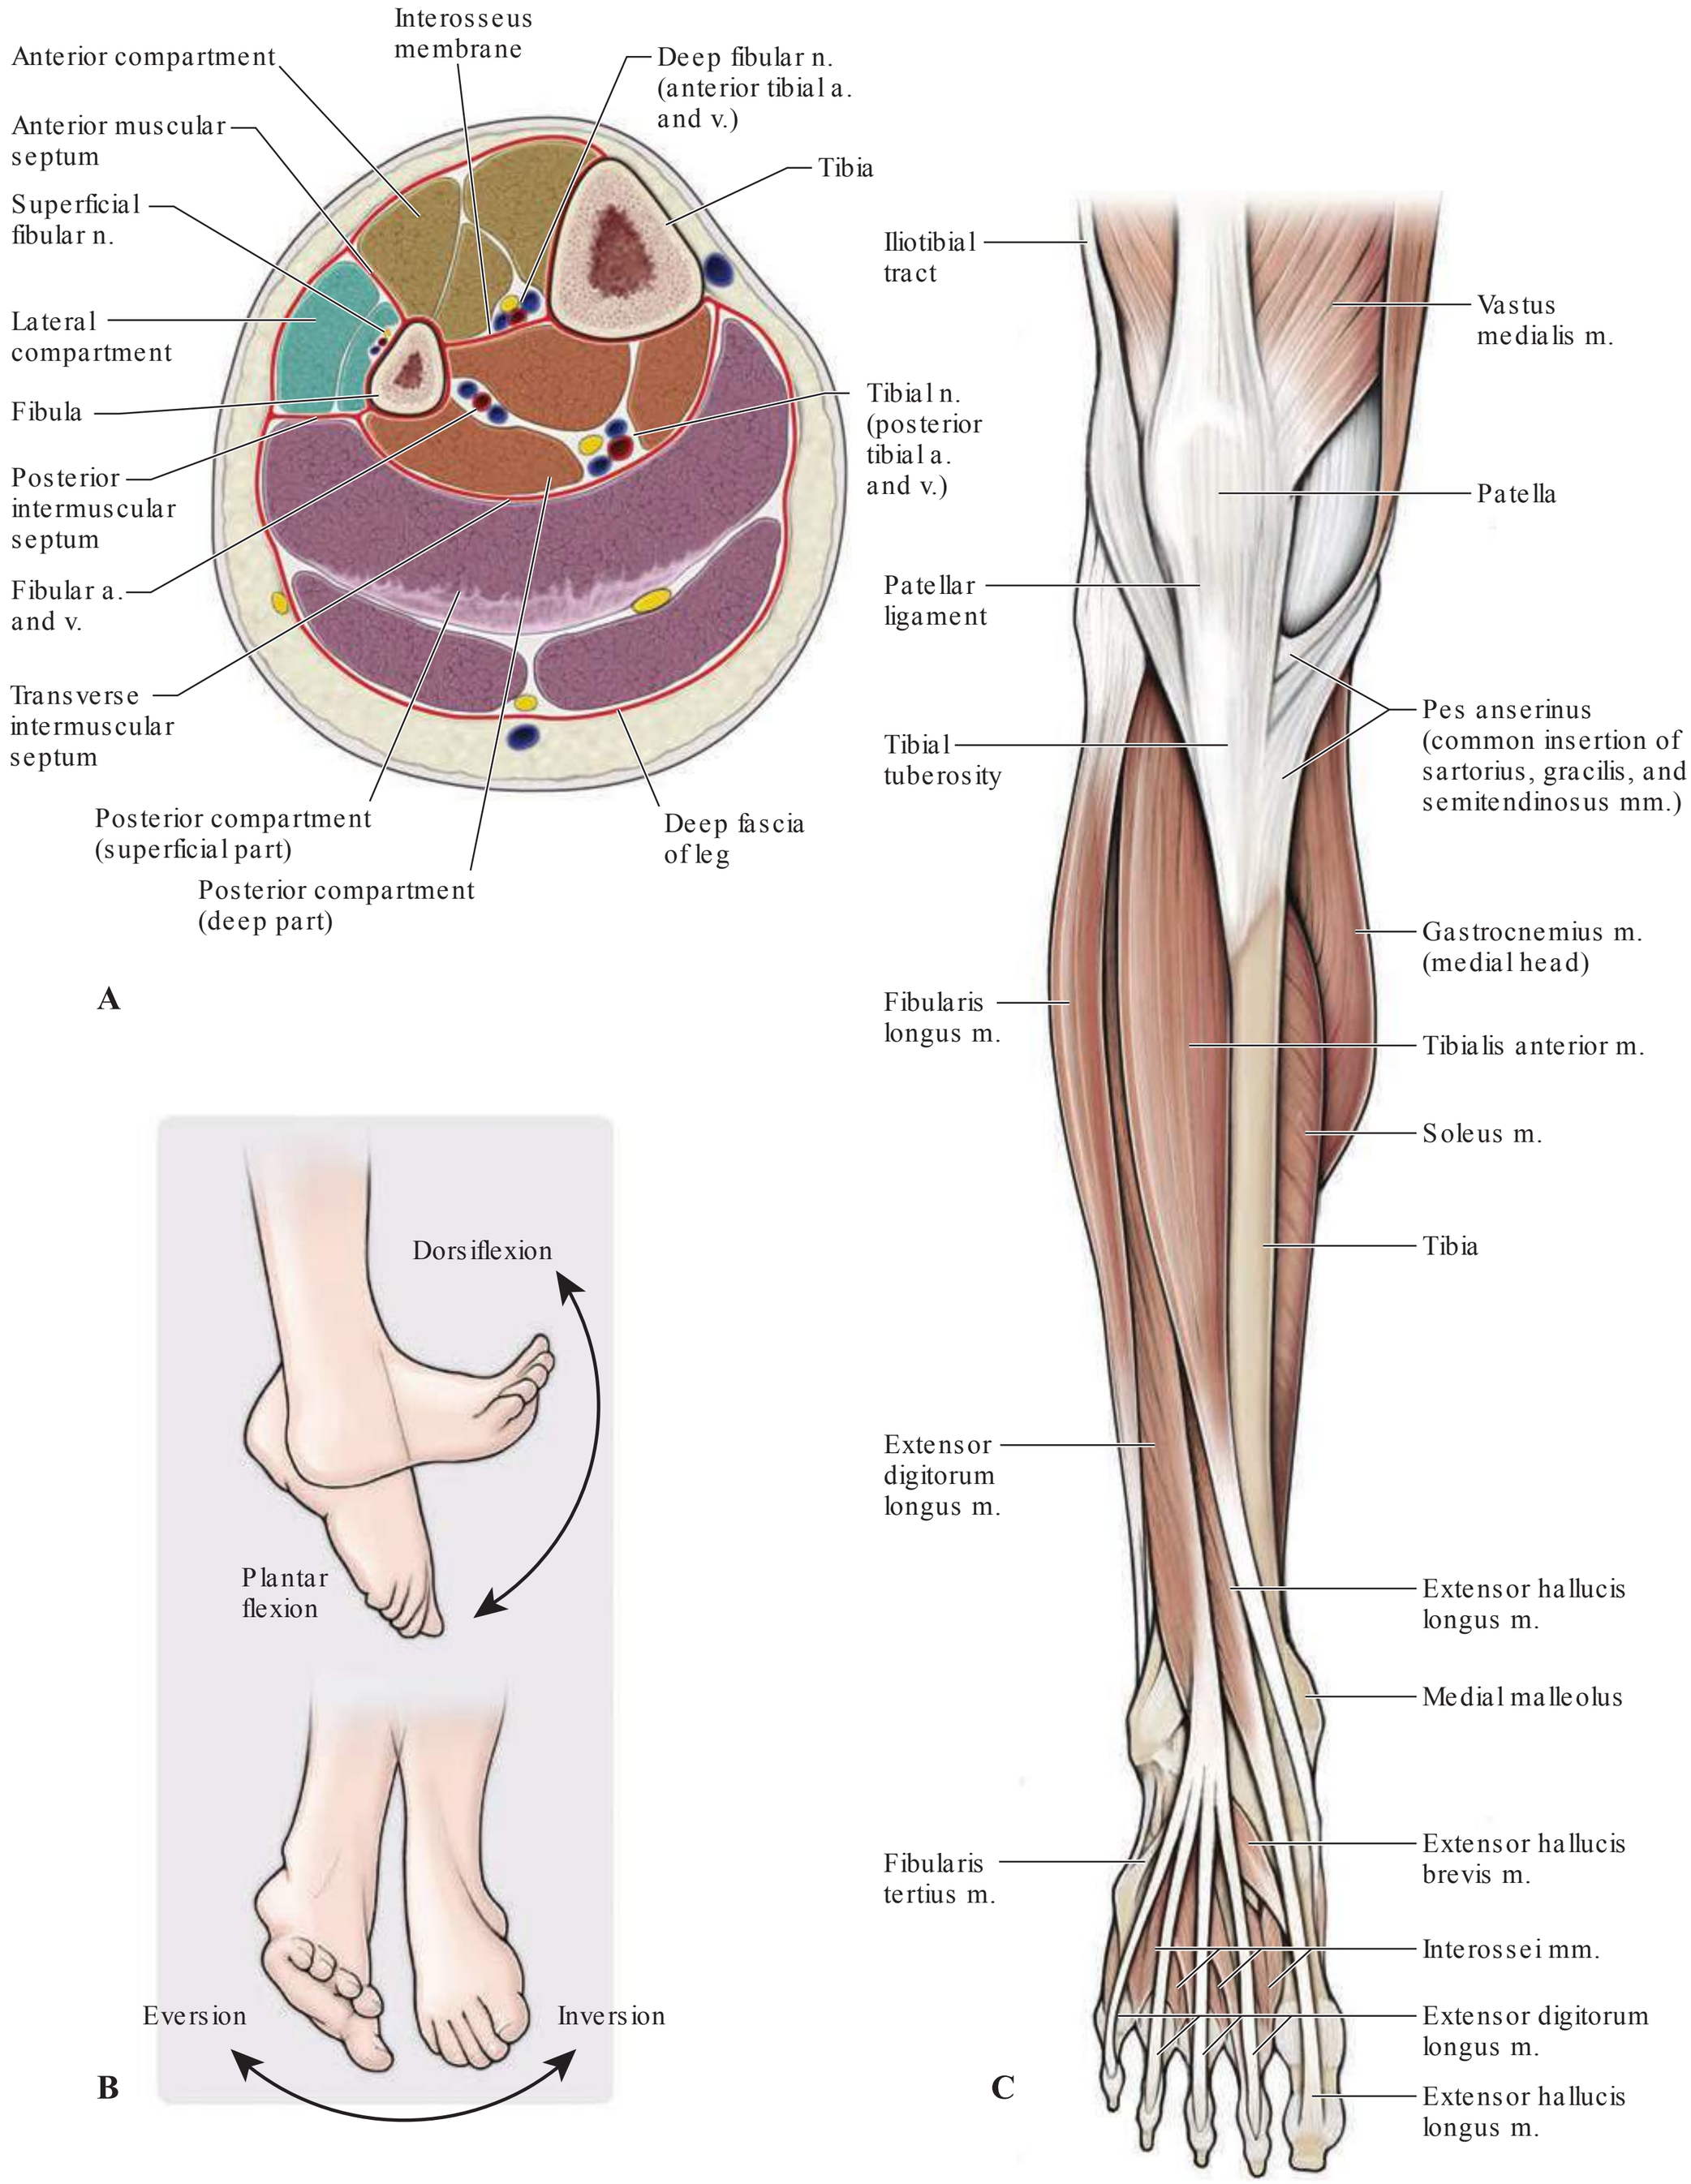

FIGURE 21-10 Ankle motions and related musculature. (Reproduced, with permission, from Chapter 37. Leg. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

FIGURE 21-11 Pronation in nonweight bearing.

Talocrural joint motion occurs around a functional axis that is obliquely oriented in both the frontal and transverse planes. The talocrural joint axis, which is rotated posteriorly by 6 degrees, has a tilt of approximately 10 degrees from horizontal in the frontal plane (i.e., superomedial to inferolateral) and it has an 18–20 degrees of obliquity in the transverse plane (i.e., anteromedial to posterorlateral).[133] The orientation of the talocrural joint axis can be roughly estimated clinically as a line that passes inferiorly from the medial malleolus to the lateral malleolus, with the adult distal leg being oriented vertically.[133] The angle of inclination provides for the majority of talocrural motion to occur in the sagittal plane during plantarflexion and dorsiflexion (Fig. 21-10), although some motion also occurs in the frontal and transverse planes, particularly during plantarflexion.[26] According to an MRI study[134] that recorded ROM during non–weight-bearing movements, the reported range of plantarflexion was 41 degrees, dorsiflexion 16 degrees, abduction 5 degrees, adduction 14 degrees, eversion 7 degrees and inversion 3 degrees. The joint translations that occurred averaged 4 mm anterior for plantarflexion and 1 mm posterior for dorsiflexion.[134] The maximum amount of dorsiflexion necessary at the talocrural joint during human gait is approximately 10 degrees of the normally available 20 degrees,[128,135,136] and occurs during the stance phase, just prior to when the heel begins to rise.[137]

FIGURE 21-12 Supination in nonweight bearing.

The trochlea of the saddle-shaped talus is wider anteriorly than posteriorly resulting in a tighter fit between the talus and ankle mortise when the ankle is in dorsiflexion. Due to this fit of the talus within the mortise, the talus is able to produce a slight separation of the tibial and fibula malleoli during the extremes of dorsiflexion and plantarflexion.[138] In addition, because of this fit, the tibia follows the talus during weight bearing so that the talocrural joint externally rotates with supination and internally rotates with pronation.[139] Conversely, the tibia internally rotates during pronation and externally rotates during supination.[140] Passive stability to this joint is also provided from its lateral and medial collateral ligaments.

Theoretically, the capsular pattern of the ankle joint is more restriction of plantarflexion than dorsiflexion, although clinically this appears to be reversed (Table 21-1). The close-packed position is weight-bearing dorsiflexion, whereas the open-packed position is midway between supination and pronation.

CLINICAL PEARL

The major contributors to stability of the ankle joint are the osseous congruency and fit of the articular surfaces when the joints are loaded, static ligamentous (ATFL, and CFL) and capsular restraints, and the surrounding musculotendinous units.[141]

Subtalar Joint

The axis of motion for the subtalar (talocalcaneal) joint, which is approximately 42 degrees from horizontal in the sagittal plane, and 16 degrees medial to the midsagittal plane referencing the anterior side of the joint.[142,143] The subtalar joint axis of rotation creates a dominant frontal plane movement (i.e., inversion and eversion), with secondary movements available in the transverse and sagittal planes. This configuration allows the subtalar joint, together with the talocrural joint, to produce the triplanar motions of pronation/supination, a motion that has been compared to a ship on the sea or an oblique mitered hinge.[144] The various components of the triplanar motion at this joint vary according to whether the joint is weight bearing or nonweight bearing.[145]

- During weight-bearing (closed-chain) activities, pronation involves a combination of calcaneal eversion (frontal plane motion), adduction (transverse plane motion), and plantarflexion (sagittal plane motion) of the talus and internal rotation of the tibia. These movements result in a lowering of the medial longitudinal arch. Closed-chain supination involves a combination of calcaneal inversion, abduction and dorsiflexion of the talus and external rotation of the tibia. These movements result in an elevation of the medial longitudinal arch.
- During non–weight-bearing (open chain) activities, pronation involves a combination of calcaneal eversion and abduction and dorsiflexion of the talus (see Fig. 21-11), whereas supination involves a combination of calcaneal inversion and adduction and plantarflexion of the talus (see Fig. 21-12).

CLINICAL PEARL

Although the terms pronation and eversion are both widely used to refer to externally directly rotation of the foot segment around the functional axis of the subtalar joint, the term eversion is typically used in the context of an ankle ligament injury mechanism that involves outward displacement of the sole of the foot.[146] Similarly, the terms supination and inversion are both widely used to refer to internally directed rotation of the foot segment around the functional axis of the subtalar joint, but the term inversion is almost exclusively used to describe the inward displacement of the sole of the foot that produces a lateral ankle ligament injury.

The subtalar joint controls supination and pronation in close conjunction with the transverse tarsal joints of the midfoot. Subtalar joint supination and pronation are measured clinically by the amount of calcaneal or hindfoot inversion and eversion. In normal individuals, there is an inversion to eversion ratio of 2:3 to 1:3, which amounts to an average of approximately 20 degrees of inversion and 10 degrees of eversion.[24,113,128,144] It is important to remember that variability of ROM across individuals is common when attempting to restore function to the subtalar joint.[26] For normal gait, a minimum of 4–6 degrees of eversion and 8–12 degrees of inversion are required.[147]

During normal gait, the foot needs to pronate and supinate 6–8 degrees from the neutral position.[148] If the foot pronates excessively, a compensatory internal rotation of the tibia may occur. This is produces an increased amount of rotatory stress and dynamic abduction moment at the knee, which has to be absorbed through the peripatellar soft tissues at the knee joint.[149–152] These stresses can force the patella to displace laterally and may result in patellofemoral dysfunction.[3,153] In addition, a change in the position of the talus can affect the functional leg length. Subtalar supination may cause the leg to lengthen while subtalar pronation shortens the leg. Thus, the midposition of the subtalar joint, subtalar joint neutral, is considered the range at which the subtalar joint should act to prevent dysfunction. The subtalar joint neutral position is actually a measurement of the angle between a line that bisects the distal third of the lower leg and a line that bisects the calcaneus.[154] The bisection of the calcaneus represents the position of the anterior (plantar) condyles because the calcaneus is almost perpendicular to the condyles. The angle between the bisections should be 0 degrees in the normal foot but is actually 2–3 degrees of varus (inverted in most subjects).[155]

CLINICAL PEARL

Mathematically, the subtalar joint neutral position is that angle at which the ratio of calcaneal inversion to eversion is approximately 2:1.[128]

Stability of the subtalar joint is provided by the CFL, the cervical ligament, the interosseous ligament, the LTCL, the fibulotalocalcaneal ligament (ligament of Rouviere), and the extensor retinaculum.[156]

The capsular pattern of this joint varies. In chronic arthritic conditions, there is an increasing limitation of inversion, but with traumatic arthritis, eversion appears most limited clinically. The close-packed position for this joint is maximum inversion, whereas the open-packed position is inversion/plantarflexion (Table 21-1).

Transverse Joint Complex

The function of the transverse tarsal joint complex (talonavicular and calcaneocuboid joints) is to provide the foot with an additional mechanism for raising and lowering the arch and to absorb some of the horizontal plane tibial motion that is transmitted to the foot during stance.[139,157] The calcaneocuboid joint is a plane synovial joint whereas the talonavicular joint is a synovial pivot joint.[26]

- Calcaneocuboid joint. The joint axes of rotation for the calcaneocuboid joint are inclined 52 degrees superior and 57 degrees medial, referencing the anterior side of the joint.[1] This is orientation yields a dominant transverse plane movement (i.e., abduction and adduction), with sagittal and frontal plane movements also available. The principal movement about the sagittal axis is internal/external rotation with the calcaneus process acting as a pivot.[54] This is rotational movement has been described as pronation/supination and obvolution/involution,[54] but inversion/eversion is used herein. The cuboid, which acts as a pulley for the fibularis (peroneus) longus tendon during gait, rotates as much as 25 degrees during inversion/eversion.[158]
- Talonavicular joint. The joint axes of rotation of the talonavicular joint are inclined superior 15 degrees and medial degrees, referencing the anterior side of the joint.[1] This is orientation creates a dominant frontal plane movement for the talonavicular joint (i.e., inversion and eversion), with a minor amount of transverse plane and sagittal plane movements available.

When combined, motions around the two axes of the transverse tarsal joint complex which are limited by the plantar calcaneocuboid ligament (short plantar ligament), long plantar ligament, plantar calcaneonavicular ligament (spring ligament), bifurcate ligament, and the plantar aponeurosis, involve[110]:

- a rotational motion about a longitudinal axis into adduction/inversion and abduction/eversion,[26] which can be observed in the elevation and depression of the medial arch of the foot during the stance phase of gait. Movements of the transverse tarsal joint complex into adduction and inversion result in less movement of the foot in the sagittal plane as the bones of the foot transform into a rigid lever. In contrast, movements of abduction and eversion result in greater movement of the foot in the sagittal plane as the foot transforms into a flexible lever.
- an oblique axis, producing the near sagittal motions of forefoot dorsiflexion and forefoot plantarflexion.[26]

Both axes are dependent on the position of the subtalar joint.[24,147,157] When the subtalar joint is pronated, the two sets of axes are parallel to one another, allowing for the maximum amount of motion at the transverse tarsal joint complex. When the subtalar joint is supinated, the two sets of axes are

in opposition, allowing only little motion to occur, thereby enhancing stability. T is connection between supination and foot rigidity and pronation and foot flexibility has clinical significance. For example, patients with feet that are unable to pronate sufficiently may have syndromes associated with the inability to absorb impact forces whereas, patients with feet that are able to supinate sufficiently, may have syndromes associated with soft-tissue loading (i.e., tendon or ligament problems).[26,159]

During gait, the transverse tarsal joint complex has following two functions[110]:

- To permit adaptation of the foot to uneven terrain in the early stance
- To provide a stable foot during terminal stance

T eoretically, as a modified ovoid, the joint complex can sublux into dorsiflexion/plantarflexion, abduction/adduction, with or without rotation. In practice, the most commonly found subluxations may be considered as inversion/dorsiflexion or eversion/plantarflexion lesions.[54] T e capsular pattern of the transverse tarsal joint complex is a limitation of dorsiflexion, plantarflexion, adduction, and internal rotation (Table 21-1). T e close-packed position for the transverse tarsal joint complex is supination (Table 21-1). T e open-packed position is midway between the extremes of ROM.

Cuneonavicular Joint

T e cuneonavicular joint has one to two degrees of freedom: plantar/dorsiflexion, inversion/eversion. T e capsular pattern of this joint is a limitation of dorsiflexion, plantarflexion, adduction, and internal rotation. T e close-packed position is supination. T e open-packed position is considered to be midway between the extremes of ROM (Table 21-1).

Intercuneiform and Cuneocuboid Joints

Due to their very plane curvature, these joints have only one degree of freedom: inversion/eversion. T e close-packed position for these joints is supination. T e open-packed position is considered to be midway between the extremes of ROM (Table 21-1).

Cubometatarsal Joint

T e capsular pattern of this joint is a limitation of dorsiflexion, plantarflexion, adduction, and internal rotation. T e close-packed position is pronation. T e open-packed position is considered to be midway between the extremes of ROM (Table 21-1).

Cubonavicular Joint

T e close-packed position for this joint is supination. T e open-packed position is midway between the extremes of ROM (Table 21-2).

Intermetatarsal Joints

T e close-packed position for these joints is supination. T e open-packed position is midway between the extremes of ROM (Table 21-1).

MTP Joints

T e MTP joints have two degrees of freedom: flexion/extension and abduction/adduction. ROM of these joints is variable, ranging from 40 to 100 degrees dorsiflexion (with a mean of 84 degrees), 3–43 degrees (mean, 23 degrees) plantarflexion, and 5–20 degrees varus and valgus.[160] T e close-packed position for the MTP joints is maximum extension. T e capsular pattern for these joints is variable, with more limitation of extension than flexion. T e open-packed position is 10 degrees of extension.

First MTP Joint

T e hallux and first MTP joint are important to foot function and frequently problematic.[26] Normal alignment of the first MTP joint varies between 5 degrees varus and 15 degrees valgus.[161] T e function of the great toe is to provide for normal propulsion during gait and to provide stability to the medial aspect of the foot. T e first MTP joint moves into extension during gait as a result of heel lift, subtalar joint supination, and normal sesamoid function.[162,163] T eoretically, motions occur in adduction and abduction around a superoinferior axis, and dorsiflexion and plantarflexion around a M-L axis. However, the amount of abduction and adduction of the joint is small compared to sagittal plane motion. Indeed, the most important motion at the first MTP is extension/dorsiflexion, which is coupled with inversion of the proximal joints of the first ray.[164] During normal gait, the first MTP joint dorsiflexes approximately 60 degrees. During sprinting (running sports), squatting (football and baseball), and relevé (in dance), greater than 90 degrees of dorsiflexion is necessary.

T e first MTP is characterized by having a remarkable discrepancy between active and passive motion. T ree-dimensional motion analysis studies suggest that passive ROM at the first MTP joint ranges from 55 degrees extension/dorsiflexion to 35 degrees flexion/plantarflexion (approximately 90 degrees of ROM) tested nonweight bearing and less weight bearing.[165] Studies have shown that less than 45 degrees of the first MTP joint extension is required during gait.[165] T e first ray of the foot consists of the first metatarsal and the first (medial) cuneiform bone. T ese two bones, along with the medial column of the foot, act as a functional unit, playing an important role in providing structural integrity to the foot during walking and running activities. An example is the late-stance phase of walking when the ankle is plantarflexing to propel the center of mass of the body up and forward.[26] T ree extrinsic muscles of the foot insert at the base of the first ray: the anterior tibialis, posterior tibialis, and fibularis (peroneus) longus. T e need for clinical assessment of the posterior (dorsal) mobility of the first ray is based on its functional role during weight-bearing activities. Any disruption to its normal motion (hypo- or hypermobility) reduces the ability of the first ray to adequately stabilize the medial column of the foot and the longitudinal arch, increasing the potential for injury to the head of the first metacarpal.[166]

IP Joints

Each of the IP joints has one degree of freedom: flexion/extension. T e capsular pattern is more limitation of flexion than of

extension. The close-packed position is maximum extension (Table 21-1). The open-packed position is slight flexion.

EXAMINATION

The examination is used to identify static and dynamic, and structural or mechanical foot abnormalities. A successful examination depends on the clinician's ability to select the most appropriate tests to address the patient-specific problem. The clinical diagnosis is based on an assessment of the changes in joint mobility and tissue changes at the foot and ankle and the effect these have on the function of the foot and ankle and the remainder of the lower kinetic chain.

The exact form of the examination is very much dependent on the acuteness of the condition. For example, weight-bearing tests cannot be done if the patient cannot bear weight, and most stress tests will prove impossible if the joints cannot be taken to their full range. In these cases, the clinician must rely heavily on the history.

CLINICAL PEARL

With an acute lesion, the purpose of the examination is to try to determine if a serious injury might have occurred and whether there is a need to refer the patient back for further medical examination. Due to the acute pain and inflammatory state of the tissues in the acute stage, the physical examination may need to be modified and sometimes curtailed.

HISTORY

The primary purposes of the history are to do the following:

- Determine the patient's chief complaint.
- Determine the mechanism of injury, if any. Information about the mechanism of injury should include when, where, how, and if an injury occurred. Details about the mechanism of injury allow the clinician to infer the pathologic status and structures involved, although it must be remembered that the patient's recollection of the mechanism involved frequently does not necessarily correspond to the structures damaged.[19,167] Most ankle sprains occur when the foot is plantarflexed, inverted, and adducted (Table 21-6). This same mechanism can also lead to a malleolar or talar dome fracture. A history involving sudden changes in training patterns may indicate an overuse injury. A dorsiflexion injury with associated snapping and pain on the lateral aspect of the ankle that rapidly diminishes may indicate a tear of the fibular (peroneal) retinaculum.[168] If there is no traumatic event, the clinician must determine if there has been a change in exercise or activity intensity (e.g., increased mileage with runners), training surface, or changes in body weight or shoe wear (causal agents).[19,167] In addition, the clinician must determine whether the symptoms vary with activity, type of terrain, or changes in position. Complaints of cramping may accompany muscular fatigue or intermittent claudication from arterial insufficiency. Plantar heel pain associated with plantar fasciitis is typically associated with an insidious onset. Achilles tendinopathy is an overuse injury associated with an insidious onset of posterior calcaneal pain. Increased symptoms, when walking or running on uneven terrain as compared with an even terrain, may suggest ankle instability. Increased symptoms, when walking or running on hard surfaces, as compared with a softer surface, may suggest a lack of shock absorbency of the foot or shoe. Pain that is related to a certain time of day may indicate

TABLE 21-6 Examination Sequence in the Presence of a History of Inversion Trauma of the Foot and Ankle

History of Inversion Trauma
Possible pathology/structure involved
Ligamentous
Lesion of the anterior talofibular/CFL
Lesion of the bifurcate ligament
Lesion of the cuboid-fifth metatarsal ligament
Lesion of the anterior tibiotalar and tibionavicular ligaments
Lesion of the tibiofibular interosseous ligament
Articular
Traumatic arthritis of the talocrural joint (TCJ)
Traumatic arthritis of the subtalar joint (STJ)
Traumatic arthritis of the transverse tarsal joints (TTJ)
Posterior tibiotalar compression syndrome
Sinus tarsi syndrome
Tibio fibular syndesmosis instability
Muscular
Tenosynovitis of the fibularis muscles
Tendinitis of the fibularis muscles
Rupture of the superior extensor retinaculum
Achillodynia
Tenosynovitis or tendinitis of the EHL
Tenosynovitis or tendinitis of the EDL
Neurologic
Overstretching of common fibular nerve/superficial fibular/deep fibular nerve
Osseous
Avulsion fracture of the base of the fifth metatarsal
Fracture of the shaft of the fifth metatarsal
Avulsion fracture at the lateral calcaneus
Avulsion fracture at the cuboid
Fracture of the anterior calcaneal process
Osteochondral fracture of the talus
Fracture of the lateral tubercle of the talus
Navicular fracture
Talar neck fracture
Talar head fracture

Data from Winkel D, Matthijs O, Phelps V. Appendix F. In: Winkel D, Matthijs O, Phelps V, eds. Diagnosis and Treatment of the Lower Extremities. 1997, Gaithersburg, MD: Aspen, 1997:645–646.

an activity-related problem or a condition such as plantar heel pain if the pain is felt when first bearing weight in the morning.

- Determine the patient's occupation, if any. The impact of the injury on the patient's personal life, work, and athletic demands will largely direct the early intervention.[19,167]
- If painless ambulation is essential, then rigid immobilization (i.e., a cast) may be appropriate.
- If a rapid return to sports competition is of paramount importance, functional immobilization is preferred.
- Determine the location and severity of the condition. Most often, the patient can point to the location of the pain. The site and severity of the pain can be measured using a body diagram and visual analog scale (VAS), respectively. The distribution of pain is important, and the clinician should determine whether the pattern is referred, associated with a structure, related to a dermatome or peripheral nerve, or systemic in nature.[169] A stress fracture or tendinopathy typically has a localized site of pain, whereas diffuse pain is associated with compartment syndromes (see Chapter 5).
- Determine which activities and positions aggravate the symptoms. Information should be gleaned about whether activities aggravate the symptoms and if so, which. For example, pain with forced dorsiflexion and eversion and with squatting activities may suggest ankle instability. Pain after activity suggests an overuse or chronic injury. Pain during an activity suggests stress on the injured structure.
- Ascertain the area, nature, and behavior of the symptoms.[170] Information about the time of injury, the time of the onset of swelling, and its location are important. The patient may report hearing a "snap," "crack," or "pop" at the time of injury, which could indicate a ligamentous injury or a fracture. The patient may report that their ankle felt weak and/or unstable at the time of the initial trauma or sometime thereafter. An inability to bear weight or the presence of severe pain and rapid swelling indicates a serious injury such as a capsular tear, fracture, or grade III ligament sprain.[171–174]
- Help determine the specific structure at fault.[175]
- Detect systemic conditions (e.g., collagen disease, neuropathy, radiculopathy, and vascular problems) or the presence of serious pathology.

In addition, questions regarding previous ankle injury, goals of the patient regarding functional goals, level and intensity of sports involvement, and past medical history are important to help the clinician individualize the intervention to the patient.

SYSTEMS REVIEW

As symptoms can be referred distally to the leg, foot, and ankle from a host of other joints and conditions, the clinician must be able to differentially diagnose from the presenting signs and symptoms (see Chapter 5). The cause of the referred symptoms may be neurologic or systemic in origin. If a disorder involving a specific nerve root (L4, L5, S1, or S2) is suspected, the necessary sensory, motor, and reflex testing should be performed. Peripheral nerve injuries may also occur in this region and often go unrecognized. These include Morton's neuroma and entrapment of the tibial nerve or its branches, the deep fibular (peroneal) nerve, superficial fibular (peroneal) nerve, and sural and saphenous nerves.[176]

Systemic problems that may involve the leg, foot, and ankle include diabetes mellitus (peripheral neuropathy), osteomyelitis, gout and pseudogout, sickle cell disease, complex regional pain syndrome, peripheral vascular disease, and rheumatoid arthritis (refer to Chapter 5). A systemic problem such as rheumatoid arthritis may be associated with other signs and symptoms, including other joint pain, although the other joint pain may also be the result of overcompensation in the rest of the kinetic chain.

Warning signs at the ankle and foot that should alert the clinician to a more insidious condition include:

- immediate and continuous inability to bear weight, which may indicate a fracture;
- nocturnal pain, which may indicate malignancy, hemarthrosis, fracture, or infection;
- gross pain during ankle valgus and tenderness with pressure on the distal fibula, which may indicate a fractured fibula;
- pain and weakness during resisted eversion, which may indicate fracture of the fifth metatarsal bases;
- calf pain and/or tenderness, swelling with pitting edema, increased skin temperature, superficial venous dilatation, or cyanosis, which may indicate the presence of a deep vein thrombosis (DVT), requiring immediate medical attention (see Chapter 5);
- feelings of warmth or coldness in the foot. An abnormally warm foot can indicate local inflammation but can also originate from a tumor in the pelvic or lumbar region.[177] An abnormally cold foot usually indicates a vascular problem.[177]

TESTS AND MEASURES

Observation

Observation of the lower extremity is extensive. It is extremely important to observe the entire kinetic chain when assessing the leg, foot, and ankle as foot and ankle posture has been implicated in foot and ankle pathology, as well as altered foot and ankle kinematics and kinetics.[178] Weight-bearing and non–weight-bearing postures of the foot are compared.

Observing the patient while they move from sitting to standing and walk to the treatment area gives the clinician a sense of the patient's functional ability in weight bearing and provides the first opportunity for gait analysis.[179] An important part of the examination of the foot and ankle is the gait assessment (see Chapter 6). During gait, the transverse and longitudinal arches can be grossly assessed—the lateral longitudinal arch bears the body weight in the early stance, whereas the medial longitudinal arch provides support in the mid- and late-stance phase of gait.[180] The foot should touch

the ground, the heel first and the heel should begin to rise at approximately 35% of the gait cycle.[180] Early heel rise may occur due to a tightness of the gastrocnemius–soleus complex whereas late heel rise may be secondary to a weakness of the calf musculature.[180] Normally, the foot pronates during the early-stance phase, but the foot should not remain pronated during heel rise and toe off.[180]

CLINICAL PEARL

Patients with an ankle injury usually avoid the normal heel-to-toe progression to decrease weight bearing and painful ankle dorsiflexion.[181] Instead, the patient is likely to adopt a toe-to-heel progression, with varying amounts of hip circumduction, or steppage gait, to further unload the ankle.[182]

The following are assessed with the patient standing:

- Shoulder and pelvic heights (see Chapters 16 and 29).
- Spinal curvature (see Chapter 27).
- Pelvic rotation (see Chapter 29).
- The degree of hip rotation. In the femur, anteversion and retroversion angles should be noted (refer to Chapter 19). Excessive internal rotation of the hip toward the opposite hip (anteversion) may result in a flattening of the medial longitudinal arch and toeing-in/internal torsion of the tibia (pigeon toes). Excessive external rotation of the hip away from the opposite hip (retroversion) may result in an elevation of the medial longitudinal arch.
- The degree of knee flexion or hyperextension. A genu recurvatum (hyperextension) places the talocrural joint in more plantarflexion than normal and can often be a compensatory mechanism in the longer limb of individuals who have a leg-length inequality; see Chapter 29.[183] An increase in knee flexion accomplishes the same compensation for a leg-length inequality.[183]
- The degree of varus and valgus of the knee and tibia. In the sagittal plane, a vertical tibia indicates normal ankle position. Tibia varum refers to the frontal plane position of the distal one-third of the leg, as it relates to the supporting surface.[184] The midshaft of the distal one-third of the lower leg should be straight within the frontal plane. Excessive tibia varum, genu varus, or forefoot varus can increase the frontal angle of the talocrural joint, which promotes excessive weight bearing on the lateral aspect of the foot unless compensatory pronation is available within the foot to bring the medial aspect of the foot to the support surface.[183]
- Rotational components of the tibia. Tibial torsion is assessed with the patient in sitting, with their feet hanging over the end of the bed so that their knees are in approximately 90 degrees of flexion.[179] The thumb of one hand is placed over the apex of one malleolus, and the index finger of the same hand is placed over the apex of the other malleolus. A qualitative estimate of the direction and magnitude of tibial torsion can be made by envisioning a line that passes through the malleoli and estimating its orientation to the frontal plane of the proximal tibia.[183] Alternatively, tibial torsion can be measured with the patient in prone with the knee flexed to 90 degrees and the subtalar joint positioned and stabilized in subtalar neutral.*

CLINICAL PEARL

The neutral subtalar position is calculated based on a normal 2:1 ratio of inversion to eversion. To locate subtalar neutral, the patient is positioned in prone with the opposite hip flexed, abducted, and externally rotated. If evaluating the right ankle, the clinician uses the thumb and forefinger of the left hand to palpate the hollows over the neck of the talus on either side of the anterior portion of the ankle. Using the thumb and forefinger of the other hand, the clinician grasps the head of the fourth and fifth metatarsals and rocks the foot back and forth. As the foot is inverted, a bulge can be felt on the lateral aspect of the foot. With eversion, the bulge can be felt to bulge medially. The point at which the talar head is felt to bulge equally on the medial and lateral sides is the subtalar neutral position.

Once the subtalar neutral position has been established, a line is drawn on the sole of the foot parallel to the length of the femur. A second line is drawn in line with the foot. The angle between these lines is the tibial torsion angle.[185] There is normally an angle of 12–18 degrees to the frontal plane.[186] Tibial torsion is generally less in children. A position of relative internal rotation of the tibia produces an increase in rigidity to the subtalar joint prior to midstance, due to premature stabilization of the longitudinal arch of the foot.[187] Excessive external rotation of the tibia places an increased strain along the longitudinal arch, as well as the first MTP joint.[187]

- Hindfoot to leg orientation. This can be an indicator of weight-bearing subtalar position. It is assessed by measuring the acute angle formed between a line representing the posterior aspect of the distal third of the leg, and a line approximately 1-cm distal to the first mark, representing the midline of the posterior aspect of the calcaneus (see Fig. 21-13).[183] The angle is assessed as the patient shifts weight on the lower extremity to simulate single-limb support. If the lines are parallel or in slight varus (2–8 degrees), the leg–hindfoot orientation is considered normal.[188] Movement of the hindfoot into eversion (hindfoot valgus) during this maneuver is indicative of subtalar pronation.[128] Pronation of the foot is manifested by eversion of the heel, abduction of the forefoot, a decrease in the medial longitudinal arch, internal rotation of the leg in relation to the foot, and dorsiflexion of the subtalar and transverse tarsal joint complex. If the heel is in too much valgus, the forefoot is excessively abducted, or there is excessive external rotation of the tibia, more toes can be seen on the affected side than the normal side when viewing the leg from behind ("too-many-toes sign").[47] If the patient is asked to raise up on the toes, the calcaneus should be observed

*The subtalar neutral position refers to the position in which all bones of the subtalar joints and the talocrural joints line up optimally in their open-packed positions—a position of neither pronation nor supination.

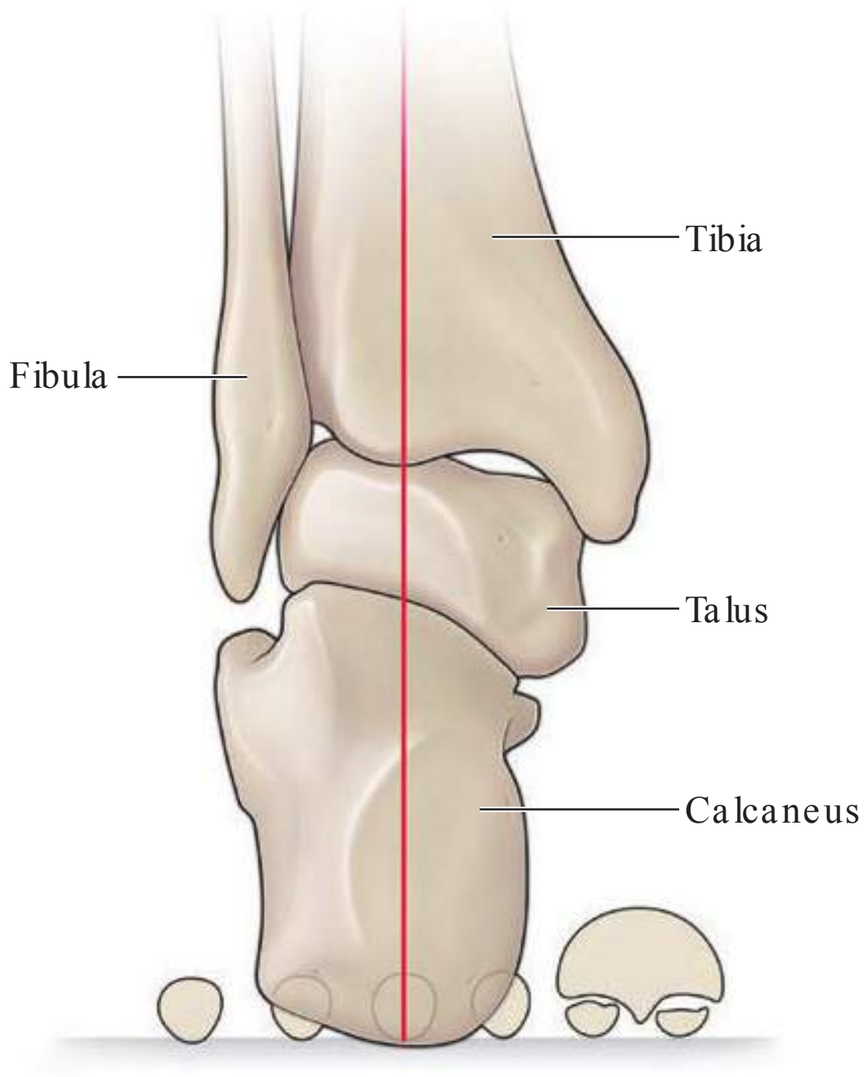

FIGURE 21-13 Hindfoot to leg orientation.

to move into a position of inversion. An inability of the calcaneus to invert with this maneuver could indicate the presence of an abnormality in the subtalar joint mechanism, or a weakness of the posterior tibialis.[47,187]

The weight-bearing foot. The following are major components of the normal weight-bearing foot[155,189]:

- Both planar condyles of the calcaneus are on the floor surface when looking from the posterior, and there should be a slight calcaneal eversion with no more than one or two of the lateral toes visible.[1] An imaginary plane representing the ground surface is applied to the anterior (plantar) surface of the calcaneus. The metatarsal heads should rest upon this plane. If the plane of the metatarsal heads is perpendicular to the bisection of the calcaneus, the forefoot-to-hindfoot relationship is normal, or neutral.
- The "normal" foot should demonstrate 6–8 degrees of calcaneal eversion during gait. The foot should pronate initially, just after initial contact (see Chapter 6).
- All of the metatarsal heads lie in one plane, which is in the same plane as the anterior (plantar) condyles of the calcaneus[190]
- The ball of the foot is level with the plantar surface of the heel.
- A normal forefoot-to-hindfoot relationship (see later).
- The orientation of the distal third of the lower leg should be vertical, to position the foot properly for the stance phase.
- The transverse tarsal joint complex is maximally pronated, while the subtalar joint, MTP, and IP joints are in neutral.
- The presence of a well-formed static medial arch should be noted, as well as its dynamic formation with heel raising. Specifically, there should be a distance between the navicular tuberosity and the floor that it easily noticeable but not excessive.[1] The distance between the navicular tuberosity and floor can be measured with a ruler or digital calipers. The arch index, which is a measurement made from footprints, involves calculation of the ratio of the area of the middle third of the arch to the total area of the foot excluding the toes.[191] The arch index demonstrates high test–retest reliability within days (intraclass correlation coefficient [ICC] = 0.94) and between days (ICC = 0.96).[191] However, it is important to note that a pilot study by Wearing et al.[192] reported that body composition influences arch index values in overweight and obese subjects.
- Forefoot-to-hindfoot relationship. Goniometric measurement of forefoot position relative to the hindfoot is a routine procedure used by rehabilitation specialists. This measurement is also frequently made by visual estimation. Neutral alignment of the forefoot relative to the hindfoot is present when a line representing the anterior (plantar) aspect of the metatarsal heads is perpendicular to the line bisecting the hindfoot. The forefoot-to-hindfoot angle is approximately 10–12 degrees.[155,189] Forefoot varus is the term used to describe inversion of the forefoot away from this neutral position, while forefoot valgus describes an everted forefoot position.[183] The relationship can be assessed with the patient positioned in prone with their knee extended and their feet over the end of the table. The subtalar neutral position is located using the method described previously. Slight pressure is applied to the metatarsal heads while maintaining subtalar neutral. This will determine the relationship of the forefoot to hindfoot, and both of these to the bisection of the lower leg. A varus or valgus tilt of the forefoot in relation to the hindfoot becomes significant when the first metatarsal is in a plantarflexed position, as this positions the hindfoot into an inverted position during weight bearing.[187] Somers et al. examined the reliability of goniometric and visual estimation of forefoot position measurements when experienced and inexperienced testers performed the evaluation. Two clinicians (≥ 10 years' experience) and two physical therapy students were recruited as testers. Ten subjects (20–31 years old), free from pathology, were measured. Each foot was evaluated twice with the goniometer and twice with visual estimation by each tester. ICC and coefficients of variation method error were used as estimates of reliability. There was no dramatic difference in the intra- or intertester reliability between the experienced and inexperienced testers, regardless of the evaluation used. Estimates of intratester reliability (ICC 2,1), when using the goniometer, ranged from 0.08 to 0.78 for the experienced clinicians and from 0.16 to 0.65 for the inexperienced clinicians. When using visual estimation, ICC (2,1) values ranged from 0.51 to 0.76 for the experienced clinicians and from 0.53 to 0.57 for the inexperienced clinicians. The estimate of intertester reliability [ICC (2,2)] for the goniometer was 0.38 for the experienced clinicians and 0.42 for the inexperienced clinicians. When using visual estimation, ICC (2,2) values

were 0.81 for the experienced clinicians and 0.72 for the inexperienced clinicians. Although experience does not appear to influence forefoot position measurements, of the two evaluation techniques, the visual estimation may be the more reliable.

- **Foot deviations in weight bearing.** These include pes planus (low inclined subtalar joint axis that is characterized by a low arch and hindfoot valgus), pes cavus (high inclined subtalar joint axis that is characterized by a high arch and hindfoot varus), talipes equinus (plantarflexed foot), talipes equinovarus (supinated foot), and hallux valgus.[179]
- **The degree of foot pronation or supination in nonweight bearing.** The patient lies in the prone position, with the foot over the edge of the table. The clinician holds the foot over the fourth and fifth metatarsal heads with one hand. Both sides of the talus are palpated on the posterior aspect of the foot using the thumb and index finger of the other hand. The clinician then passively dorsiflexes the foot until a resistance is felt. At this point, and while maintaining the dorsiflexed position, the clinician moves the foot back and forth through the arc of supination and pronation. During supination, the talus should be felt to bulge laterally, while, during pronation, the talus should be felt to bulge medially. Supination at the subtalar joint occurs in association with 20 degrees of calcaneal inversion while pronation occurs in association with 10 degrees of calcaneal inversion.
- **The degree of toe-out.** The normal foot in relaxed standing adopts a slight toe-out position of approximately 12–18 degrees from the sagittal axis of the body (Fick angle).[176]
- **Forefoot equinus.** To assess for forefoot equinus, the clinician stabilizes the hindfoot with one hand and applies pressure on the entire forefoot via pressure across the metatarsal heads, into dorsiflexion. If the plantar declination of the lateral structures cannot be reduced so that the plantarflexed attitude is no longer visible, a positive identification of forefoot equinus can be made.[189]
- **The presence of a talar bulge.** The patient is positioned in standing, and the clinician observes to see whether the talar head bulges excessively on the medial side of the midfoot, indicating excessive subtalar joint pronation in weight bearing. Adaptive shortening of the gastrocnemius/soleus group is indicated with a prominence of the soleus, particularly on the medial side of the teno-calcaneum.

The Modified Foot Posture Index[193–195] can be used to quantify the degree to which the foot is pronated, supinated, or in the neutral position. The user attaches a score based on a 5-point Likert scale to a series of six observations (Table 21-7). All observations are made with the subject standing at a relaxed angle and base of gait, double limb support, static stance position. When the scores are combined, the aggregate value gives an estimate of the overall foot posture. The six clinical criteria employed are [193,194]

1. Talar head palpation. The head of the talus is palpated on the medial and lateral side of the anterior aspect of the ankle and scored accordingly.
2. Supra and infra lateral malleollar curvature. In the neutral foot, the curves should be approximately equal.
3. Calcaneal frontal plane position. With the patient standing in the relaxed stance position, the posterior aspect of the calcaneus is visualized with the observer in line with the long axis of the foot.
4. Prominence in the region of the talonavicular joint. In the foot, the area of the skin immediately superficial to the talonavicular joint is flat. However, the talonavicular joint becomes more prominent if the head of the talus is abducted in the rearfoot pronation, indicating a pronated foot. In the supinated foot, this area may be indented.
5. Congruence of the medial longitudinal arch. In a neutral foot, this curvature of the arch should be relatively uniform, similar to a segment of the circumference of a circle. When a foot is supinated, the curve becomes acuter at the posterior end of the arch. In an excessively pronated foot, the arch becomes flattened in the center.
6. Abduction/adduction of the forefoot on the rear foot. In a supinated foot, the forefoot will adduct on the rear foot resulting in more of the forefoot being visible on the medial side. Conversely, pronation of the foot causes the forefoot to abduct resulting in more of the forefoot been visible on the lateral side.

The final FPI score will be a whole number between –12 and + 12. High positive aggregate values indicate a pronated posture, whereas significantly negative aggregate values indicate a supinated foot posture. The score for a neutral foot should lie somewhere around zero. The Modified Foot Posture Index demonstrates good intrarater reliability and moderate interrater reliability.[196]

Other areas that should be examined include the following:

- **The condition of the nails.** When examining the nails a systematic approach is used, involving an inspection of the shape, contour, and color of the nails. The clinician should observe for the presence of subungual hematomas, subungual exostosis, onychocryptosis, onychia, onychauxis, onychomycosis, paronychia, tinea pedis, or blisters.
- **Toe deformities.** Contractions of the capsule of the IP or MTP joints of the toes in association with tendon shortening may produce a series of deformities, ranging from hammer toe to mallet toe to claw toe. Hammer toe usually involves a flexion contracture of the anterior (plantar) surface of the PIP, with a mildly associated extension contracture of the MTP joint. Mallet toe results from a flexion deformity of the distal IP joint (DIP) with plantar contracture. Often a corn or callus is present on the posterior aspect of the affected joint. Corns are similar to calluses but have a central nidus. Claw toe deformity is a more advanced contracture of capsules and intrinsic musculature, which may also be associated with pes cavus and neurologic or primary muscle pathology to the lumbrical and interosseous muscles. The claw toe results in hyperextension of the MTP joints and flexion of the PIP and DIP joints.
- **Functional hallux limitus.** Clinically, the presence of functional hallux limitus, an inability of the first MTP joint

TABLE 21-7 Modified Foot Posture Index Scoring

Talar head palpation				
–2	–1	0	1	2
Talar head palpable on lateral side/but not on medial side	Talar head palpable on lateral side/slightly palpable on medial side	Talar head equally palpable on the lateral and medial side	Talar head slightly palpable on lateral side/palpable on medial side	Talar head not palpable on lateral side/but palpable on medial side
Supra and infra lateral malleollar curvature				
–2	–1	0	1	2
Curve below the malleolus either straight or convex	Curve below the malleolus concave, but flatter/more shallow than the curve above the malleolus	Both infra and supra malleolar curves roughly equal	Curve below malleolus more concave than curve above malleolus	Curve below malleolus markedly more concave than curve above malleolus
Calcaneal frontal plane position				
–2	–1	0	1	2
More than an estimated 5 degrees inverted (varus)	Between vertical and an estimated 5 degrees inverted (varus)	Vertical	Between vertical and an estimated 5 degrees everted (valgus)	More than an estimated 5 degrees either (valgus)
Prominence in the region of the talonavicular joint				
–2	–1	0	1	2
Area of the talonavicular joint is markedly concave	Area of the talonavicular joint slightly, but definitely concave	Area of the talonavicular joint is flat	Area of the talonavicular joint is bulging slightly	Area of the talonavicular joint is bulging markedly
Congruence of the medial longitudinal arch				
–2	–1	0	1	2
Arch high and acutely angled toward the posterior end of the medial arch	Arch moderately high and slightly acute posteriorly	Arch height normal and concentrically curved	Arch is lowered with some flattening in the central portion	Arch very low with severe flattening in the central portion—arch making ground contact
Abduction/adduction of the forefoot on the rear foot				
–2	–1	0	1	2
No lateral toes visible. Medial toes clearly visible	Medial toes clearly more visible than lateral	Medial and lateral toes equally visible	Lateral toes clearly more visible than medial	No medial toes visible. Lateral toes clearly visible

to extend without pain, can be determined by assessing the ROM available at the first MTP joint, while the first ray is prevented from plantarflexing. The patient is positioned in standing, the feet shoulder-width apart. The patient is asked to actively raise the great toe off the floor while keeping the remaining toes and foot on the ground. The amount of hallux extension is measured; less than 10 degrees is considered limited.[197] This test has been found to have a sensitivity of 0.72 and a specificity of 0.66.[197]

- The leg, foot, and ankle are examined for the presence of bruising, swelling, or unusual angulation. Ecchymosis may be present, but the blood usually settles along the medial or lateral aspects of the heel.[19,167] The appearance of bluish-black plaques on the posterior and posterolateral aspect of one or both heels in a young distance runner is found in a condition called black-dot heel, which results from a shearing stress or a pinching of the heel between the counter and the sole of the shoe at initial contact during running.

Extracellular fluid pools on the posterior aspect of the foot and around the malleoli after injury or surgery.[179] Shortly after a lateral ligament sprain, the swelling is limited to the lateral ankle. Subsequently, the swelling is diffuse, and the localization of tenderness may be difficult. An objective measure of the amount of swelling present can be made using the figure-of-eight method (see "Special Tests" section).

- Callus formation. Calluses provide the clinician with an index as to the degree of shear stresses applied to the foot and clearly outline abnormal weight-bearing areas.[198] In adequate amounts calluses provide protection, but in excess they may cause pain. Callus formation under the second and third metatarsal heads could indicate excessive pronation in a flexible foot, or Morton's (interdigital) neuroma (see Chapter 5) if under the second through fourth. A callus under the fifth and sometimes the fourth metatarsal head may indicate an abnormally rigid foot.
- Any evidence of circulatory impairment or vasomotor changes. Brick-red coloring or cyanosis, when the leg is dependent, is an indication of vascular impairment, especially if the color changes when the leg is elevated. Vasomotor changes include toenail changes, changes in skin texture, abnormal skin moisture or dryness, and loss of hair on the foot. Vasomotor changes may be associated with complex regional pain syndrome (see Chapter 5).
- The type of shoes. High-heeled shoes have been associated with adaptive shortening of the gastrocnemius–soleus complex, knee pain, and low-back pain.[58,199] They have also been associated with an increased potential for ankle sprains, hallux valgus, bunions, metatarsalgia, interdigital neuromas, peripheral nerve compression, and stress fractures.[58,199] Shoes with a negative heel may result in hyperextension of the knees.
- The weight-bearing and wear patterns of the shoe. The greatest amount of wear on the sole of the shoe should occur beneath the ball of the foot, in the area corresponding to the first, second, and third MTP joints and slight wear to the lateral side of the heel. Old running shoes belonging to patients who excessively pronate tend to display overcompression of the medial arch of the midsole and extensive wear of the lateral regions of the heel counter and medial forefoot. The upper portion of the shoe should demonstrate a transverse crease at the level of the MTP joints. A stiff first MTP joint can produce a crease line that runs obliquely, from forward and medial to backward and lateral.[200] The cup at the rear of the shoe, which is formed by the heel counter, should be vertical and symmetrical with respect to the shoe and should be of a durable enough material to hold the heel in place.[201] A medial inclination of the cup, with bulging of the lateral lip of the counter, indicates a pronated foot.[200] A lateral bulge of the heel counter indicates a supinated foot. Scuffing of the shoe might indicate tibialis anterior weakness.[110] The shape of the last influences the amount of motion that the shoe permits.[202] As the degree of curvature in the last increases, more foot mobility is available.

The non–weight-bearing component of the examination is initiated by having the patient seated on the edge of the bed, feet dangling. The feet should adopt an inverted and plantarflexed position. A mobile or nonstructural flatfoot will take on a more normal configuration in nonweight bearing, whereas a fixed or structural flatfoot will maintain its planus state. By placing one hand on the patella and the other hand on the tips of the malleoli, the clinician should note approximately 20–30 degrees of external rotation of the ankle in relation to the knee.[187]

Palpation

Careful palpation should be performed on the leg, foot, and ankle to differentiate tenderness of specific ligaments and other structures. Areas of localized swelling and ecchymosis over the ligaments on the medial or lateral aspects of the foot and ankle should be noted (see "Assessing Ankle Girth" under "Special Tests" section). The clinician should also make temperature comparisons and corroborate the findings with palpation of pedal pulses. For example, a cold foot may be indicative of limited circulation especially in the presence of a diminished pedal pulse (see "Special Tests" section). Finally, the patient should assess sensitivity to light touch (see "Neurological Tests" section) to help rule out the presence of sensory polyneuropathy in individuals with diabetes mellitus, peripheral nerve entrapment, or spinal nerve root impingement.

CLINICAL PEARL

The Ottawa Ankle Rules [203] (see "Imaging Studies" section) are a set of clinical criteria based on palpation that can determine the need for foot and ankle radiographs.[1]

Posterior Aspect of Foot and Ankle

Achilles Tendon

The Achilles tendon is inspected for contour changes such as swelling, erythema, and thickening. Any gaps or nodules in the tendon and specific sites of pain should be carefully examined. Palpable gaps in the tendon accompanied by an inability to rise up on the toes could indicate a rupture of the tendon.

Calcaneus

At the distal end of the Achilles tendon is the calcaneal tuberosity. The posterior aspect of the calcaneus and surrounding soft tissue is palpated for evidence of exostosis ("pump bump" or Haglund's deformity) and associated swelling (retrocalcaneal bursitis). The inferior medial process of the calcaneus, just distal to the weight-bearing portion of the calcaneus, serves as the attachment of the plantar fascia and is often tender with plantar heel pain.

Anterior and Anteromedial Aspects of the Foot and Ankle

While reading the next section, the reader may find it helpful to remove a shoe and sock and self-palpate.

Great Toe and the Phalanges

Beginning medially, the clinician locates and palpates the great toe and its two phalanges. The first metatarsal bone is more proximal, the head of which should be palpated for tenderness on the lateral aspect (bunion) and inferior aspect (sesamoiditis).

Moving laterally from the phalanges of the great toe, the clinician palpates the phalanges and metatarsal heads of the other four toes.

Tenderness of the second metatarsal head could indicate the presence of Freiberg's disease, an osteochondritis of the second metatarsal head (see Chapter 5). A callus under the second and third metatarsal heads may indicate a fallen metatarsal arch. Palpable tenderness in the region of the third and fourth metatarsal heads could indicate a Morton's neuroma, especially if the characteristic sharp pain between the toes of this condition is relieved by walking barefoot. Tenderness on the lateral aspect of the fifth metatarsal head could indicate the presence of a tailor's bunion.

Cuneiform

The first cuneiform is located at the proximal end of the first metatarsal (see Fig. 21-1) and is palpated for tenderness.

Navicular

The navicular is the most prominent bone on the medial aspect of the foot. The navicular tuberosity can be located by moving proximally from the medial aspect of the first cuneiform (see Fig. 21-1). The talonavicular joint line lies directly proximal to the navicular tuberosity. In addition, the posterior tibialis, which can be made more prominent with resisted plantarflexion, adduction, and supination, can be used as a reference as it inserts on the plantar surface of the navicular (see later). Tenderness of the navicular could indicate the presence of a fracture or osteochondritis of the navicular (Köhler's disease).

Second and Third Cuneiforms

These two bones can be palpated by moving laterally from the first cuneiform (see Fig. 21-1). Tenderness of these bones may indicate a cuneiform fracture.

Posterior (Dorsal) Pedis Pulse

The pulse of the posterior (dorsal) pedis artery, a branch of the anterior tibial artery, can be palpated over the talus (Fig. 21-14), cuneiform bones, between the first and second cuneiforms or between the first and second metatarsal bones.

Medial Malleolus

The medial malleolus is palpated for swelling or tenderness. Moving proximally from the anterior aspect of the medial malleolus, the distal aspect of the tibia is palpated. Distal to that is the talus bone. Moving distal from the tibia, the clinician palpates the long extensor tendons, the tibialis anterior, and the superior and inferior extensor retinaculum. The tendon of the tibialis anterior is visible at the level of the medial cuneiform and the base of the first metatarsal bone, especially if the foot is positioned in dorsiflexion and supination.

FIGURE 21-14 Dorsal pedis pulse.

Talus

The talus can be located by moving from the distal aspect of the medial malleolus along a line joining the navicular tuberosity. It can be more easily located by everting and inverting the foot. Eversion causes the talar head to become more prominent while inversion causes the head to be less visible.

Sustentaculum Tali

Distal and inferior to the medial malleolus, a shelf-like bony prominence of the calcaneus, the sustentaculum tali, can be palpated. At the posterior aspect of the sustentaculum tali, the talocalcaneal joint line can be palpated.

Posterior Tibialis Tendon

This tendon is palpable at the level of the medial malleolus, especially with the foot held in plantarflexion and supination. Distal and medial to this tendon, the crossing of the FDL and flexor hallucis tendons can be felt.

Posterior Tibial Artery

The posterior tibial artery (Fig. 21-9) can be located posterior to the medial malleolus and anterior to the Achilles tendon.

Medial (Deltoid) Ligament of the Ankle

The medial (deltoid) ligament of the ankles is very difficult to differentiate, so they are usually palpated as a group on the medial aspect of the ankle (see Fig. 21-4).

Anterior and Anterolateral Aspects of the Foot and Ankle

Tibial Crest

The tibial crest is palpated for tenderness, which may indicate the presence of shin splints. Swelling in this area may indicate the presence of anterior compartment syndrome (see Chapter 5). The muscles of the lateral (peronei) and anterior compartments (tibialis anterior and the long extensors) are palpated here for swelling or tenderness. Swelling or tenderness of these structures usually indicates inflammation.

Lateral Malleolus

The lateral malleolus is located at the distal aspect of the fibula. Distal to the lateral malleolus is the calcaneus.

Fibularis (Peroneus) Longus

The tendon of the fibularis (peroneus) longus runs superficially behind the lateral malleolus. Resisted pronation and plantarflexion of the foot make the tendon more prominent.

Fibularis (Peroneus) Brevis

The origin for the fibularis (peroneus) brevis is more distal to the fibularis (peroneus) longus and lies deeper. It becomes superficial on the lateral aspect of the foot, at its insertion on the tuberosity of the fifth metatarsal.

Anterior Talofibular Ligament

The ATFL can be palpated two to three finger-breadths anteroinferior to the lateral malleolus (see Fig. 21-5). This is usually the area of most extreme tenderness following an inversion sprain. The anterior aspect of the distal tibiofibular syndesmosis may also be tender following this type of sprain.

Calcaneofibular Ligament

The CFL can be palpated one to two finger-breadths inferior to the lateral malleolus (see Fig. 21-5).[171]

Posterior Talofibular Ligament

The PTFL can be palpated posteroinferior to the posterior edge of the lateral malleolus (see Fig. 21-5).[171]

Sinus Tarsi

The sinus tarsi is visible as a concave space between the lateral tendon of the EDL muscle and the anterior aspect of the lateral malleolus. The origin of the EDB is at the level of this tunnel. Tenderness with palpation of the sinus tarsi is considered one hallmark clinical sign of subtalar joint inflammation.[1]

Cuboid

The cuboid bone can be palpated by moving distally approximately one finger-breadth from the sinus tarsi.

Active and Passive Range of Motion

ROM testing is divided into an active range of motion (AROM) and a passive range of motion (PROM) examination, with overpressure being superimposed at the end of the available range to assess the end-feel. AROM tests are used to assess the patient's willingness to move and the presence of movement restriction patterns such as a capsular or noncapsular pattern. The end-feel may provide the clinician with information as to the cause of a motion restriction. The normal ranges of motion and end-feels for the lower leg, ankle, and foot are outlined in Table 21-8. The open- and close-packed positions and capsular patterns for the ankle and foot are outlined in Table 21-1.

General AROM of the foot and ankle in the non–weight-bearing position is assessed first, with painful movements being performed last. The hip and knee joints may also be examined as appropriate. Weight-bearing tests are usually performed after the non–weight-bearing tests.

TABLE 21-8 Normal Ranges of Motion and End-Feels for the Lower Leg, Ankle, and Foot

Motion	Normal Range (Degrees)	End-Feel
Talocrural plantarflexion	50	Tissue stretch
Talocrural dorsiflexion	20	Tissue stretch
Supination	45–60	
Pronation	15–30	
Hindfoot inversion	20	Tissue stretch
Hindfoot eversion	10	Tissue stretch
Toe flexion	Great toe: MTP, 45; IP, 90 Lateral four toes: MTP, 40; PIP, 35; DIP, 60	Tissue stretch
Toe extension	Great toe: MTP, 70; IP, 0 Lateral four toes: MTP, 40; PIP, 0; DIP, 30	Tissue stretch

Data from Rasmussen O. Stability of the ankle joint. Acta Orthop Scand Suppl. 1985;211:56–78.; Seto JL, Brewster CE. Treatment approaches following foot and ankle injury. Clin Sports Med. 1985;13:295.

If the symptoms are experienced during the general tests, then passive, active, and resisted tests of specific structures must be performed. If the general tests are negative, there is probably no immediate need to proceed with a more detailed examination, although this may have to be done if no other region appears to be the cause of the problem.

Although specific motions at the distal tibiofibular joint cannot be produced voluntarily, the function of this joint can be assessed indirectly by asking the patient to twist around both feet in each direction while bearing weight.

The reliability of foot and ankle measurements has been reported.[204–208] The interrater reliability of non–weight-bearing measurements is as follows[1]:

- Ankle dorsiflexion ROM is between ICC = 0.00 to 0.87, Non–weight-bearing ankle plantarflexion is ICC = 0.74
- Transverse tarsal inversion ranged between ICC = 0.302 to 0.88
- Transverse tarsal eversion ranged between ICC = 0.222 to 0.79
- First MTP joint dorsiflexion is between ICC = 0.04 to 0.16
- First MTP joint plantarflexion is between ICC = 0.07 to 0.21.

The intrarater reliability of non–weight-bearing ankle dorsiflexion measurement is estimated to be good (ICC = 0.74).[209]

Dorsiflexion

The patient lies in the supine position, with the knee slightly flexed and supported by a pillow, while the clinician stands at the foot at the table, facing the patient VIDEO

FIGURE 21-15 Ankle dorsiflexion.

Active dorsiflexion is initially performed with the knee flexed (Fig. 21-15). Care must be taken to prevent pronation at the subtalar and oblique transverse tarsal joint complex during dorsiflexion. The foot is slightly inverted to lock the longitudinal arch.[187] Passive overpressure is applied. With the knee flexed to approximately 90 degrees, the length of the soleus muscle is examined. Passive overpressure into dorsiflexion, when the knee is flexed, assesses the joint motion, as well as the soleus length. The soleus is implicated if the pain is produced in this test, especially if resisted plantarflexion is painful or more painful with the knee flexed than with the knee extended. With the knee flexed, 20 degrees of dorsiflexion past the anatomic position (the foot at 90 degrees to the bones of the leg) is found in the normally flexible person.[210] The flexibility of the soleus muscle may also be assessed in standing in able-bodied individuals by asking the patient to perform a deep squat or a lunge.

- Squat. If the muscle length is normal, the patient should be able to place the whole foot on the floor, including the heel, while in the full squat position (Fig. 21-16). If the soleus is short, the heel will not touch the floor.
- Lunge. A standard goniometer is aligned along the lateral aspect of the leg and the floor. The subject steadies themselves and then performs a weight-bearing lunge maneuver (Fig. 21-17). The angle recorded on the goniometer indicates the range of dorsiflexion under load. If the goniometer is set so that vertical is zero, the arm of the goniometer always aligns to the vertical and the scale rotates to indicate the inclination from the vertical. This angle is then recorded as the ankle dorsiflexion range. This method is considered the most appropriate method of measuring ankle dorsiflexion range, as it reflects the functionally available range for the individual. Bennell et al.[211] evaluated the inter- and intrarater reliability of a weight-bearing dorsiflexion lunge using a gravity goniometer in 13 healthy subjects. Two methods were used to assess the dorsiflexion lunge: (1) the distance from the great toe to the wall and (2) the angle between the tibial shaft and the vertical using an inclinometer. The average of three trials was used in data analysis. Intrarater ICCs ranged from 0.97 to 0.98. Interrater ICC values were 0.97 (angle) and 0.99 (distance), indicating excellent reliability for both methods of assessing a DF lunge.[211]

FIGURE 21-16 Ankle dorsiflexion during a squat.

FIGURE 21-17 Ankle dorsiflexion during lunge with a goniometer.

CLINICAL PEARL

Chronic adaptive shortening of the soleus muscle can be caused by excessive running, a weak posterior tibialis, or a weak quadriceps. Adaptive shortening of the soleus can result in forefoot pronation and a valgus stress at the knee.

To assess the length of the gastrocnemius, the patient is placed in the supine position with the knee extended, and the ankle positioned in subtalar neutral. The patient is then asked to dorsiflex the ankle (Fig. 21-18). Passive overpressure into dorsiflexion is applied. The normal range is 20 degrees. If the gastrocnemius is shortened, dorsiflexion of the ankle will be reduced as the knee is extended and increased as the knee is flexed. A muscular end-feel should be felt with the knee extended, and a capsular end-feel should be felt with the knee flexed.

FIGURE 21-18 Active ankle dorsiflexion (knee extended).

CLINICAL PEARL

Limited dorsiflexion with knee extension, combined with hindfoot valgus, is thought to be a sign of tight plantarflexors, particularly the gastrocnemius muscle.[26] A decrease in the flexibility of the gastrocnemius can result from a number of dysfunctions, including dysfunction of the subtalar joint or transtarsal joint, an ankle sprain, high-heeled footwear, or poor gait/running mechanics.

Plantarflexion

The patient is placed in the supine position, while the clinician stands at the foot of the table, facing the patient VIDEO. The patient is asked to plantarflex the ankle (Fig. 21-19). Plantarflexion of the ankle is approximately 30–50 degrees.[128] When tested in weight bearing with the unilateral heel raise, heel inversion should be seen to occur. Failure of the foot to invert may indicate instability of the foot/ankle, posterior tibialis dysfunction (see "Strength Testing" section), or adaptive shortening.[212] It is worth noting that both the forefoot and hindfoot work together to achieve heel height. Houck et al.[213] reported that the hindfoot and first metatarsal both plantarflexed over 20 degrees to achieve a maximum heel height.

FIGURE 21-19 Ankle plantarflexion.

CLINICAL PEARL

The moment arms of the lateral and medial gastrocnemius muscles can vary depending on the degree of inversion or eversion. Studies have demonstrated that when the foot was positioned in 15 degrees of eversion, both the lateral and medial gastrocnemius muscles had moments toward eversion. However, when the foot was positioned in neutral or in inversion, the lateral and medial gastrocnemius muscles had moment arms toward inversion.[77,214] This would tend to suggest that the gastrocnemius and soleus muscles may play a role in frontal plane actions at the subtalar joint when the foot is either supinated or pronated.[26] For example, when the hindfoot is everted (as found in flatfoot deformity), the triceps surae may contribute to eversion, whereas when the hindfoot is in supination (as found in the late-stance phase of gait), the triceps surae muscles may contribute to inversion.[26]

Hindfoot Inversion (Supination) and Hindfoot Eversion (Pronation)

Both hindfoot inversion (Fig. 21-20) and hindfoot eversion (Fig. 21-21) are tested by lining up the longitudinal axis of the leg and vertical axis of the calcaneus. Passive motion of hindfoot inversion (supination) is normally 20 degrees.[190] The amount of hindfoot eversion (pronation) is normally 10 degrees.[190]

Great Toe Motion

The patient is positioned in supine, with the leg being supported by a pillow, while the clinician stands at the foot at the

FIGURE 21-20 Ankle inversion.

FIGURE 21-21 Ankle eversion.

table, facing the patient. Active extension of the great toe is performed and assisted passively without dorsiflexing the first ray. The amount of posterior (dorsal) mobility is usually classified as normal, hypomobile, or hypermobile. Although this method of assessment is common, its reliability and validity have been shown to be poor.[166] Extension of the great toe occurs primarily at the MTP joint. Passive extension of the great toe at the MTP joint should demonstrate elevation of the medial longitudinal arch (windlass effect), and external rotation of the tibia.[215] Passive MTP joint extension of between 55 and 90 degrees is necessary at the terminal stance,[216] depending on length of stride, shoe flexibility, and toe-in/toe-out foot placement angle.[183] Forty-five degrees of first MTP flexion and 90 degrees of IP joint flexion are considered normal.[187]

Strength Testing

Ankle

Gastrocnemius and Plantaris Muscles. Plantarflexion strength can be tested initially in nonweight bearing (Fig. 21-22). However, unless there is significant weakness clinician strength is usually insufficient to overcome ankle plantarflexor force, which necessitates a weight-bearing assessment of ankle plantarflexor strength. If no plantarflexion weakness is apparent in nonweight bearing, a heel-raise test is performed in the functional position, standing with the knee extended and the opposite foot off the floor VIDEO. Technically, one heel raise through full ROM, while standing with support on one leg, scores a 3/5 (fair) with manual muscle testing, with five single-limb heel raises scoring a 4/5 (good) and 10 single-limb heel raises scoring a 5/5 (normal). From a functional viewpoint, a wider range of scoring can sometimes prove more useful. Table 21-9 outlines an alternative scoring method. An alternative test, which is frequently used to assess talocrural and overall ankle function and is often prescribed an exercise, is the heel rise task. The task is performed using a block or a step, and the patient is positioned in standing with the balls of both feet on the block/step edge and the remaining parts of the feet over the edge. The patient may use a solid object for balance only. The patient is then asked to rise and lower his or herself on the balls of their feet as far as possible in each direction. The test can be also applied having the patient stand on only one leg. It is interesting to note that one study[217] that measured both the ankle plantarflexion angle and the ankle dorsiflexion angle during this task found that the angles achieved were 23.7 degrees and 30.4 degrees, respectively. The apparently large dorsiflexion angle compared to what is typically measured using a goniometer is likely the result that the motion combines both talocrural movement and forefoot movement.[26] Although the task of raising up on the toes is generally thought to be predominantly performed by the triceps surae, a study by Kulig et al.[218] reported significant contributions of the fibularis muscles and tibialis posterior during this task.

FIGURE 21-22 Manual muscle testing of the plantarflexors.

Soleus Muscle. The soleus muscle produces plantarflexion of the ankle joint, regardless of the position of the knee. To determine the individual functioning of the soleus as a plantarflexor, the knee is flexed to minimize the effect of the gastrocnemius muscle. The soleus is tested in a similar manner to that of the gastrocnemius, except that the patient performs the unilateral heel raise with some degree of knee flexion. Ability to perform 10–15 raises in this fashion is considered normal, 5–9 raises graded as fair, 1–4 raises graded as poor, and zero repetitions graded as nonfunctional. Alternatively, the strength of the soleus can be tested with the patient in prone VIDEO.

Tibialis Anterior Muscle. The tibialis anterior muscle produces the motion of dorsiflexion and inversion. The knee must remain flexed during the test to allow complete dorsiflexion. The patient's foot is positioned in dorsiflexion and inversion. The leg is stabilized, and resistance is applied to the medial posterior aspect of the forefoot into plantarflexion and eversion (Fig. 21-23) VIDEO.

Tibialis Posterior Muscle. The tibialis posterior muscle produces the motion of inversion in a plantarflexed position. The leg is stabilized in the anatomic position, with the ankle in slight plantarflexion. The plantarflexion is important to minimize the influence of the tibialis anterior muscle.[219] Resistance is applied to the medial border of the forefoot into eversion and dorsiflexion (Fig. 21-24) VIDEO. The standing heel-raise test can also be used to detect tibialis posterior weakness. It is thought that during a standing heel rise that the tibialis posterior and fibularis muscles co-contract to control hindfoot position. Thus, when the hindfoot everts during

TABLE 21-9 Functional Testing of the Foot and Ankle

Starting Position	Action	Functional Test
Standing on one leg	Lift toes and forefeet off ground (dorsiflexion)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetition: nonfunctional
Standing on one leg	Lift heels off ground (plantarflexion)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetition: nonfunctional
Standing on one leg	Lift lateral aspect of foot off ground (ankle eversion)	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor 0 repetition: nonfunctional
Standing on one leg	Lift medial aspect of foot off ground (ankle inversion)	5–6 repetitions: functional 3–4 repetitions: functionally fair 1–2 repetitions: functionally poor 0 repetitions: nonfunctional
Seated	Pull small towel up under the toes or pick up and release small object (i.e., pencil, marble, cotton ball) (toe flexion)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetitions: nonfunctional
Seated	Lift toes off ground (toe extension)	10–15 repetitions: functional 5–9 repetitions: functionally fair 1–4 repetitions: functionally poor 0 repetitions: nonfunctional

Data from Palmer ML, Epler M. Clinical Assessment Procedures in Physical Therapy. Philadelphia, PA: JB Lippincott; 1990.

the heel-rise task, this is seen as a clinical sign of tibialis posterior weakness.

Fibularis (Peroneus) Longus, Fibularis (Peroneus) Brevis, and Fibularis (Peroneus) Tertius Muscles. VIDEO The lateral compartment muscles and the fibularis (peroneus) tertius muscle VIDEO produce the motion of eversion. The patient is positioned in supine, with the foot over the edge of the table and the ankle in the anatomic position. Resistance is applied to the lateral border of the forefoot (Fig. 21-25).

Digits. Grades for the toes differ from the standard format because gravity is not considered a factor.

0: No contraction.

Trace or 1: Muscle contraction is palpated, but no movement occurs.

Poor or 2: Subject can partially complete the ROM.

Fair or 3: Subject can complete the test range.

Good or 4: Subject can complete the test range but is able to take less resistance on the test side than on the opposite side.

FIGURE 21-23 Manual muscle testing of the tibialis anterior.

FIGURE 21-24 Manual muscle testing of the tibialis posterior.

FIGURE 21-25 Manual muscle testing of the fibularis (peroneus) muscle group.

N or 5: Subject can complete the test range and take maximal resistance on the test side as compared with the normal side.

Flexor Hallucis Brevis and Longus Muscles. The FHB VIDEO and FHL muscles VIDEO produce MTP joint flexion and IP joint flexion. The foot is maintained in midposition. The first metatarsal is stabilized, and resistance is applied beneath the proximal and distal phalanx of the great toe into toe extension.

Flexor Digitorum Brevis and Longus Muscles. The FDL and brevis muscles produce IP joint flexion. The motion is tested with the foot in the anatomic position. If the gastrocnemius muscle is shortened, preventing the ankle from assuming the anatomic position, the knee is flexed. The toes may be tested simultaneously.

The foot is held in the midposition, and the metatarsals are stabilized. Resistance is applied beneath the distal and proximal phalanges VIDEO.

Extensor Hallucis Longus and Brevis Muscles. VIDEO The EHL and the EHB muscles produce the motion of extension of the IP and MTP joints. The foot is maintained in midposition. Resistance is applied to the posterior aspect of both phalanges of the first digit into toe flexion.

Extensor Digitorum Longus and Brevis Muscles. The EDL and the EDB muscles produce the motion of extension at the MTP and IP joints of the lateral four digits from a flexed position VIDEO. Resistance is applied to the posterior (dorsal) surface of the proximal and distal phalanges into toe flexion.

Intrinsic Muscles of the Foot. The intrinsic muscles of the foot are tested with the patient in either the supine or the sitting position. Most subjects are unable to voluntarily contract the intrinsic muscles of the foot individually.

Abductor Hallucis Muscle. The metatarsals are stabilized, and resistance is applied medially to the distal end of the first phalanx VIDEO.

Adductor Hallucis Muscle. The metatarsals are stabilized, and resistance is applied to the lateral side of the proximal phalanx of the first digit VIDEO.

Lumbrical Muscles. The lateral four metatarsals are stabilized, and resistance is applied to the middle and distal phalanges of the lateral four digits.

Plantar Interossei Muscles. The lateral three metatarsals are stabilized, and resistance is applied to the middle and distal phalanges.

Posterior (Dorsal) Interossei and Abductor Digiti Minimi Muscles. The metatarsals are stabilized, and resistance is applied:

- Posterior (Dorsal) interossei. Applied to the middle and distal phalanges.
- Abductor digiti minimi. Applied to the lateral side of the proximal phalanx of the fifth digit.

Functional Tests

Self-Report Measures

The Ankle Joint Functional Assessment Tool. The Ankle Joint Functional Assessment Tool (AJFAT)[220] is composed of 12 questions rating the ankle's functional ability (Table 21-10). The AJFAT questions are based on assessment tools previously used for evaluating the functional level of the knee.[221–223]

The Foot Function Index. The Foot Function Index (FFI)[224] is a functional outcome measure that consists of three subsections: pain, disability, and activity. A study by Budiman-Mak et al.[224] examined test–retest reliability (ICC = 0.87), internal consistency (0.96), and construct and criterion validity of the questionnaire.

Olerud–Molander Ankle Score. Introduced in 1984, the Olerud–Molander Ankle Score continues to be widely used as a patient-reported outcome among people with ankle fractures.[225] The assessment includes nine parameters: walking, stiffness, swelling, stairclimbing, running, jumping, squatting, physical supports, and work capacity. Although this scale is quite practical, it has been criticized for lacking a methodologically robust content foundation and focusing solely on physical symptoms and performance.[226]

Ankle Fracture Outcome of Rehabilitation Measure (A-FORM). This measure, intended to address a notable gap in the patient-reported outcome measures currently available, was developed as a condition-specific, patient-reported outcome measure that reported life impacts following ankle fractures.[227] The framework assesses eight life impacts: physical, psychological, daily living, social, occupational or domestic, financial, anesthetic, and medication taking.

Foot and Ankle Ability Measure. The Foot and Ankle Ability Measure (FAAM) is a region-specific instrument designed to assess activity limitations and participation restrictions for individuals with general musculoskeletal foot and ankle disorders, including those who have sustained an ankle sprain.[228] The FAAM consists of the 21-item activities of daily living (ADLs) subscale and separately scores the 8-item sports subscale. The FAAM has been found to have strong evidence for content validity, construct validity, test–retest reliability, and responsiveness for general musculoskeletal foot and ankle disorders.[229]

Foot and Ankle Disability Index.[230] This questionnaire, which is a former version of the Foot and Ankle Disability Index (FAAM), is identical to the FAAM with the exception of an additional five items, four of which assess pain, with the other questioning an individual's ability to sleep. These five

TABLE 21-10 Ankle Joint Functional Assessment Tool (AJFAT)

1. How would you describe the level of pain you experience in your ankle?
   _____(0) Much more than the other ankle
   _____(1) Slightly more than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly less than the other ankle
   _____(4) Much less than the other ankle
2. How would you describe any swelling of your ankle?
   _____(0) Much more than the other ankle
   _____(1) Slightly more than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly less than the other ankle
   _____(4) Much less than the other ankle
3. How would you describe the ability of your ankle when walking on uneven surfaces?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in ability to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
4. How would you describe the overall feeling of stability of your ankle?
   _____(0) Much less stable than the other ankle
   _____(1) Slightly less stable than the other ankle
   _____(2) Equal in stability to the other ankle
   _____(3) Slightly more stable than the other ankle
   _____(4) Much more stable than the other ankle
5. How would you describe the overall feeling of strength of your ankle?
   _____(0) Much less strong than the other ankle
   _____(1) Slightly less strong than the other ankle
   _____(2) Equal in strength to the other ankle
   _____(3) Slightly stronger than the other ankle
   _____(4) Much stronger than the other ankle
6. How would you describe your ankle's ability when you descend stairs?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
7. How would you describe your ankle's ability when you jog?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
8. How would you describe your ankle's ability to "cut," or change direction, when running?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
9. How would you describe the overall activity level of your ankle?
   _____(0) Much less than the other ankle
   _____(1) Slightly less than the other ankle
   _____(2) Equal in amount to the other ankle
   _____(3) Slightly more than the other ankle
   _____(4) Much more than the other ankle
10. Which statement best describes your ability to sense your ankle beginning to "roll over"?
    _____(0) Much later than the other ankle
    _____(1) Slightly later than the other ankle
    _____(2) At the same time as the other ankle
    _____(3) Slightly sooner than the other ankle
    _____(4) Much sooner than the other ankle
11. Compared with the other ankle, which statement best describes your ability to respond to your ankle beginning to "roll over"?
    _____(0) Much later than the other ankle
    _____(1) Slightly later than the other ankle
    _____(2) At the same time as the other ankle
    _____(3) Slightly sooner than the other ankle
    _____(4) Much sooner than the other ankle
12. Following a typical incident of your ankle "rolling," which statement best describes the time required to return to activity?
    _____(0) More than 2 days
    _____(1) 1–2 days
    _____(2) More than 1 hour and less than 1 day
    _____(3) 15 minutes to 1 hour
    _____(4) Almost immediately

Data from Rozzi SL, Lephart SM, Sterner R, et al. Balance training for persons with functionally unstable ankles. J Orthop Sports Phys Ther. 1999;29:478–486.

items were subsequently removed after factor analysis and item response theory analysis,[229] and is now comprised of the 26-item ADL and 8-item sports subscales.[1]

Physical Performance Tests

Weight-Bearing Tests

In weight bearing, with the feet fixed, the patient should be asked to perform the following while the clinician notes any reproduction of pain or abnormal motion:

- Range of motion. Ankle dorsiflexion is necessary for normal gait, climbing stairs and rising from a squatting position. The dorsiflexion lunge test can be used to assess functional dorsiflexion. This weight-bearing test is performed by placing the foot perpendicular to a wall and lunging the knee toward the wall. The heel should not be lifted off from the floor, and the subtalar joint should be locked. The foot is sequentially moved further away from the wall until the maximum range of dorsiflexion is achieved. The distance from the foot to the wall is measured; less than 9–10 cm is considered restricted.[211] The angle of the tibial shaft in reference to the wall is also measured; less than 35–38 degrees is restricted.[211]

- Single-leg stance. Chronic ankle instability is a frequent consequence after lateral ankle sprain. The inability to maintain quiet stance during single standing has consistently been shown to be associated with ankle instability.[231]
- Gait assessment. An observational movement analysis of gait (see Chapter 6) can provide the clinician with information about the movement strategy used to complete a weight-bearing task. Typically, the gait analysis is first performed grossly before being followed by a joint by joint review during each phase of the gait cycle.
- Weight bearing on the foot borders. The patient is asked to bear weight on the medial borders of the feet while keeping the knees extended. The patient is then asked to bear weight on the lateral borders of the feet while maintaining the knee extension.
- Heel raising. In addition to being a general screening test, heel raising also assesses the ability of the medial arch to increase and produce a supinated/inverted arch. Under normal conditions, the tibialis posterior tendon inverts the hindfoot as the patient raises their heel. With poor or absent tibialis posterior function, the patient just rolls on the outside of the foot and demonstrates a decreased ability to unilaterally raise the heel.
- Twisting of the lower leg. Twisting tests the ability of the foot to supinate on the ipsilateral side, and its ability to pronate on the contralateral side.

The results of these tests may not be helpful in forming an actionable diagnosis, but they may be the only way to reproduce the patient's symptoms and will, therefore, be of use in determining the involved structure.

Running Tests

Return to activity tests for the running athlete can include any of the following:

- 40 m run time. The patient is asked to run 40 m in a straight line, and the run is timed.
- Figure-of-eight run. Two or more cones are set out at about 10–15 ft apart. The patient stands beside one of the cones to begin so that the distant cone is to the side of the patient. The patient is instructed to face the same direction throughout the exercise while running sideways from the near side of one cone to the far side of the other, looping around the cones as a figure-of-eight pattern. The patient should keep the hips slightly flexed, and move on the balls of the feet, as quickly as possible. After running the figure-of-eight pattern in one direction for at least 30 seconds, the patient then reverses the direction while still facing in the same direction.

Hopping Tests

For those athletes returning to activities that require such factors as multiple changes in directions, cutting, and jumping/landing, the following series of hopping tests can be used:

- Single-limb hop for distance (see Chapter 20).
- Triple hop (see Chapter 20).
- Crossover hop (see Chapter 20).
- Stair hop (see Chapter 20).
- Side-to-side hop (see Chapter 20).
- 6 m crossover hop. The test is performed as follows: the patient places his or her feet on one side of a white line or tape. A mark is made on the line/tape to indicate 6 m. The patient is asked to stand on one leg to the right of the line/tape. The patient is then asked to jump, on one leg, to the left side of the line/tape, back to the right, and then back to the left, attempting to propel himself or herself as far forward as possible with each hop until they 6 m mark is reached. The performance is timed.
- Square hop. A 2 × 2 foot square is marked out on the floor. Each of the four corners of the square is given a number from 1 to 4. The patient is asked to stand in the middle of the square on one leg and is then asked to jump to the corners of the square corresponding to the number sequence that the clinician calls out, returning to the center after each hop. For example, if the clinician calls out the sequence 1–3–2–4, the patient hops to corner number one, then hops back to the middle. The patient then hops to corner number three and back to the middle, and so on, ending with corner number four.

Star Excursion Balance Test

The star excursion balance test (SEBT) is a clinical test purported to detect functional performance deficits in unilateral balance and dynamic neuromuscular control associated with lower extremity pathology in otherwise healthy individuals.[231] The SEBT consists of a series of lower extremity reaching tasks in directions that challenge subjects' postural control, strength, ROM, and proprioceptive abilities. The farther a subject can reach with one leg while balancing on the opposite leg, the better the functional performance they are deemed to have. The subject stands barefoot at the center of the grid with eight lines extending in a star pattern at 45-degree increments from the center of the grid.[232] Subjects are asked to maintain a single-leg stance while reaching with the contralateral leg to touch as far as possible along the chosen line, and then to return to a bilateral stance while maintaining their equilibrium.[232] The test is then repeated using the other leg. The SEBT has excellent intraobserver reliability,[233] is sensitive to ankle instability,[234] and has been used as a predictive measure of lower extremity injury in high school basketball players.[235]

Agility T-Test

The qualities required for agility include physical demand, cognitive processing, and technical skill. The agility T-test measures movement in multiple directions as the individual navigates a T-shaped course, which consists of horizontal and longitudinal arms that are each 10 yards long (Fig. 21-26). The patient sprints from the base of the longitudinal arm to the center of the horizontal arm and then, facing forward, he or she sidesteps to one end of the horizontal arm without crossing feet, and then continues to the other end. To finish, he or she sidesteps back to the center of the horizontal arm and runs backward down the longitudinal limb to the

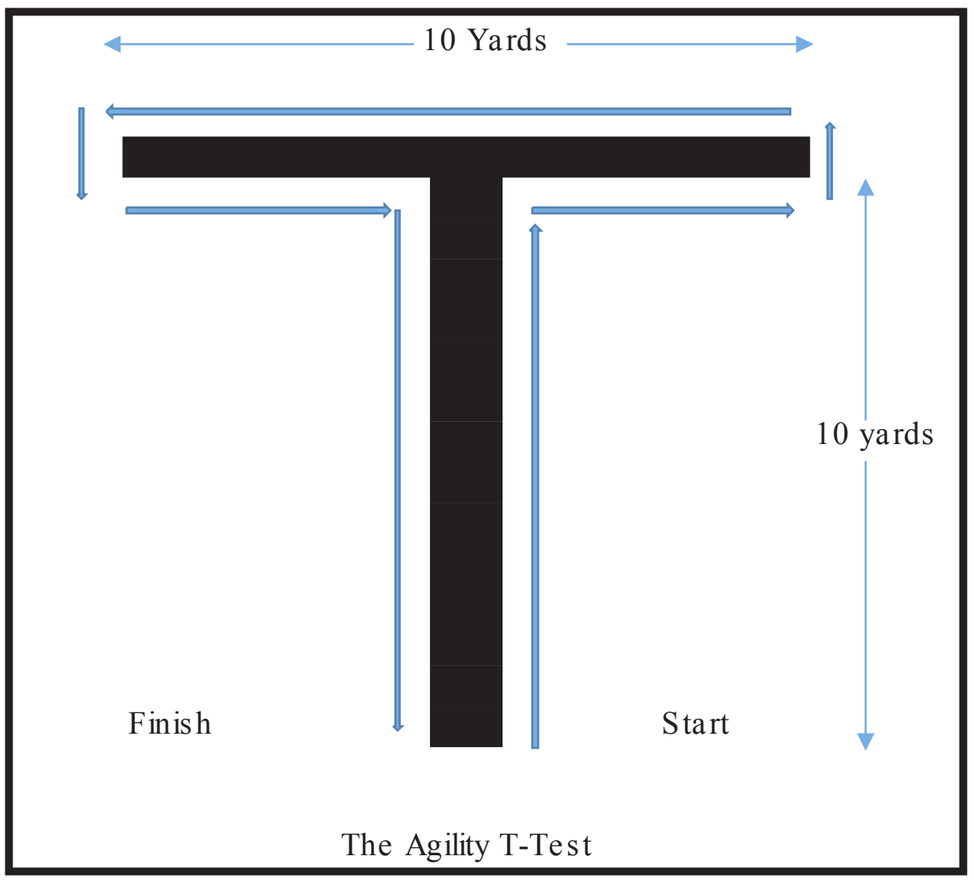

FIGURE 21-26 Agility T-test.

starting point (Fig. 21-26). Typical times for athletic adults are between 8.92 and 13.5 seconds.[236]

Sargent/Vertical Jump Test

The Sargent jump test[237] is designed to evaluate strength, speed, energy, and dexterity and to estimate power jumps. The individual squats and jumps upward into full extension, reaching with one hand for a cardboard disk above.[238] The distance jumped is calculated using the following equation:

Efficiency index = weight (lb) × jump (in)/height (in).

Functional Examination

Functional assessment of the ankle foot can be accomplished using gait analysis (see Chapter 6). Specifically related to the dysfunction of the ankle and foot are those listed in Table 21-11.

Passive Articular Mobility

Passive articular mobility tests assess the accessory motions available between the joint surfaces. These same techniques can be used to increase joint play using the varying grades of mobilization (see "Joint Mobilizations" under "Techniques to Increase Joint Mobility" section). As with any other joint complex, the quality and quantity of joint motion must be assessed to determine the level of joint involvement. The joint play movement tests must be performed on both sides so that comparisons can be made. The patient is positioned in lying.

Distal Tibiofibular Joint

During ankle dorsiflexion, the fibula is thought to glide superiorly at the proximal tibiofibular joint and the tibia and fibula are thought to glide superiorly and separate slightly at the distal tibiofibular joint, while the talus is thought to glide posteriorly under the tibiofibular mortise.[1] Although the glide at this joint would appear to be negligible, Mulligan has proposed that some ankle inversion injuries may be the result of a distal fibular positional fault. One study[239] examined the talar posterior glide of the ankles of 25 subjects for the amount of joint excursion. Of the 50 ankles, six had been diagnosed with an acute ankle sprain. Two ankles exhibited an increase in joint excursion, both of which had been sprained suggesting that in approximately one-third of diagnosed ankle sprains, the true cause might be an anterior positional fault of the talus. During ankle plantarflexion, the reverse occurs.

FIGURE 21-27 Mobility testing of the distal tibiofibular joint.

To perform the mobility tests of this joint, the patient is placed in supine, and the clinician grips the tibia and fibula using one hand for each (Fig. 21-27). While one hand prevents downward motion of the medial malleolus, the other hand glides the fibula anteriorly and posteriorly in relation to the tibia. To assess the motion of the tibial component, one hand stabilizes the fibula and lateral malleolus, while the other hand glides the tibia anteriorly and posteriorly in relation to the fibula. Theoretically, a superior and inferior glide can also be assessed at this joint, but it is unclear whether the information provided by such testing would help the clinician in making a diagnosis or designing a plan of care.

Long-Axis Distraction of Ankle and Foot

The clinician stabilizes the proximal segment and applies traction to the distal segment. This test is performed at the talocrural joint (Fig. 21-28), the subtalar joint (Fig. 21-29), the MTP joints (Fig. 21-30), and the IP joints (Fig. 21-31).

FIGURE 21-28 Long-axis distraction of talocrural joint.

TABLE 21-11 Potential Causes of Gait Dysfunction

Phase of Gait	Observed Dysfunction	Probable Cause(s)
Initial contact	Low heel/flatfoot/forefoot	Limited ankle dorsiflexion Short step length
Loading response	Rapid ankle plantarflexion	Limited ankle plantarflexion Ankle dorsiflexor muscle weakness Limited eccentric control of the knee extensors
	Excessive foot pronation	Excessive midfoot mobility Excessive hindfoot mobility Rigid pes planus deformity Limited eccentric control of the hip abductor and external rotator muscle groups
	Limited foot pronation	Limited midfoot mobility Limited hindfoot mobility Rigid pes cavus deformity
Mid stance	Limited tibial progression	Limited ankle dorsiflexion range of motion Limited eccentric control of the ankle plantarflexor muscles
	Limited foot pronation	Limited midfoot mobility Limited hindfoot mobility Rigid pes cavus deformity
	Excessive foot pronation	Excessive midfoot mobility Excessive hindfoot mobility Rigid pes planus deformity
Terminal stance	Limited trailing limb posture	Limited ankle dorsiflexion range of motion Limited eccentric control of the ankle plantarflexor muscles Limited knee extension range of motion Limited hip extension range of motion
Pre-swing	Limited ankle plantarflexion	Limited ankle plantarflexion range of motion Limited knee extension range of motion Limited knee flexion range of motion Limited hip extension range of motion
Initial swing	Limited foot clearance	Limited ankle dorsiflexion range of motion Concentric weakness of the ankle dorsiflexors Limited knee flexion range of motion

Data from Davenport TE. Examination of the foot and ankle. In: Hughes C. Independent Home Study Course 22.3.3: Foot and Ankle. La Crosse, WI: Orthopedic Section, APTA, 2014, pp. 1–54.

FIGURE 21-29 Long-axis distraction of subtalar joint.

FIGURE 21-30 Long-axis distraction of the MTP joint.

Anterior–Posterior Glide

To test the anterior glide of the talocrural joint, the clinician stabilizes the tibia and fibula and draws the talus and foot forward together (Fig. 21-32). Pushing the talus and foot together in a posterior direction on the tibia and fibula (Fig. 21-33) tests the posterior movement. The anterior glide of the talus assesses the joint's ability to move into plantarflexion, whereas the posterior glide of the talus assesses the joint's ability to move into dorsiflexion.

The anterior–posterior glides can also be applied to the midtarsal (Fig. 21-34), intertarsal (Figs. 21-35 and 21-36), MTP (Fig. 21-37), and IP (Fig. 21-38) joints.

FIGURE 21-31 Long-axis distraction of the IP joint.

FIGURE 21-32 Anterior glide of the talocrural joint.

FIGURE 21-33 Posterior glide of the talocrural joint.

Calcaneal Inversion–Eversion (Subtalar)

Subtalar joint motion is extremely important to normal foot function. A loss of eversion causes weight bearing to occur along the lateral side of the ankle joint. The patient lies in the prone position with the knee slightly flexed and supported

FIGURE 21-34 A-P glide of midtarsal joints.

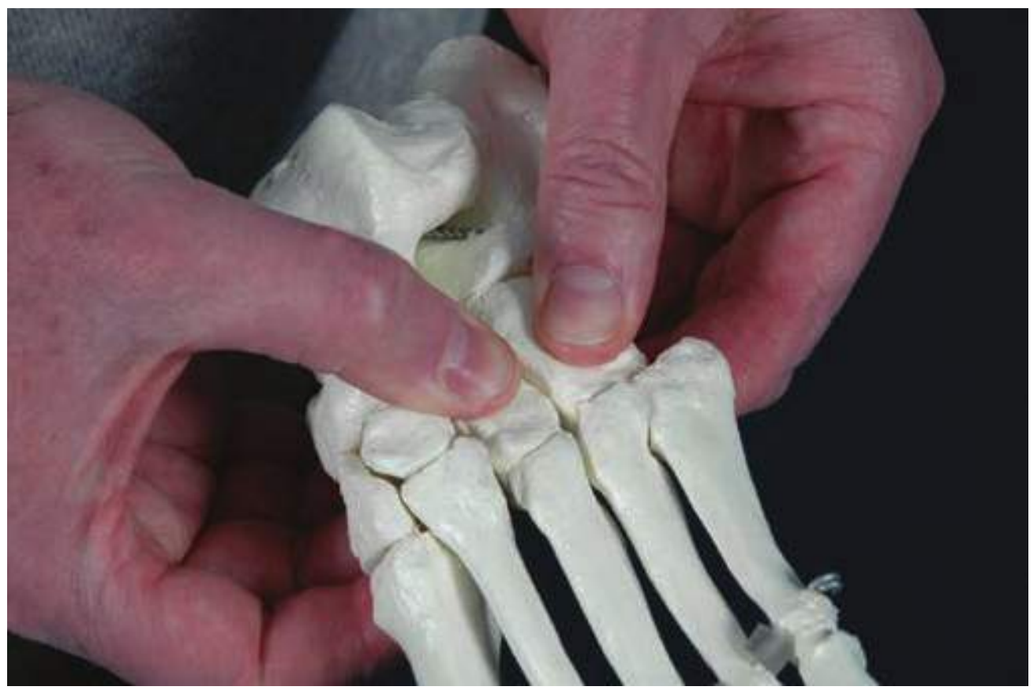

FIGURE 21-35 A-P glide of intertarsals.

FIGURE 21-36 A-P glide of intertarsals.

FIGURE 21-37 A-P glide of MTP.

by a pillow, while the clinician stands at the foot of the table, facing the patient. T e clinician grasps the calcaneus in one hand while the other hand locks the talus. T e calcaneus is passively inverted (varus) and everted (valgus) on the talus (Fig. 21-39). T e amount and quality of the motions as compared with the other foot are noted. Although some differences exist, generally calcaneal eversion will measure 5–10 degrees while calcaneal inversion will measure approximately 20–30 degrees.[24,128,187] A similar technique can be used to assess medial and lateral gapping at this joint. Medial gapping is associated with subtalar joint eversion, whereas lateral gapping is associated with subtalar joint inversion.

Transverse tarsal joint complex Motion

T e rotational movements of the transverse tarsal joint complex, which allow the forefoot to twist on the hindfoot, can be observed in the non–weight-bearing position. T e clinician stabilizes the calcaneus with one hand while inverting and everting the foot at the transverse tarsal joint complex with the other hand (Fig. 21-40).[115]

First MTP Joint (First Ray) Motion

T e patient lies in the supine position, with the clinician at the foot of the table facing away from the patient. T e clinician grasps and locks the first MTP joint, before grasping the great toe and moving it into extension and flexion (posteriorly [dorsally] and anteriorly [ventrally], respectively)

FIGURE 21-38 A-P glide of IP joints.

FIGURE 21-39 Calcaneal inversion and eversion.

(Fig. 21-41). Long-axis distraction and compression can also be applied (Fig. 21-42) to assess capsular and articular integrity, respectively.

T e limited range may result from a combination of biomechanical factors such as excessive pronation or joint glide restriction.[240] To examine the conjunct rotation of the metatarsals, the clinician locks the second metatarsal to evaluate the first and locks the third to evaluate the second. T e quantity and quality of motion are noted and compared with the other side.

FIGURE 21-40 Mobility testing midtarsal inversion/eversion.

FIGURE 21-41 First MTP motion.

Special Tests

Special tests are merely confirmatory tests and should not be used alone to form a diagnosis. Selection for their use is at the discretion of the clinician and is based on a complete patient history. The results of these tests are used in conjunction with the other clinical findings. To assure accuracy with these tests, both sides should be tested for comparison.

Assessing Ankle Girth

As many foot and ankle pathologies are associated with quantifiable edema that may be associated with disablement, physical therapists need a reliable method by which to measure ankle girth following injury so that there can be clinical quantification of the volume of edema. Two methods are described:

- Figure-*of*-eight tape method. The patient lies in the supine position or seated with the ankle to be measured in a neutral or comfortable position. The clinician places the zero endpoint of a tape measure midway between the tibialis anterior tendon and lateral malleolus. The tape is then drawn medially and is placed just distal to the navicular tuberosity. The tape is then pulled medially around the foot to then cross the plantar aspect (arch) toward the base of the fifth metatarsal. The tape is then pulled across the tibialis anterior tendon and around the ankle to a point just distal to the medial malleolus, before being finally pulled across the Achilles tendon and placed just distal to the lateral malleolus and across the start of the tape. It has been reported that the ankle figure-of-eight method (Fig. 21-43) demonstrates very high inter- and intrarated reliability (ICC = 0.98–0.99).[241–243]
- Volumetry method. This is a direct measure of the volume of the foot and ankle through measurement of displaced water. A volumeter, which is a clear acrylic box measuring 32.5 cm x 12.5 cm x 22.5 cm is filled with a known volume of water, and the patient's foot is placed into the volumeter with toe tips touching the front wall. As the patient's foot enters the box, water flows from the spout in the box into a graduated cylinder. The amount of water displaced is measured.

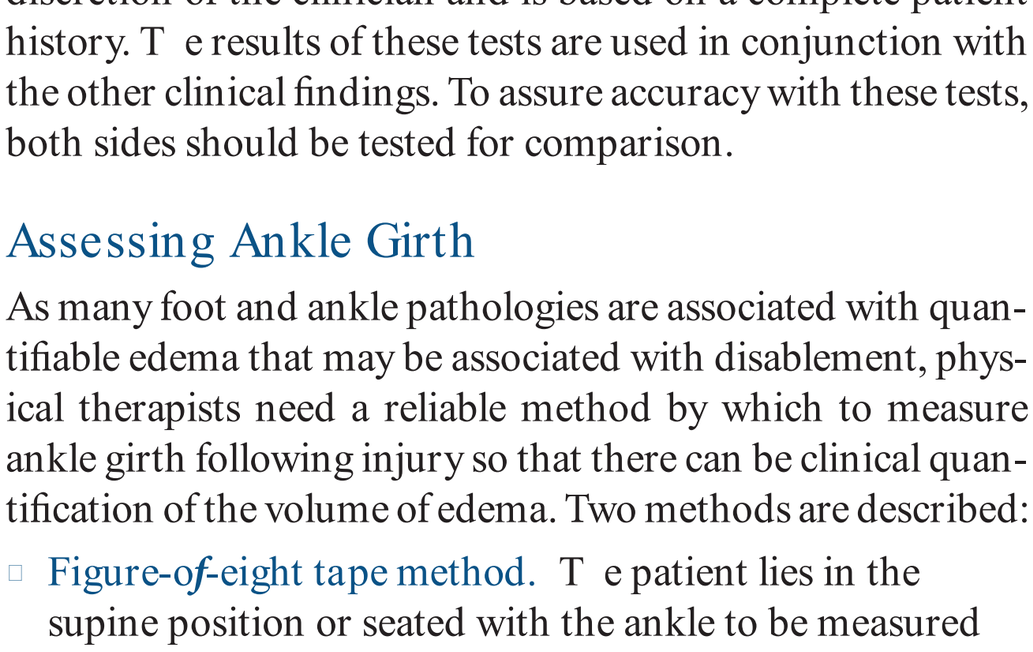

FIGURE 21-42 Long-axis distraction and compression at the first MTP joint.

FIGURE 21-43 Figure-of eight tape method.

Petersen et al.[241] performed a study to determine the inter- and intrarater reliability of water volumetry and the figure-of-eight method on subjects with ankle joint swelling and found high interrater reliability for both the water volumetry (ICC = 0.99) and the figure-of-eight methods (ICC = 0.98). In addition, intrarater reliability was high for both (ICCs = 0.98–0.99). The authors concluded that both methods are reliable measures of ankle swelling, although they recommended the figure-of-eight method because of its ease of use, time efficiency, and cost effectiveness. However, water volumetry may be more appropriate when measuring diffuse lower extremity swelling.

Ligamentous Stress Tests

The examination of the ligamentous structures in the ankle and foot is essential, not only because of their vast array but also because of the amount of stability that they provide. Positive results for the ligamentous stability tests include excessive movement, as compared with the same test on the uninvolved extremity, pain (depending on the severity), or apprehension.

Mortise/Syndesmosis

Cotton (Clunk) Test

The patient lies in the position with their foot over the end of the bed. One hand is used to stabilize the distal leg on the bed while the clinician uses the other hand to grasp the heel and move the calcaneus laterally (see Fig. 21-44).[244] A clunk can be felt as the talus hits the tibia and fibula if there has been significant mortise widening.[171] Beumer et al.[245] found this test to have a sensitivity of 46%.

FIGURE 21-44 Cotton (Clunk) test.

Kleiger (External Rotation) Test

The Kleiger (external rotation) test[21,181,246] is a general test to implicate the syndesmosis if pain is produced over the anterior or posterior tibiofibular ligaments and the interosseous membrane, but can also be used to assess the integrity of the medial (deltoid) ligament of the ankle complex.[247,248] If this test is positive, further testing is necessary to determine the source of the symptoms.

The patient sits with their legs dangling over the end of the bed; the knee flexed to approximately 90 degrees, and the foot relaxed. The clinician stabilizes the lower leg with one hand and, using the other hand, grasps the foot and externally rotates it (Fig. 21-45). Pain experienced at the anterolateral aspect of the distal tibiofibular syndesmosis is a positive sign for syndesmosis injury,[249] whereas pain on the medial aspect of the ankle and/or displacement of the talus from the medial

FIGURE 21-46 The point test.

malleolus (depending on severity) with the ankle positioned in plantarflexion may indicate a tear of the medial (deltoid) ligament of the ankle. Alonso et al.[249] reported data that indicate that the external rotation stress test is more reliable than the squeeze test and the dorsiflexion–compression test for diagnosing syndesmosis injuries.

The Point Test

The point test also referred to as the palpation test, is used to impose pressure on the anterior distal tibiofibular syndesmosis.[249,250] The patient can be positioned in supine or sitting. The clinician applies pressure directly to the anterior aspect of the distal tibiofibular syndesmosis (Fig. 21-46). Pressure is applied gradually, and a positive test involves a report of pain by the patient.

The Dorsiflexion Compression Maneuver

The dorsiflexion compression maneuver is performed to force the wider anterior portion of the talar dome into the ankle mortise, thereby inducing separation of the distal fibula and tibia.[250,251] The patient sits at the edge of the examination table, and the clinician stabilizes the patient's leg with one hand, while the clinician's other hand passively moves the foot into dorsiflexion (Fig. 21-47). Pain experienced at the distal tibiofibular syndesmosis is a positive test result. A variation of the dorsiflexion maneuver exists, known as the dorsiflexion compression test,[249] which involves patients moving their ankle joints into extreme dorsiflexion in bilateral weight bearing. Patients are asked to note the pain they experience

FIGURE 21-45 Kleiger (external rotation) test.

FIGURE 21-47 The dorsiflexion compression maneuver.

FIGURE 21-48 Fibula translation test.

in this position and the position of the tibia is noted with an inclinometer. The patient then assumes an upright position and the clinician applies medial–lateral compression with two hands on the malleoli of the injured leg. The clinician maintains the medial–lateral compression, as the patient is asked to move the ankle into dorsiflexion again and to report if the end-range pain has changed compared with the previous movement. A positive test result is either a reported reduction in the end-range pain or an increase in dorsiflexion ROM.

Fibula Translation Test

The patient is placed in the side-lying position with the tested leg uppermost. The clinician applies an anterior and posterior force on the fibula at the level of the syndesmosis (Fig. 21-48). A positive test is a pain during translation and more displacement of the fibula than the compared side. Although a cadaver study by Beumer et al.[245] found this test to have a sensitivity of 82% and specificity of 88% (LR+ 6.8; LR− 0.2), the study only found increased translation when all ligaments were removed in the cadavers.

The One-legged Hop Test

The one-legged hop test is performed by having the patient stand on the injured leg and hop continuously.[250] Nussbaum et al[252] reported that patients with syndesmosis injuries could not complete 10 repetitions of unilateral hopping without significant pain. However, the one-legged hop test should be used with caution, and perhaps only if the other special tests are negative because performing this test may impose further separation of the distal tibiofibular syndesmosis.[250]

The Crossed-Leg Test

The crossed-leg test mimics the squeeze test (see later) and attempts to induce separation of the distal syndesmosis.[250,253]

FIGURE 21-49 The crossed-leg test.

The patient sits in a chair, with the injured leg resting across the knee of the uninjured leg. The resting point should be at approximately mid-calf. The clinician then applies a gentle force on the medial aspect of the knee of the test leg (Fig. 21-49). Pain experienced in the area of the distal syndesmosis suggests the presence of injury. This test may not be useful for patients with knee or hip pathology because it may be difficult for them to assume the test position. Reliability and validity data for this test are not yet available.

The Heel-Thump Test

The heel-thump test is performed to force the talus into the mortise, in an attempt to impose a separation of the distal syndesmosis.[250,254] The patient lies at the edge of the examination table, with the ankle resting in plantarflexion. The clinician holds the patient's leg with one hand and with the other hand applies a gentle but firm thump on the heel with their fist (Fig. 21-50). This force is applied at the center of the heel and in line with the long axis of the tibia. Pain experienced at the distal tibiofibular syndesmosis suggests the presence of

FIGURE 21-50 The heel-thump test.

FIGURE 21-51 Posterior drawer test.

injury. Although the heel-thump test has been recommended to help differentiate between a syndesmotic sprain and a lateral ankle sprain, this test may not be specific for a syndesmotic sprain as the test has also been recommended to assess the possible presence of tibial stress fractures.[255] Reliability and validity data for this test are not yet available.

Posterior Drawer Test

The posterior drawer test can also be used to test for the presence of instability at the distal tibiofibular joint. The patient is supine. The hip and knee are flexed to provide as much dorsiflexion of the ankle as possible. This drives the wide anterior part of the talus back into the mortise. An anterior stabilizing force is then applied to the cruris, and the foot and talus are translated posteriorly (Fig. 21-51). If the distal tibiofibular joint is stable, there will be no drawer available, but if there is instability, there will be a drawer.

Squeeze Test

In the squeeze test, the patient lies in supine or side-lying position and the clinician squeezes over the syndesmosis using one hand (Fig. 21-52).[181] Pain felt in the distal third of the leg may indicate a compromised syndesmosis (high-ankle sprain), if the presence of a tibia and/or fibula fracture, calf contusion, or compartment syndrome (see Chapter 5) has been ruled out.[168,247]

FIGURE 21-52 Squeeze test.

FIGURE 21-53 Calcaneus tilt.

Lateral Collaterals

The lateral collateral ligaments of the ankle resist inversion. An additional function is to prevent excessive varus movement, especially during plantarflexion. In extreme plantarflexion, the mortise no longer stabilizes the broader anterior part of the talus, and varus movement of the ankle is then possible.

Calcaneus Tilt

The patient lies in the supine position. The lower leg is stabilized using a lumbrical grip while the other hand grasps the foot and calcaneus. The clinician applies a medially directed force in an attempt to adduct the calcaneus, thereby gapping the lateral side of the ankle (Fig. 21-53). Pain on the lateral aspect of the ankle with this test, and/or displacement (depending on severity) may indicate a sprain of the ligament. Hertel et al.[256] found this test to have a sensitivity of 78% and a specificity of 75% (LR+ 3.1; LR− 0.29).

Talar Tilt

This test is used to determine whether the CFL is torn. The patient lies in a supine or side-lying position with the foot relaxed and the knee flexed. The clinician places the foot in the anatomical (90 degrees) position to bring the CFL perpendicular to the long axis of the talar. The talus is then tilted from side to side into adduction and abduction (Fig. 21-54). Adduction tests the CFL and, to some degree, the ATFL, whereas abduction stresses the deltoid ligament. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

FIGURE 21-54 Talar tilt.

Anterior Drawer Test

The anterior drawer stress test is performed to estimate the stability of the ATFL. The test is performed with the patient seated at the end of the bed or lying supine with their knee flexed, to relax the gastrocnemius–soleus muscles, and the foot supported perpendicular to the leg.[257,258] The clinician uses one hand to stabilize the distal aspect of the leg, while the other hand grasps the patient's heel and positions the ankle in 10–20 degrees of plantarflexion (Fig. 21-55). Either the heel is very gently pulled forward, or the clinician can manually apply a posterior force on the tibia. The clinician attempts to visually and manually since the quantity of talar movement and to determine if an asymmetry exists between the involved in the uninvolved ankle. If the test is positive, the talus, and with it the foot, rotates anteriorly out of the ankle mortise around the intact medial (deltoid) ligament of the ankle, which serves as the center of rotation. Variances in hand position, joint congruency, forces imparted, the perception of movement, scoring methods, and tissue variability are factors that may affect the reliability of this test.[259] Tohyama et al.[260] reported that a relatively low anterior load (30 N) during this test was more sensitive than a higher load (60 N) in distinguishing a significant distance between injured to normal anterior displacement. This is seemingly occurs because a greater load would tend to elicit a protective muscle contraction that could mask the anterior talar displacement.

This test has limited reliability, particularly if it is negative or if it is performed without anesthesia in the presence of muscle guarding.[261] It has been reported that 4 mm of laxity in the ATFL, resulting from posttraumatic attenuation or fibrosis, will give a clinically apparent anterior drawer (2 mm is normal)—false-positive findings may be seen in up to 19% of uninjured ankles in those with ligamentous laxity.[262,263] As is often the case, when combining the results from several tests, diagnostic accuracy can be enhanced. For example, van Dijk et al.[264] reported that when the combination of pain on lateral ligament palpation, hematoma formation of the lateral ankle, and a positive anterior drawer test were used a lateral ligament lesion was correctly diagnosed in 95% of cases. A 2013 study by Croy et al.[262] reported similar conclusions.

The Dimple Sign

Another positive sign for a rupture of the ATFL, if pain and spasm are minimal, is the presence of a dimple located just in front of the tip of the lateral malleolus during the anterior drawer test.[265] This results from a negative pressure created by the forward movement of the talus, which draws the skin inward at the site of the ligament rupture.[264] This dimple is also seen with a combined rupture of the ATFL and CFLs.[265] However, the dimple is only present within the first 48 hours after injury, due to organized hematoma and repair tissue blocking the communication between the joint and subcutaneous tissues.[265]

Medial Collaterals (Deltoid Complex)

The medial collaterals function to resist eversion. Given their strength, these ligaments are usually only injured as the result of a major trauma.

Tendon Tests

Thompson Test for Achilles Tendon Rupture

In this test, the patient lies in the prone position or in kneeling with the feet over the edge of the bed (Fig. 21-56). With the patient relaxed, the clinician gently squeezes the calf muscle and observes for the production of plantarflexion. An

FIGURE 21-55 Anterior drawer test.

FIGURE 21-56 Patient position for the Thompson test.

FIGURE 21-57 Matles test for Achilles tendon rupture.

absence of plantarflexion indicates a complete rupture of the Achilles tendon.[266] T is test has been found to have surprisingly low sensitivity (40%).[266]

Matles Test for Achilles Tendon Rupture

T e patient lies in the prone position with the foot over the end of the table, and the clinician stands at the end of the table. T e patient is asked to actively flex the knee to 80–90 degrees while the position of the foot is observed throughout the motion (Fig. 21-57). If the foot falls into neutral or slight dorsiflexion, the test is positive for Achilles tendon rupture (in normal patients, the foot remains in plantarflexion). Maffulli[267] found this test to have a sensitivity of 0.88, a specificity of 0.85, and a positive predictive value of 0.92.

Articular Integrity Tests

Navicular Drop Test

T e navicular drop test is a method to assess the degree to which the talus plantarflexes in space on a calcaneus that has been stabilized by the ground, during subtalar joint pronation.[268,269]

T e clinician palpates the position of the navicular tubercle as the patient's foot is nonweight bearing but resting on the floor surface, with the subtalar joint maintained in neutral. T e clinician then attempts to quantify the amount of inferior displacement of the navicular tubercle, as the patient assumes 50% weight bearing on the tested foot (relaxed standing).[183] A navicular drop that is greater than 10 mm from the neutral position to the relaxed standing position suggests an excessive medial longitudinal arch collapse of abnormal pronation.[269,270]

FIGURE 21-58 Feiss line.

T is test has been found to have an intratester reliability that ranged from ICC = 0.61 to 0.79, and intertester reliability of ICC = 0.57.[183] However, it is questionable whether a significant drop is also indicative of dysfunction.

Feiss Line

T e Feiss line test is used to assess the height of the medial arch, using the navicular position.[271] With the patient nonweight bearing, the clinician marks the apex of the medial malleolus and the plantar aspect of the first MTP joint, and a line is drawn between the two points (Fig. 21-58). T e navicular is palpated on the medial aspect of the foot, and assessment is made of the position of the navicular relative to the imaginary line. T e patient is then asked to stand with their feet approximately 3–6 in apart. In weight bearing, the navicular normally lies on or very close to the line. If the navicular falls one-third of the distance to the floor, it represents a first-degree flatfoot; if it falls two-thirds of the distance, it represents a second-degree flatfoot; and if it rests on the floor, it represents a third-degree flatfoot. No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Longitudinal Arch Angle

T e longitudinal arch angle (LAA) can be used to classify and measure foot arch posture. One study,[272] using digital imaging, found that static measurements of the LAA strongly predicted dynamic foot arch postures at mid support in running and mid stance in walking. Another study[209] reported that measurement of the LAA with an 8-in goniometer was a highly reliable static measure, with an intrarater reliability of 0.90 and interrater reliability of 0.81. When using a goniometer, measurement landmarks for the LAA include the medial malleolus, navicular tuberosity, and medial aspect of the first metatarsal head. Typical arch posture is defined as having an LAA between 130 and 150 degrees, pes planus as having an arch posture of less than 130 degrees, and pes cavus as having an arch posture of greater than 150 degrees.[273]

Jack's Test

T is test is used to assess for the presence of hallux limitus/rigidus. T e patient is positioned in sitting. While stabilizing the heel with one hand, the clinician dorsiflexes the hallux

holding it at the IP joint. The clinician then measures the angle created between the hallux and the first metatarsal shaft on the medial aspect of the foot. Approximately 65 degrees of movement should be available. If the angle is between 15 and 40 degrees, hallux limitus is present. If the angle is less than 15 degrees, hallux rigidus should be suspected.

Vascular Status

Homans' Sign

This was the traditional test used to detect a deep vein thrombophlebitis (DVT). The patient lies in the supine position with their knee extended. The clinician stabilizes the thigh with one hand and passively dorsiflexes the patient's ankle with the other. Pain in the calf with this maneuver was considered a positive sign for DVT. However, a positive Homan's sign has been found to be insensitive, nonspecific, is present in fewer than 30% of documented cases of DVT,[274,285] and the performance of the test may increase the risk of producing a pulmonary embolism (PE).

Buerger's Test

The patient is placed in the supine position with the knee extended. The clinician elevates the patient's leg to approximately 45 degrees and maintains it there for at least 3 minutes. Blanching of the foot is positive for poor arterial circulation, especially if, when the patient sits with the legs over the end of the bed, it takes 1–2 minutes for the limb color to be restored.

Posterior (Dorsal) Pedis Pulse

The posterior (dorsal) pedis pulse can be palpated just lateral to the tendon of the EHL over the posterior aspect of the foot (see Fig. 21-14). In individuals with diabetes mellitus, absent pedal pulses may indicate the onset of ischemic changes to the ankle and foot region.[276] Diminished or absent pedal pulses have been reported as specific but not sensitive for the early detection of peripheral arterial disease in individuals without diabetes mellitus.[277] The interrater agreement of pedal pulse palpation has been found to range from fair to good,[278] with reliability being enhanced by the use of standardized bony landmarks to locate the pulses.[279]

Plantar Fasciitis Test

Windlass Test

This test is used to detect the presence of fascial and ligamentous impairments of the foot. There are two parts to the test:

Part 1: The patient is positioned in sitting. Using one hand just proximal to the first metatarsal head, the clinician stabilizes the ankle in the neutral position. The clinician then extends the first phalange while allowing the IP joint to flex. A positive test is considered if the passive extension is continued to the end range or until the patient's pain is reproduced.

Part 2: The patient stands on a stool with the metatarsal heads just over the edge of the stool. The patient is instructed to place equal weight on both feet. The clinician passively extends the first phalange while allowing the IP to flex. A positive test is considered if the passive extension is continued to end range or until the patient's pain is reproduced.

Neurologic Tests

The applicable sensory, motor, and reflex tests should be performed if a disorder related to a spinal nerve root (L4–S2) or peripheral nerve is suspected. Although published descriptions of the sensory distributions of the spinal nerve root and peripheral nerves vary substantially, in general, the L4 dermatome involves the medial ankle and dorsum of the first toe, the L5 dermatome involves the lateral aspect of the dorsal surface of the foot and ankle, and the S1 dermatome involves the lateral border of the foot and heel.[1] A neurogenic cause of foot pain must be considered in a patient, especially if the pain is refractory. The patient usually complains of pain that is poorly localized, which is aggravated by activity but may also occur at rest. Any difference in sensation between extremities should be noted and can be mapped out in more detail by testing pinprick sensation (Fig. 21-59). The segmental and peripheral nerve innervations are listed in Chapter 3. Common muscle stretch reflexes tested in this area are the Achilles reflex (S1–2) and the posterior tibialis reflex (L4–5). Specific pathologies associated with peripheral nerve entrapment are described in the intervention strategies section.

The pathologic reflexes (Babinski and Oppenheim), tested when an upper motor neuron lesion is suspected, are described in Chapter 3.

Morton's Test

The patient is positioned in supine. The clinician grasps the foot around the metatarsal heads and squeezes the heads together. The reproduction of pain with this maneuver indicates the presence of a neuroma or a stress fracture.[280] No diagnostic accuracy studies have been performed to determine the sensitivity and specificity of this test.

Tinel's Sign

The posterior tibial nerve may be tapped behind the medial malleolus (Fig. 21-60). Tingling or paresthesia with this test is considered a positive finding. As with all Tinel's test throughout the body, this test provides only marginal sensitivity (58%).[281]

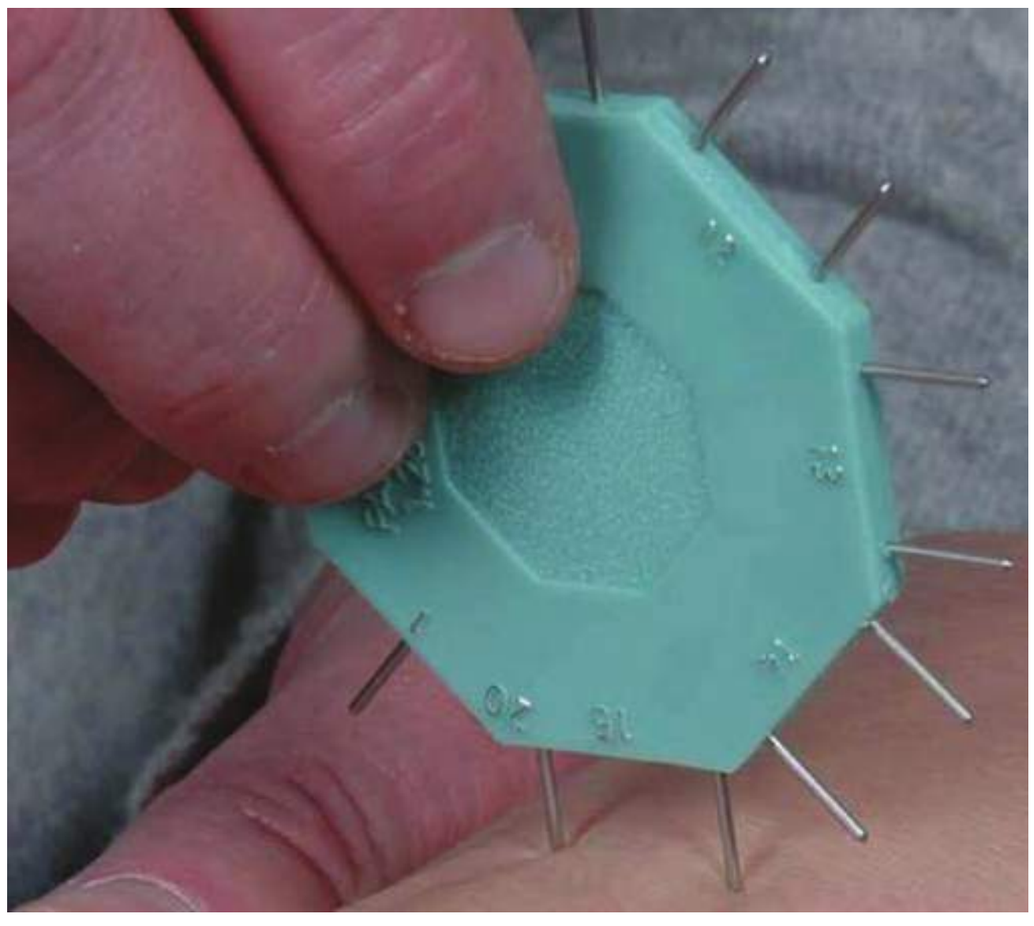

FIGURE 21-59 Sensory testing using pinprick.

FIGURE 21-60 Tinel's sign.

Dorsiflexion-eversion Test

The dorsiflexion-eversion test[282] can be used to help determine if the patient's symptoms are the result of entrapment of the posterior tibial nerve (tarsal tunnel syndrome [TTS]). To perform the test, the clinician places the patient's foot and ankle in maximal dorsiflexion and eversion with the MTP joints in extension. This position is held for 5–10 seconds, and any reproduction of symptoms indicates a positive test. A study by Alshami et al.[283] reported that the dorsiflexion-eversion test is more sensitive when performed in combination with hip flexion and knee extension.

Imaging Studies

Radiography

According to the Ottawa rules for ankle x-rays (with Buffalo modifications),[284,285] X-rays are indicated to rule out fracture of the ankle when there is bone tenderness in the posterior half of the lower 6 cm of the fibula or tibia and an inability to bear weight immediately after injury.[284–286] Similarly, if there is bone tenderness over the navicular and/or fifth metatarsal, and an inability to bear weight immediately after injury, then radiographs of the foot are indicated (see Chapter 7).[284,286] The Bernese ankle rules were developed to improve the specificity of the Ottawa ankle rules in identifying a fracture after low-level malleolus and/or midfoot trauma.[287] This is examination consists of three consecutive steps: indirect fibular stress applied 10 cm proximal to the fibular tip, direct medial malleolar stress and simultaneous compression of the midfoot and hindfoot. In a prospective cohort of 364 patients who had sustained a low-energy supination-type injury, sensitivity and specificity were 1.0 and 0.91, respectively.[287]

Other imaging techniques include arthrography, fibular (peroneal) tenography, and magnetic resonance imaging (MRI).

Outcome Measures

Outcome measures for this region include the FAAM,[228] the FADI, the Lower Extremity Functional Scale (LEFS),[288] the Sports Ankle Rating System,[289] the AJFAT, the Chronic Ankle Instability Scale,[290] and the FFI.

- Foot and Ankle Ability Measure (FAAM). This is a region-specific instrument designed to assess activity limitations and participation restrictions for individuals with general musculoskeltal foot and ankle disorders. It consists of the 21-item ADLs and separately scored 8-item sports subscales. The FAAM has strong evidence for content validity, construct validity, test–retest reliability, and responsiveness with general musculoskeletal foot and ankle disorders.[229] There is also evidence for validity in those with chronic ankle instability.[291]
- Foot and Ankle Disability Index (FADI). This is a former version of the FAAM, and the two instruments are identical, with the exception of an additional five items found on the FADI. Four of these items assess pain, and the other item assesses an individual's ability to sleep.[50]
- Lower Extremity Functional Scale (LEFS). This is a broad region-specific measure appropriate for individuals with musculoskeletal disorders of the hip, knee, ankle, or foot. The LEFS consists of 20 items that assess activity limitations and participation restrictions.
- Sports Ankle Rating System. This was developed as a region-specific measure consisting of both self-reported and clinician completed outcome measures. It consists of the quality-of-life measure, clinical rating score, and single assessment numeric evaluation.
- Ankle Joint Functional Assessment Tool. This is a region-specific instrument that contains six items generally related to impairment and six generally related to activity.[50]
- Chronic Ankle Instability Scale. This is designed to quantify the multidirectional profile of patients with chronic ankle instability. It contains four subscales with a total of 14 items. The subscales are defined as impairment, disability, participation, and emotion.
- Foot Health Status Questionnaire (FHSQ).

THE EVALUATION

Following the examination, and once the clinical findings have been recorded, the clinician must determine a specific diagnosis or a working hypothesis, based on a summary of all of the findings. This is diagnosis can be structure related (medical diagnosis) (Table 21-12) or a diagnosis based on the preferred practice patterns as described in the Guide to Physical Therapist Practice.

INTERVENTION STRATEGIES

Due to the incorporated nature of the foot and ankle structures in functional activities, the rehabilitation of this region is best organized around a common framework for most foot and ankle pathologies.[292]

The techniques to increase joint mobility and the techniques to increase soft-tissue extensibility are described in the "Therapeutic Techniques" section.

Acute Phase

The goals during the acute phase include:

- decreasing pain, inflammation, and swelling;
- protecting the healing area from reinjury;
- re-establishing pain-free ROM;
- preventing muscle atrophy;
- increasing weight-bearing tolerance;
- increasing neuromuscular control;
- maintaining fitness levels; and
- attaining patient independence with a home-exercise program.

The control of pain, inflammation, and swelling is accomplished by applying the principles of PRICEMEM (protection, rest, ice, compression, elevation, manual therapy, early motion, and medication). Icing for 20–30 minutes several times a day, concurrent with nonsteroidal anti-inflammatory drugs (NSAIDs) can aid in reducing pain and swelling.

The injured ankle should be positioned and supported in the maximum amount of dorsiflexion allowed by pain and effusion. Maximal dorsiflexion places the joint in its close-packed position or position of greatest congruency.[293] This allows for the least capsular distension and resultant joint effusion. With ankle sprains, this position produces an approximation of the torn ligament ends in grade III injuries to reduce the amount of gap scarring and reduces the tension in the grades I and II injured ligaments.[19,167]

The means by which to support or protect the joint during this phase will vary depending on the severity of the injury and the anticipated compliance of the patient to any restrictions placed on them by the physician.[19,167] For example, mild-to-moderate ankle sprains (grade I and II sprains) can be readily supported by the use of an elastic bandage, open Gibney strapping (with or without felt-pad incorporation), taping,[294–300] or the use of some type of thermoplastic stirrup such as an Air Cast (see next section).[301,302] One of the main advantages of this type of immobilization is that pain-free protected plantarflexion and dorsiflexion are possible, whereas inversion and eversion are minimized.

To increase ROM, the clinician can perform gentle capsular stretches and grades I–II joint mobilizations. Exercises in this phase include towel stretches VIDEO (Fig. 21-61), ankle circles VIDEO and pumps, VIDEO low-level biomechanical ankle platform system (BAPS) exercises (Fig. 21-62), and active and active-assisted exercises in straight planes (plantarflexion, dorsiflexion, inversion, and eversion) and proprioceptive neuromuscular facilitation (PNF) planes. Exercises for the foot intrinsics may include toe curl exercises with a towel VIDEO (Fig. 21-63) or having the patient pick up marbles from the floor with their toes and place the marbles in a small container or bowl VIDEO.

FIGURE 21-62 BAPS exercise.

Isometric exercises within the patient's pain tolerance and pain-free ROM are initiated for all motions. These exercises are initially performed submaximally at multi-angles, progressing to maximal isometric contractions as tolerated. Mild manual resistive isometrics in all planes may also be started throughout the pain-free range. Active motion and exercise may also be used to effectively increase local circulation and further promote the resorption of any persistent edema.[303,304] Exercises are progressed to include concentric exercises, once the isometric exercises are pain free. Seated lower extremity closed kinetic chain exercises (Fig. 21-64) may also be performed during this phase.

Each muscle or muscle group should be strengthened with a specific exercise that isolates the muscle or group. Resistance (rubber tubing/bands, weights, isokinetic devices, body weight exercises, etc.) is increased as tolerated. Emphasis should initially be at low resistance and endurance in all pain-free positions. As the program progresses, the joint

FIGURE 21-61 Towel stretch.

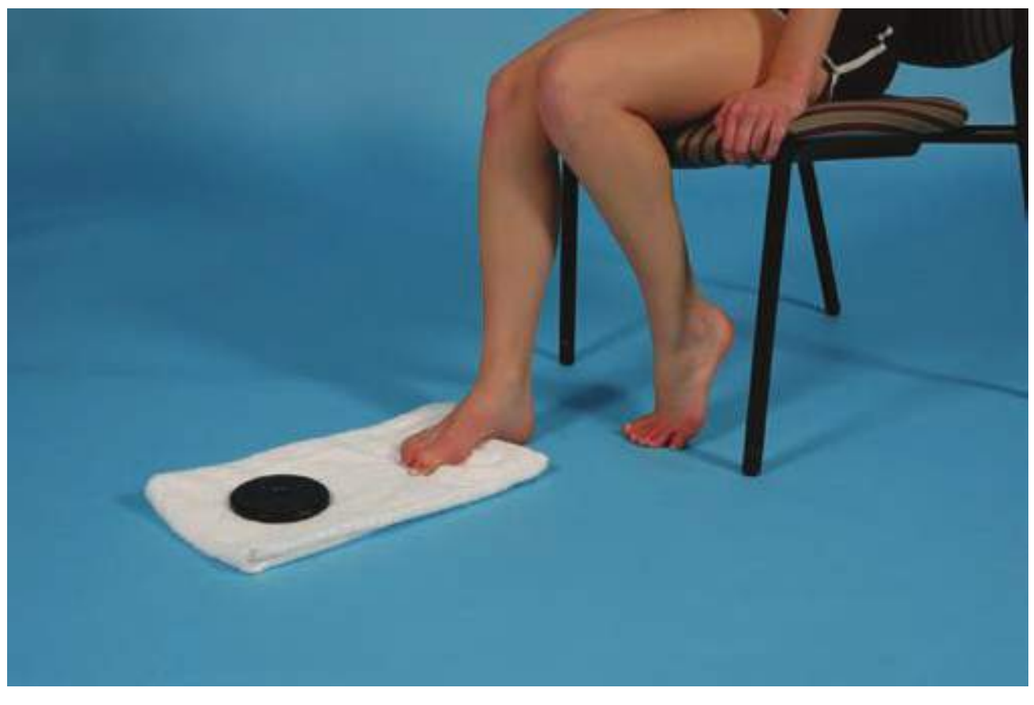

FIGURE 21-63 Towel toe curls.

FIGURE 21-64 Seated heel raises.

range is increased from a stress-free position to a more stressful position. As with all exercises, the patient should become an active participant at the earliest opportunity. The exercises learned in the clinic need to be integrated appropriately into a home-exercise regimen.

Pain-free weight bearing, as tolerated, is encouraged with the use of any appropriate support or assistive device, such as taping, a brace, a cane or crutches VIDEO. The use of an assistive device is usually continued until the patient has a pain-free uncompensated gait. Even when using an assistive device, pain-free ankle motion during the normal gait cycle and as normal a gait as possible continues to be encouraged VIDEO.

Specific joint mobilization techniques and muscle stretching are initiated to begin to increase ROM.

Bracing

Braces can play an important role in both the initial intervention and prevention of ankle injuries. Acutely, their role is to compress, protect, and support the ankle. They also function to limit ROM of the injured ankle, most importantly plantarflexion, and inversion, which is a precarious position for the sprained ankle.[171]

Functional braces that provide medial–lateral stabilization such as the Air Cast (Air Cast, Inc., Summit, NJ) also provide a compressive force that assists in decreasing effusion.[19,167] Patients who suffer a grade III ligament injury may require more protection and support than can be afforded by a thermoplastic device. In cases such as this, consideration should be given to using a functional walking orthosis, either with a fixed ankle or a hinged ankle (which can be motion restricted) that allows only plantarflexion and dorsiflexion.[19,167] The advantage of the orthosis is that it is removable to allow the patient to continue to ice to minimize inflammation.

Overall, braces have been demonstrated to be biomechanically effective in preventing, decreasing, or slowing motions that cause injury to the lateral ankle ligaments.[305] Because of the deterioration of support, and the cost of tape (see "Taping" section), removable and reusable ankle braces were designed as an alternative to taping.[19,167]

Although, one study[306] reported that braces were not as effective as freshly applied tape (see "Taping" section), clinically, braces appear to be as effective, if not more effective, than tape in the prevention of lateral ankle sprains.[307–311] The injury rate in one study by Sitler et al.[309] reported that the ankle injury rate was more than triple in the nonbraced players compared with braced players during intramural basketball at West Point.

In the presence of instability, the ankle joint is best supported by a commercial brace, with or without taping, depending on the stress of the sport.[19,167]

Functional Phase

For the patient to progress to the functional phase of the rehabilitation program, pain-free weight bearing, and an uncompensated gait pattern must be present. However, pain may still be felt with activities more vigorous than walking. In addition, there should be minimal pain and tenderness, full PROM and strength rated at 4/5 to 5/5 with manual muscle testing as compared with the uninvolved side.[292] A recurrence of symptoms should not be provoked. The goals of this phase are as follows:

- to restore normal joint kinematics;
- to attain full range of pain-free motion;
- to improve neuromuscular control of the lower extremity in a full-weight-bearing posture on both level and uneven surfaces;
- to improve or regain lower extremity strength and endurance through the integration of local and kinetic chain exercises;
- to return to the previous level of function or recreation.

Exercises during this phase include manually resisted exercises, concentric exercises with tubing into dorsiflexion (Fig. 21-65), VIDEO plantarflexion VIDEO, inversion VIDEO, and eversion (Fig. 21-66) VIDEO. Exercise tubing can also be used for toe flexion VIDEO and extension VIDEO. Closed-chain exercises include, but are not limited to, seated marching on the floor VIDEO or pillow VIDEO, unilateral stance on the floor VIDEO, weight shifting VIDEO, standing bilateral or unilateral heel raises VIDEO, standing gastrocnemius stretch VIDEO, wall slide VIDEO, toe walking VIDEO, heel walking VIDEO, and supine leg press VIDEO. Emphasis should be placed on regaining any dorsiflexion that was lost. Regaining dorsiflexion can also be

FIGURE 21-65 Dorsiflexion PRE with resistive tubing.

FIGURE 21-66 Eversion PRE with resistive tubing.

assisted by the use of a tilt board or heel cord stretching box. The gastrocnemius is stretched by keeping the knee straight (Fig. 21-67) and the soleus is stretched by flexing the knee (Fig. 21-68).[297,312]

Proprioceptive exercises are especially important for full functional return and injury prevention.[19,167] Three factors are thought to cause functional instability of the ankle joint[313]:

- Anatomic or mechanical instability.
- Muscle weakness.
- Deficits in joint proprioception.

One of the all-to-common consequences of an ankle injury is an alteration of the motor conduction velocity of the fibular (peroneal) nerve and the protective function of the fibularis (peroneal) muscles on the ankle joint.[301,314,315] A decrease in fibular (peroneal) reaction time has been demonstrated to

FIGURE 21-67 Gastrocnemius stretch.

FIGURE 21-68 Soleus stretch.

continue for up to 12 weeks after injury[301,314] despite a nearly full return of strength (96%) in comparison with the contralateral side.[314] An increase in the latency response of the fibularis (peroneal) muscles has also been demonstrated in normal subjects with an increase in plantarflexion, indicating a loss of protective reflexes when in this position.[316] The patient must train and be rehabilitated in all potential positions of injury.[19,167]

A study by Rozzi et al.[220] demonstrated that a 4-week course of single-leg balance training showed an improvement in balance ability in both the trained and the untrained limbs. Examples of exercises to perform to enhance proprioception include unilateral stance on a pillow VIDEO, side (lateral) step up VIDEO, standing unilateral heel raise VIDEO, lunges onto VIDEO, or over VIDEO a pillow, backward step ups VIDEO, and cross-over walking VIDEO.

After isolated strength exercises are initiated in the early portion of this phase, multidirectional, multijoint exercises should begin. Ankle PNF exercises are started based on the patient's tolerance.[317]

Multidirectional balance activities should progress from the non–weight-bearing, open-chained exercises until the ROM is full and painless, at which time closed-chain exercises are introduced with a progression to full weight bearing.[19,167] The greater the severity of injury, the more significant the need for multidirectional balance and weight-bearing rehabilitation activities.[318–325] These activities are effective in progressing the patient toward a progressive return to function. This progression involves beginning with a phase of walking or jogging on flat surfaces, ascending and descending stairs both forward and backward, with a progression to turning, changing directions and lateral movements while running, and eccentric loading with stair running.[171]

Further work is needed to fully determine the effect of training the responsiveness to ankle musculature to counteract potentially injurious stimuli. Until then, multidirectional balance activities and proprioceptive training should continue to be stressed as part of a clinical rehabilitation program.

Tests found to correlate well with good recovery are descending stairs, walking on heels and toes, and balancing on a square beam.[171,326] For some patients, the goal may be to return to sport. Progression to this level occurs when there is[292]:

- full pain-free active and passive ROM;
- no complaints of pain or tenderness;
- 75–80% strength of the plantarflexors, dorsiflexors, invertors, and evertors compared to the uninvolved side;
- adequate unilateral stance balance (30 seconds with eyes closed).

Before being allowed to return to full competition, the patient should be put through a functional test that simulates all requirements of his or her sport.[19,167] Observational analysis should be made of the patient's quality of movement and whether or not they are favoring the injured extremity in any way.[19,167] Activities during this phase involve cutting drills, shuttle runs, carioca crossover drills, and sports-specific activities such as lay-ups and dribbling.[171]

Full-strength, fibular (peroneal) latency response time and proprioceptive sense about the ankle may not return for many weeks even though the patient has returned to activity.[301,314,327]

Running-related injuries are common, especially in novice runners.[328] Providing advice on training progressions to runners following injury can be difficult. The so-called 10% rule is commonly used as a guideline for a maximum training progression. However, a well-designed randomized control trial (albeit with a small sample size, n = 60) failed to identify an increased risk of injury in novice runners progressing a weekly running distance by 24% over an 8-week period compared to those progressing their weekly running distance by the recommended 10% over a 12-week period.[329] It is likely that a number of running injuries, including Achilles tendinopathy, hamstring strains, tibial stress fractures, and iliopsoas strains are linked to those who run further faster. In contrast, sudden increases in running distance may be linked to other types of running related injuries, such as iliotibial band syndrome, greater trochanteric bursitis, gluteus medius/tensor fascia latae strain, patellofemoral pain, patellar tendinopathy, and medial tibial stress syndrome (MTSS).[330] In all likelihood, most training injuries are the result of "too much, too soon, too fast, too quick."[331]

CLINICAL PEARL

During slow-speed running, the cumulative load at the knee joint is higher than the accumulative load during faster running.[331]

Taping

Historically, ankle taping has been the athletic trainer's method of choice to attempt to prevent ankle sprains. Ankle taping is effective in restricting the motion of the ankle and has also been proved to decrease the incidence of ankle sprains by providing external stabilization.[333–339]

The material properties of athletic tape must be able to provide long-term support without interfering with athletic performance. However, although traditional taping has been shown to restrict motion, the tape loses 50% of its net support after as little as 10 minutes of exercise.[19,167,306,333,339–347] Ideally, the material properties of athletic tape should mimic those of the ligaments and tendons and demonstrate low stiffness at lowest strain and high stiffness in regions of higher strain.[348]

CLINICAL PEARL

A controlled laboratory testing using a single group, prospective, repeated-measures design demonstrated that use of a composite athletic tape with highly hyperelastic properties could be constructed and could maintain a larger portion of support during short duration exercises (less than 30 minutes) than conventional athletic tape.[294]

The use of tape for increased proprioception remains controversial. It is hypothesized that the tape can either provide additional cutaneous cues or provide a general facilitation at spinal or higher levels, thereby enhancing the perception of movement signals from other proprioceptive sources,[349–352] although this has yet to be proved conclusively.[350,353,354]

The more common instabilities treated with taping include splaying of the mortise, inversion instability of the ankle, plantar instability of the talonavicular joint, and inversion or eversion instability of the talocalcaneal joint.[19,167]

- The mortise is taped circumferentially around the lateral and medial malleolus.
- Talocalcaneal instabilities are taped around the neck of the talus and the heel. With the exception of the inferior tibiofibular joint (which is a syndesmosis), the taping can effect a temporary improvement in symptoms and function.

The decision whether or not to use some type of protective taping or bracing upon return to activity to prevent reinjury is a decision based on the individual athlete and his or her case. No type of taping or bracing will prevent all injuries.[19,167]

CLINICAL PEARL

Often a player may argue that their performance will be adversely affected by the use of taping or bracing.[19,167] A review of the literature demonstrates that for normal athletic movement and function there does not appear to be an adverse impact on function or performance.[307,346,355–359] Indeed, one study involving soccer players, demonstrated a fivefold decrease in the incidence of recurrent ankle sprains when using semi-rigid orthoses, without significantly affecting sports performance.[311]

Footwear

Traditional, everyday, footwear has undergone many changes over the past 10,000 years, whereas athletic shoes were only introduced around 200 years ago.[360] Most of the impetus for athletic footwear has been driven by runners, and throughout the years athletic footwear has become increasingly more cushioned and supportive. Nowadays athletic footwear can be differentiated into three classifications: cushioning, stability, and motion control.

- Cushioning. T is type of shoe was developed for runners with high-arched, rigid feet that tended to excessively supinate or exhibit reduced pronation. For example, a runner with a high medial longitudinal arch and a C-shaped foot, often characterized as a "supinator" tends to underpronate during midstance and is often prescribed a shoe with a softer midfoot and one that is more cushioned, especially on the lateral edge of the shoe.
- Stability. T is type of shoe was designed with some cushioning and some control as they were intended for runners with a neutral foot and normal running mechanics.
- Motion control. T is type of shoe was intended for runners with flat feet and was designed to control rear foot and midfoot pronation. For example, a runner with a low medial longitudinal arch, often characterized as a "pronator," tends to produce an excessive medial roll of the foot during the stance phase and is often prescribed a shoe designed for motion control of the hindfoot and with hard or rigid midsoles made from plastic or high density foam that permit only minimal pronation.

However, despite the fact that the purpose of matching footwear to foot type was to assist in reducing injury, a number of studies[361–363] have shown that matching footwear to foot type has no influence on the injury. On average, running shoes wear out between 300 and 500 miles, although these figures are merely estimates and the actual distance at which a shoe breaks down may vary according to running style, training techniques, and environmental conditions, including terrain and weather. Running in a shoe that no longer provides the correct protection in terms of traction and support may lead to heel pain, shin splints, tendinopathy, and stress fractures.

Outside of the world of running shoes, the type of sneaker worn during basketball, high top versus low top has been studied and shown to have no relationship to the incidence of injury.[335] However, it does appear that increased shoe height can enhance the passive resistance to inversion when the foot is in plantarflexion and can also increase the passive resistance afforded by tape and orthoses.[306]

CLINICAL PEARL

On average, running shoes wear out between 300 and 500 miles, although these figures are merely estimates and the actual distance at which a shoe breaks down may vary according to running style, training techniques, and environmental conditions, including terrain and weather. Running in a shoe that no longer provides the correct protection in terms of cushioning, traction, and support may lead to heel pain, shin splints, tendinopathy, and stress fractures.

Orthoses

An orthosis, or orthotic, can be defined as any device used to support, align, or protect joints or body segments, thus improving function.[364] If significant biomechanical variations from normal are noted during the examination, an orthosis may be indicated. A wide variety of materials is available for the fabrication of custom-made orthotics, which vary in elasticity, plasticity, compliance, and rigidity. A rigid orthosis is usually constructed from a hard thermoplastic, graphite, or fiberglass material. Semirigid devices can be composed of materials including leather, rubber, cork, polypropylene, and copolymers. Two main theories have emerged to explain the benefits of an orthosis:

- Balanced Foot. T is theory, proposed by Dr. Merton Root,[128] evolved in the late 1960s and early 1970s and is still in use today. T e theory emphasized the importance of maintaining the subtalar joint neutral position during the midstance portion of gait. T eoretically, any deviation from the typical foot posture caused abnormal foot motion, which could lead to excessive foot pronation. T ese deviations, which included forefoot varus, forefoot valgus, rear foot varus, and rearfoot valgus in relation to the frontal plane, were then corrected with the incorporation of wedges, also referred to as posts, to control excessive foot pronation. T ese posts may be an addition of an extrinsic (relatively noncompressible) material to the shell of the orthoses, or an intrinsic post (using relatively rigid material) built into the design of the shell, which functions to balance the malalignment of the foot. Extrinsic posts offer the advantage of being easy to adjust, whereas intrinsic posts are much more difficult to adjust. Despite its widespread use, subsequent studies[365,366] have not supported the hypothesis that the subtalar joint neutral position occurs during midstance. In addition, the determination of subtalar neutral, the measurement that is the cornerstone for the prescription of orthotics, is relatively unreliable. While the intrarater reliability in determining subtalar neutral has been found to be acceptable,[205] the interrater reliability scores have demonstrated that clinicians are frequently unable to agree with other clinicians in determining subtalar neutral.[205,207] T e other issue that is often raised is that any definition of "normal" foot alignment assumes that anything that falls outside the criteria for "normal" must be abnormal and associated with pathology; yet, studies have shown that the criteria we use to describe "normal" apply to very few individuals and that many asymptomatic individuals display foot abnormalities but meet those criteria.[207,367,368] Before correcting a malalignment using an orthotic, the clinician needs to determine more definitively the causal relationship between the malalignment and the patient's symptoms.

- Total Contact Foot Orthotic. The aim of this theory is to provide total plantar surface contact, including the medial and lateral longitudinal arches, to control excessive foot motion, particularly hindfoot and midfoot motion. In addition, any prescribed orthosis serves to unload or protect the symptomatic tissues rather than focusing on maintaining the position of a particular joint. This theory appears to have more support in terms of research.[369,370]

Somewhat ironically, despite differing viewpoints as to the cause of foot dysfunction, both methods produce similar results in regard to controlling foot pronation.[371]

Combining the principles of both theories, the principal purposes of a foot or ankle orthosis are as follows[364]:

- evenly distribute the weight-bearing forces on the plantar aspect of the foot;
- reduce stress on anatomic structures local or proximal to the foot and ankle by either force (shock) attenuation or control of joint motion;
- prevent, correct, or compensate for the presence of foot or ankle deformities through augmentation of lower limb neuromuscular control; and
- enhance patient comfort.

CLINICAL PEARL

It is important to remember that an orthotic cannot control movements at more proximal joints to the pelvis (i.e., hip and knee) without detrimental consequences. For example, attempting to control tibial movement with foot orthosis leads to increased stress at the knee. Instead, proximal control mechanisms (e.g., a major component is muscle control of the hip), should be the focus of the intervention.[26]

Heel Lifts

The use of heel lifts is advocated in the literature for a variety of conditions, including Achilles tendinopathy, plantar fasciitis, and calcaneal apophysitis.[48]

The material used to make the heel lift can be modified to increase shock absorption in cases of calcaneal bruising and heel spurs.[372]

Heel Cups

Heel cups are used for similar conditions as heel lifts, with the added benefit that the heel cup is able to help redistribute the forces through the heel better, and because the medial and lateral walls help contain the fat pads of the calcaneus, thus improving the natural shock-absorptive ability.[44,364,373]

Wedges

Prefabricated or custom-made wedges are referred to as a "post" when used in functional foot orthoses. Wedges are typically used to slant the entire foot or part of the foot either medially or laterally to prevent motion or change the weight-bearing aspect of the foot.

PREFERRED PRACTICE PATTERN 4B: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH IMPAIRED POSTURE

Clinical findings with this pattern can include pain with sustained positions, structural deformities and deviations, limited ROM in a noncapsular pattern of restriction, and altered kinematics.

The Pronated Foot

In the normal foot, the angle of the hindfoot and forefoot intersect at 90 degrees, with a downward projection of the center of mass at 135 degrees, such that all of the forces counteract one another, resulting in zero net force and zero rotational velocity.[374] Any changes in this anatomical relationship can affect the static equilibrium. Pronation of the foot creates an angle greater than 90 degrees between the hindfoot and the forefoot. Static equilibrium can only now be maintained through a counteracting force such as the passive stretch of the passive plantar mechanism. Pronation of the ankle and foot during the stance phase of gait is, in essence, a temporary collapse of the ankle, hindfoot, and midfoot, which serves to provide a more adaptable structure. This is adaptability allows for shock absorption and ground terrain changes and helps to prevent excessive strain on the joints or ligaments.[115] Although some pronation of the foot is necessary during functional activities, excessive pronation has been linked to lower limb overuse injuries, because maintenance of the equilibrium becomes the function of the muscles, specifically the fibularis (peroneus) brevis, and the posterior tibialis.[48,375–378] Excessive pronation can occur as a result of a number of different factors, including the following[189]:

- Congenital, including tarsal coalitions, metatarsus varus, and convex pes valgus.[4,56,379]
- Developmental, including talipes calcaneovalgus, talipes calcaneovarus, ligament laxity, and/or a tight Achilles tendon and forefoot varus.[4,56,379,380]
- Equinus at the ankle, resulting in increased dorsiflexion of the forefoot at the hindfoot around the oblique transverse tarsal joint complex axis;
- Subtalar varus;
- A plantarflexed lateral column, which results in pronation due to the fact that the fourth and fifth metatarsals are lower than the adjacent third metatarsal, which produces a pronatory force with weight bearing;
- Hindfoot varus associated with excessive forefoot pronation and delayed resupination.

The patient with a symptomatic pronated foot typically complains of pain along the medial longitudinal arch. Occasionally, there is pain laterally beneath the tip of the fibula secondary to impingement of the calcaneus against the fibula. The pain is usually aggravated with prolonged standing and walking and relieved by rest.[381] Often these patients become symptomatic when they suddenly increase their level of activity.

T e examination often reveals a flattening of the longitudinal arch associated with a valgus deformity of the heel, a medial bulge at the talonavicular joint, a low medial longitudinal arch, and abduction of the forefoot on the hindfoot at the transverse tarsal joint.[381,382]

Two terms can be used to describe the pronated foot: weak and hypermobile. Both the weak and the hypermobile flatfoot can cause symptoms in everyday weight-bearing activities due to postural fatigue.

The Weak Foot

T e weak foot produces moderate pronation. Severe pronation with flattening of the foot is associated with congenital or ligamentous laxity and is deemed to be occurring if the foot is pronating beyond 25% of the stance phase.[4,148,189,383] Acquired flatfoot deformity is a symptomatic and progressive flatfoot deformity, resulting from the loss of function of the tibialis posterior muscle/tendon and/or the loss of integrity of the ligamentous structures supporting the joints of the arch and the hindfoot. T e weak foot is characterized by a general increase in the ROM at the subtalar and transverse tarsal joint complexes, with the heel positioned in valgus, and the medial arch is dropped. In addition, the forefoot is externally positioned on the hindfoot, and the foot is usually toed out.[189]

The Hypermobile Foot

Occasionally, a foot that appears normal in nonweight bearing (static examination) can excessively pronate while running (dynamic examination). Consequently, it is usual for this type of foot to only give symptoms with running, which emphasizes the importance of performing both a static and a dynamic examination of the foot.

Hypermobility at the foot and ankle can lead to increased stress on the bone and soft tissues, especially the ligaments, and an overreliance on muscular support.[110]

T e intervention for an abnormally and symptomatic pronated foot depends on the type, but typically involves the following:

- Removal or alleviation of the abnormal tissue stress.
- Stretching of the gastrocnemius–soleus complex.
- Activity and shoe modification.[110,384] A straighter last is more desirable for a person with excessive pronation.
- Taping or arch strapping: can be used to limit excessive pronation.[385,386]
- Orthotics.

THE FLATFOOT

A flatfoot or pes planus is manifested by little or no longitudinal arch with full-weight bearing, which is present beyond the age of 6 years.[387]

Current models of flatfoot suggest a combination of body weight and ankle plantarflexor forces that drive the calcaneus into plantarflexion, thereby lowering the medial longitudinal arch.[124] Acquired flatfoot is the result of a failure of either the active or passive mechanisms that support the medial longitudinal arch and control arch lowering.[26] In most cases, a pes planus is flexible demonstrated by the fact that the arch can be recreated with the patient standing up on their toes, or the presence of a flexible foot at push-off during gait.[116] Flexible pes planus has been reported to occur in 15% of the general population,[388] with the majority being asymptomatic.[389] If a flatfoot is painful, other causes must be sought out, such as tarsal coalition, vertical talus, or accessory navicular.[67]

CLINICAL PEARL

The abnormal positions associated with flatfoot deformity include the following:

- plantarflexion of the talus
- lateral drift of the calcaneus
- lateral drift of the cuboid as it follows the calcaneus
- dorsiflexion of the metatarsals and
- abduction of the forefoot

Extrinsic congenital deformities can cause abnormal pronation. T ese include hip dysplasia, femoral anteversion, tibial torsions, and genu varum or valgus. T ese deformities produce a rotation of the lower limb, which can have the following consequences:

- Excessive external rotation *of* the lower limb. T is may shift the center of gravity in weight bearing to the medial aspect of the foot. Ideally, the center of gravity during weight bearing should pass through the center of the foot. T is increase in medial stress causes the talus to plantarflex and adduct while the calcaneus tilts laterally (into valgus) and adopts a severe hindfoot eversion posture.[390] T e plantarflexion of the talus loads the plantar calcaneonavicular ligament, which may eventually rupture.[52] T e loss of this ligament results in a higher reliance on other ligaments and a progressive flatfoot deformity.[26] Other ligaments commonly associated with flatfoot different interosseous talocalcaneal, deltoid, and plantar metatarsal.[26]
- Excessive internal rotation *of* the lower limb. T is produces excessive weight bearing on the lateral aspect of the foot. In an attempt to shift the center of gravity more medially, the forefoot abducts on the hindfoot or the foot abducts on the leg. T ese compensations produce excessive pronation of the subtalar joint.

CLINICAL PEARL

A rigid flatfoot, a relatively rare condition, positions the calcaneus in a valgus position and the midtarsal region in pronation, resulting in a displaced navicular (posteriorly [dorsally]) and a talus that faces medially and inferiorly.

THE STIFF FOOT

Pes cavus (high arch) is an abnormally supinated and stiff foot. Common causes are neuromuscular problems in childhood and in the elderly.[391] While normal supination is designed

to allow the foot to function as a rigid lever during push-off, torque conversion, and a lengthening mechanism of the leg,[115] the stiff foot prevents normal pronation from occurring during the stance phase of gait. Without the normal amount of pronation needed to allow the dissipation of stresses, the foot loses its ability to absorb shock. T e stiff foot is characterized by a high arch, increased external rotation of the tibia, and increased forefoot varus.

T ere are three classifications of abnormal supination[4,189]:

- Pes cavus. T is classic type is characterized by a fixed plantarflexed forefoot, or an equinus forefoot, which places the hindfoot in neutral during weight bearing.[380] T e high longitudinal arch of the cavus foot results in limited weight bearing on the plantar aspect of the foot. T is produces increased pressure on the heel and on the metatarsal heads.[381] T e physical examination reveals a varus configuration of the heel, a marked elevation of the longitudinal arch, no medial bulge at the talonavicular joint, an adducted forefoot relative to the hindfoot, and external rotation of the leg.[381,382]
- Pes cavovarus. T is type is characterized by a fixed plantarflexed medial column or first ray. T is places the calcaneus in varus or inversion during weight bearing, so that the foot lands on its lateral border.[380]
- Pes equinovarus. T is foot type demonstrates a fixed plantarflexed forefoot and hindfoot, with no compensation occurring with weight bearing.

T e intervention for a symptomatic case of cavus foot is supportive and involves having the patient wear a soft shoe with adequate padding to increase the weight-bearing surface of the foot and provide more midsole cushion for the plantar aspect of the foot.[381] Total-contact foot orthoses increase the weight-bearing surface of the foot and are recommended for this foot type.[392]

SPECIFIC JOINT DEFORMITIES AND DEVIATIONS

Talocrural Joint

Talipes Equinus

T e lack of a minimum of 10 degrees of dorsiflexion at the talocrural joint is termed as talipes equinus.[128] A common cause for a lack of dorsiflexion at the ankle is adaptive shortening of the gastrocnemius and soleus muscle groups. Other causes include trauma, spasticity, structural bone deformities, and inflammatory disease. T is dysfunction often results in excessive forces being transferred to the forefoot and increased pronation at the subtalar joint.[186]

Common problems associated with this foot type include medial arch pain, posterior leg pain, plantar heel pain, metatarsalgia, lateral ankle sprain, and talonavicular pain.[110]

Subtalar Joint

Hindfoot Varus

T is is the most common structural foot deformity and is the most common abnormality of the subtalar joint. T e most important component of a hindfoot varus is a calcaneal varus (subtalar varus). A calcaneus varus is characterized by an inverted position of the calcaneus when in the subtalar joint neutral position. T is may result in limited eversion and pronation of the subtalar joint when the foot is in contact with the ground. T e combination of calcaneal varus and any medial inclination of the tibia produce a total hindfoot varus. A 2–3-degree hindfoot varus is common and generally presents no problems.[393]

T e practical significance of a hindfoot varus is that at heel strike, the calcaneus is inverted more than normal, and the medial condyle of the calcaneus is farther from the ground, resulting in an increase in lateral heel contact.[155] To bring the medial side of the foot to the ground, the calcaneus must evert.[155] Eversion of the calcaneus is produced by the subtalar joint pronating.

T us, a hindfoot varus forces the subtalar joint to go through an excessive amount of pronation. In addition, the pronation occurs too rapidly. Rapid pronation from this varus contact position can result in retrocalcaneal exostosis.

Partial compensation occurs if the subtalar joint pronates abnormally but does not have enough available pronation ROM to bring the medial condyle of the calcaneus to the ground.[155] In response to a hindfoot varus, a callus will often form under the second metatarsal head and, to a lesser degree, under the third and fourth metatarsal heads.[155] T e callus does not occur under the first metatarsal head because the stability of the latter depends on the fibularis (peroneus) longus muscle.

If no compensation occurs at the subtalar joint, the midtarsal may compensate for increased mobility and medial longitudinal arch collapse.[115]

When the hindfoot varus is large, the metatarsal joint and the forefoot may be excessively mobile, when the heel rises from the ground during propulsion.[155] In addition, the foot may not become rigid until after the heel rises, instead of just before heel rise.

Other tissue disorders that can result from hindfoot varus include plantar heel pain, metatarsalgia, or stress fractures of the second ray and hallux valgus. T e proximal effects of subtalar joint compensation for a hindfoot varus are substantial. T e excessive and rapid pronation that occurs during the contact phase of gait puts a tremendous stress on the primary muscle that decelerates subtalar joint pronation, the tibialis posterior muscle, producing symptoms of overuse in this muscle.[155]

In addition to the extreme stress placed upon the tibialis posterior muscle, abnormal subtalar joint pronation may produce an excessive internal rotation of the lower leg.[155] Normally, the tibia rotates an average of 19 degrees during ambulation.[24] At the beginning of the stance phase, the tibia internally rotates as the talus plantarflexes and adducts. At the end of the stance phase, the tibia must externally rotate, pushing the talus into dorsiflexion and abduction. Any extra rotation must be absorbed in the knee, hip, or sacroiliac joint, or between the lumbar vertebral segments. For example, abnormal subtalar joint pronation increases the valgus stress on the knee, and symptoms of a mild strain of the medial collateral ligament can arise.[155]

Hindfoot varus commonly occurs with tibia vara or pes cavus.[110]

Hindfoot Valgus

Hindfoot valgus involves eversion of the calcaneus when the subtalar joint is in its neutral position. T e midtarsal and subtalar joints supinate to compensate. T is structural deformity is often associated with genu valgum, or with tibia valgus, and can lead to excessive pronation and limited supination.

Transverse Tarsal Joint Complex

Forefoot Varus

Forefoot varus is defined as an inversion of the forefoot on the hindfoot when the subtalar joint is held in neutral.[128] Some forefoot varus is normal, and in asymptomatic individuals, there is usually approximately 7 degrees of forefoot varus.[394]

T is sagittal plane osseous deformity of the forefoot/first ray,[395] with increased stress applied to the medial plantar aspect of the foot, is considered to be the single most common intrinsic cause of mechanical pain and dysfunction within the foot, lower one-third of the leg, and knee (Table 21-13).[380]

Since the medial side of the foot is higher than the lateral side, the forefoot assumes an inverted or varus position. To assist the medial side of the forefoot in reaching the ground, the subtalar joint may excessively pronate as the midstance phase begins. T is compensation places the transverse tarsal joint complex in its maximally mobile position, at the time when it should be in a stable supinated position (just before and during propulsion). T e compensation can create the following:

- extreme stresses on the fibularis (peroneus) longus and the forefoot;
- dorsiflexion and subsequent hypermobility of the first ray.[155,190]
- plantar heel pain;[155] and
- hallux valgus, bunion deformity, and a subluxation of the first MTP joint.[380]

Since the first-ray complex cannot effectively contribute to propulsion, the second metatarsal head will experience excessive loading, with the potential for callus formation under the second metatarsal head, or metatarsalgia or stress fracture of the second metatarsal.[155,396]

In addition, the forefoot-to-hindfoot alignment in the frontal plane is abnormal, which predisposes the fifth toe to receive pressure from the shoe, which can result in a fifth-digit hammer toe.[189] Terminal knee extension during the midstance phase requires the tibia to externally rotate on the femur. If the knee joint compensates by having the femur rotate medially with the tibia, the problem is transferred to a more proximal structure, mainly the hip joint, or the sacroiliac joint, increasing stress to both contractile and noncontractile tissues.[155]

Forefoot Valgus

T is dysfunction occurs when the plane of the metatarsal head is in an everted, or valgus, position. Two structural types of forefoot valgus deformities exist[155]:

- All of the metatarsal heads may be everted.
- T e first metatarsal head may be plantarflexed while the second to fifth metatarsal heads lie in the appropriate plane (pes cavovarus).

If the first ray is plantarflexed, compensation may occur at the subtalar joint in the form of rapid supination of the subtalar joint. T is shifts the weight laterally to the fifth metatarsal head.[128,380] If no subtalar joint compensation occurs in response to a forefoot valgus, the body weight is borne on the medial side of the forefoot.[155] To bring the lateral side of the foot to the ground, compensatory supination must occur at the subtalar joint.[155] T is supination occurs at a rate that is much sooner than in a normal foot.[189] One of the distal effects of the abnormally supinated foot is that the transverse tarsal joint complex is unable to adapt to uneven surfaces, which leads to an increased susceptibility to lateral inversion sprains (Table 21-14).[155]

In addition, the shock-absorbing ability of the knee is also compromised, as the necessary internal rotation of the lower leg required for flexion is delayed. T is may play a role in the

development of problems around the lateral aspect of the knee or patellofemoral joint.[154,190] The increased forces may also travel up the lower extremity and contribute to the development of sacral and low-back dysfunction.

Forefoot Equinus

This is also a forefoot deformity, but it occurs in the sagittal plane. The metatarsal heads, although possibly perpendicular to the calcaneal bisection, are not level with the plantar condyles of the calcaneus. This results in a relative plantarflexion of the forefoot structures when compared with the hindfoot. The functional effect of this deformity is that the ankle joint must move through a greater excursion of dorsiflexion to allow the body to move forward over the foot during the midstance phase.[155]

The subtalar joint itself is unable to compensate directly for a forefoot equinus because it has very little dorsiflexion. Thus, the transverse tarsal joint complex usually becomes the source of the dorsiflexion. If the transverse tarsal joint complex is to provide the necessary dorsiflexion, the subtalar joint must be pronated. However, the time when maximum subtalar pronation is needed by the transverse tarsal joint complex (at terminal stance) coincides with the time when the subtalar joint should be in a supinated position for propulsion.

More proximally, if the foot and ankle are not able to provide the necessary dorsiflexion, the motion in the sagittal plane may be achieved at the knee joint. This may result in a hyperextension force at the knee, as the body progresses forward over the foot and the tibia.

Combined Hindfoot and Forefoot Deformities

Combinations of deformities frequently occur together.

- A hindfoot varus can occur with either a forefoot varus or a forefoot valgus.[155] In a foot that exhibits a hindfoot and a forefoot varus, the compensatory subtalar joint pronation is accentuated throughout the initial contact, midstance, and terminal stance phases of the gait cycle.[155]
- A hindfoot varus may be combined with a flexible forefoot valgus.[155] Clinically, this foot type demonstrates a significant amount of pronation during stance. As the subtalar joint begins to pronate, the transverse tarsal joint complex mobility increases and the forefoot valgus becomes flexible.[155] The foot is abnormally pronated, but the abnormal pronation occurs at the transverse tarsal joint complex as well as at the subtalar joint.
- A rigid forefoot valgus can occur with a hindfoot varus.[155] This combination creates extreme bone stress in the middle of the foot, particularly the tarsal bones. Degenerative joint changes and tarsal stress fractures are potential problems, as are lateral ankle sprains and the most proximal problems that occur with a forefoot valgus.[155]

Congenital Variations of the Foot

Clubfoot

The term club*foot* encompasses a wide range of deformities, most of which involve the heel to some degree. The most common clubfoot deformity is talipes equinovarus. Two categories exist: a flexible form and a resistant form. The former is amenable to conservative intervention with orthotics and footwear modification. The latter type is invariably associated with stiffness and requires surgical intervention.

Convex Pes Valgus

This deformity is also known as "rocker bottom" foot. It is characterized by a primary posterior (dorsal) and lateral dislocation of the talocalcaneonavicular joint. This results in the navicular articulating with the posterior aspect of the talus, locking it in the vertical position and preventing normal dorsiflexion of the hindfoot.[380,397] The compensation for this loss of hindfoot dorsiflexion is dorsiflexion at the midfoot.[115]

Metatarsal Deformities

Four metatarsal deformities are commonly recognized[395]:

- Metatarsus adductus. This is a transverse plane deformity with adduction of all of the five metatarsals, which occurs at the tarsometatarsal joint.
- Metatarsus varus. This deformity is characterized by a medial subluxation of the tarsometatarsal joints with an adduction and inversion deformity of the metatarsals. This results in an inability of the forefoot to be passively abducted to the neutral position.[380]
- Metatarsus adductovarus. This is a combined transverse and frontal plane deformity of forefoot adduction and inversion that occurs at the tarsometatarsal joint.
- Fore*foot* adductus. This is a combined transverse and frontal plane deformity of forefoot adduction and inversion that occurs at the transverse tarsal joint complex.

PREFERRED PRACTICE PATTERN 4D: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH CONNECTIVE TISSUE DYSFUNCTION

Seronegative Spondyloarthropathies

Ankylosing spondylitis (AS), psoriatic arthritis, and Reiter's syndrome are all capable of producing foot and ankle pain. Although AS predominantly affects the axial skeleton, it can also affect the MTP joints.[381]

Psoriatic arthritis usually occurs with accompanying skin lesions. However, in 10–15% of cases, no dermatologic problems exist.[381] The condition is characterized by symmetrical involvement of the hands and feet, most often at the level of the DIP joints.[381]

Reiter's syndrome consists of a triad of conjunctivitis, urethritis, and asymmetric arthritis. This is condition usually affects the knees, feet, and ankles.[381]

Posttraumatic Arthritis

Posttraumatic arthritis, which is associated with repeated inversion sprains, is more common than osteoarthritis at the

ankle. T e trauma may result from direct injuries to the cartilage and/or altered biomechanics (malalignment, altered weight-bearing forces, and incongruent joint loading). Individuals with posttraumatic arthritis of the ankle generally report isolated ankle pain and stiffness and complaints of catching, locking, clicking, and painful giving-way episodes.[398] T e objective examination typically reveals swelling and limited and painful ankle dorsiflexion and plantarflexion ROM. Because of a unique set of challenges presented, posttraumatic arthritis in this region is difficult to treat conservatively. T e conservative treatment approach can include medication (NSAIDs, corticosteroid), patient education (weight loss, activity modification or avoidance, the use of a cane), shoe modification (heel lift to reduce dorsiflexion) bracing (AFO), stretching, mobilization, strengthening, and symptom management (heat, ice, and/or electrical stimulation), as appropriate. Surgical options include ankle arthrodesis and arthroplasty.

Osteochondrosis

Osteochondrosis is an injury to an ossification center, resulting in inflammation, degeneration, recalcification, necrosis, and/or fragmentation. It can occur at an epiphyseal center of a long bone or apophyseal area where a tendon inserts. Osteochondrosis at an apophyseal area is typically referred to as an apophysitis. An adolescent may develop apophysitis due to an overuse injury while an adult typically develops tendinopathy.[399] Common examples of osteochondrosis include Sever's disease (see later) and Freiberg's disease.

- Freiberg's disease. Osteochondrosis of the epiphyseal center of the metatarsal (the second metatarsal is most commonly involved) due to abnormal stress on the metatarsal, resulting in localized pain and swelling. Freiberg's disease can result from abnormal pronation or an excessively long second metatarsal. T e intervention for Freiberg's disease includes the restoration of normal biomechanics, including the use of a metatarsal pad or bar to reduce the weight-bearing forces on the metatarsal.

Osteochondritis Dissecans

Osteochondritis dissecans[399] and osteochondral lesions represent the same entity and relate to an injury to the articular cartilage and/or the underlying bone. T e anterolateral and posteromedial locations on the talus are susceptible to injury when the talocrural joint undergoes torsional stress, through either impact or cyclical loading.[400] When the subchondral bone is involved, avascular necrosis with resulting bone infarction can occur. If the overlying articular cartilage remains intact, space is created between the living bone and articular cartilage. An in-growth of fibrous tissue may result, and, if this tissue is not displaced, healing takes place. T e associated symptoms are related to the stability of the fragment and can be similar to those commonly reported after an ankle sprain. If the fragment is maintained by the cartilage, symptoms may be mild. T e symptoms will be more severe if a fragment breaks off into the joint, with sensations of giving way secondary to sharp pain, catching, and/or locking. T e intervention and prognosis depend on the size and location of the lesion as well as the stability of the fragment. Activities that may disrupt the healing fragment must be avoided. T is would include weight-bearing activities where twisting may occur, such as challenging balance and proprioceptive exercises. Surgical treatment can involve debridement and stabilization of the fragment. In cases when significant bone necrosis has occurred, bone grafting may be required.

Hallux Limitus/Rigidus

Hallux limitus is typically a progressive degenerative disorder characterized by decreased dorsiflexion (limitus) of the first MTP joint, and pain and swelling in the posterior (dorsal) aspect of the joint.[58] If left untreated, joint ankylosis (rigidus) results. Dysfunction of the first-ray complex ultimately causes MTP joint arthrokinematic changes, dorsal articular compression of the proximal phalanx on the metatarsal head, and chronic erosion of the dorsal metatarsal head.[11] Chronic synovial effusion eventually develops, resulting in periarticular pain and chronic hypomobility of the hallux with eventual end-stage autofusion of the MTP joint.[401] Two types of hallux rigidus have been described: adolescent and adult.

- Adolescent. T e adolescent type is consistent with an osteochondritis dissecans or localized articular disorder.
- Adult. T e adult type is a more generalized degenerative arthritis and is the more common of the two types—the incidence is 35–60% in those > 65 years of age.[401] T e cause of this degenerative process is unknown. Possible etiologies include crystal-induced arthropathy (gout and pseudogout), rheumatoid arthritis, the seronegative spondyloarthropathies, posttraumatic degeneration, an intraarticular fracture, or an osteochondrotic lesion of the first metatarsal head.[57,402] Repetitive dorsiflexion of the first MTP joint could also potentially lead to the development of hallux rigidus, although no studies have linked levels of physical activity to the development of hallux rigidus.[402]

T e characteristics of both types include stiffness and pain in the MTP joint. T is is associated with difficulty during the gait cycle, especially when walking or running up hills, climbing stairs or during the terminal stance phase of gait.[57] T is pain during weight-bearing hallux extension typically results due to the impingement of dorsal osteophytes of the first metatarsal head and dorsal base of the proximal phalanx.[11] Since approximately 45 degrees of MTP extension/dorsiflexion is needed for normal gait, limited extension of the great toe gives the feeling of vaulting over the toe. T is may necessitate external rotation of the foot to allow for toe clearance. T us, patients may present with lateral stress transfer as they attempt to unload the hallux MTP joint. T is may produce synovitis of the lesser MTP joints or even stress fractures of the lesser metatarsals.[57]

A posterior (dorsal) metatarsal head osteophyte, or posterior (dorsal) bunion, may rub against footwear, causing an abrasion or ulceration. T e patient may also experience tingling and numbness on the posterior aspect of the toe due to compression of the cutaneous nerves.

Tenderness is usually present on palpation of the posterior (dorsal), and especially lateral, aspects of the joint. Other

findings include abnormal biomechanics during gait (excessive pronation and decreased push-off or vaulting), loss of MTP joint extension/dorsiflexion, possible decreased first-ray joint mobility, decreased sesamoid mobility, and a positive Jack's test. Radiographs typically demonstrate loss of the first MTP joint space, the formation of posterior (dorsal) and lateral osteophytes on the metatarsal head, and occasionally loose fragments about the joint.[240] The differential diagnosis for hallux limitus includes acute/chronic dislocation, gout, metatarsalgia, sesamoiditis, neuroma, and proximal radicular conditions.[11]

The initial intervention for hallux limitus involves shoe modifications, rest, and NSAIDs. Joint mobilizations (first MTP distraction/joint glides, proximal and distal sesamoid glides, and first metatarsal plantarflexion), active ROM, calf stretching, and FHL strengthening and stretching are recommended.[11] A shoe with an extra-deep toe box can be helpful to decrease posterior (dorsal) pressure on the first MTP joint, while a stiff-soled shoe or a rigid custom orthotic with a Morton's extension can be helpful in limiting toe dorsiflexion. A rocker-bottom sole can also help to decrease the extension of the hallux during normal gait. An intraarticular corticosteroid injection may be considered as a temporizing measure. If symptoms increase, or when conservative measures fail, surgical intervention may provide the solution.

The most common surgical procedure for hallux rigidus is the cheilectomy, which is an excision of the posterior (dorsal) 25–33% of the metatarsal head. This removes the offending osteophytes, improves toe dorsiflexion, and preserves the good articular cartilage on the middle and plantar aspects of the metatarsal head.[403] A dorsiflexion osteotomy of the proximal phalanx (Moberg procedure) may be used concurrently with a cheilectomy in selected patients to increase functional toe dorsiflexion.[404]

Tarsal Coalition

Tarsal coalition is a fibrous, cartilaginous, or bony connection of two or more bones in the midfoot or hindfoot.[67,405] It usually presents during adolescence, at an average age of 13 years,[406] when the coalition is ossifying, and subtalar motion becomes more limited. Most tarsal coalitions are bilateral,[405,407] and have been reported to occur in less than 1% of the general population.[405] Calcaneonavicular and talocalcaneal are the most common coalitions seen.[67,405,406,408,409]

A partial or complete talocalcaneal coalition significantly alters the mechanics of the ankle joint complex, as compensatory motions occur at the ankle joint level.

The patient with a tarsal coalition typically presents with pain that is vague and has an insidious onset. They may present with a history of frequent "ankle sprains" or generalized hindfoot or midfoot pain.[406] Symptoms often begin or are exacerbated by athletic training.

The physical examination will show limited or no subtalar motion compared with the other foot and occasional tight fibularis (peroneal) muscles.[410] Spastic fibularis (peroneal) muscles have been reported to occur in less than 1% of these patients.[409]

The diagnosis of such malformations is often very difficult. Plain radiographs should include AP, lateral, and oblique views of the foot.[67,405]

The goal of conservative treatment of tarsal coalition is to reduce stress in the foot, relax the fibularis (peroneal) muscles, and support the foot. This can usually be accomplished with orthotics and exercise, although temporary casting may be necessary.[67,405] If conservative treatment fails, however, a resection may be necessary to restore mobility and decrease pain.[405,406]

Hallux Valgus

Hallux valgus, sometimes referred to as HAV, describes a deformity of the first MTP joint, in which the proximal phalanx is deviated laterally with respect to the first metatarsal. Specifically, there is an abduction of the first MTP joint and adduction of the first metatarsal. Hallux valgus may also be used to describe varying degrees of metatarsus primus varus/valgus deviation of the proximal phalanx, medial deviation of the first metatarsal head, and bunion formation on the lateral side of the head of the first metatarsal. With increasing lateral deviation of the hallux, the MTP joint becomes incongruent, the sesamoids subluxate laterally, the hallux pronates, the medial aspect of the first metatarsal head becomes more prominent, and weight-bearing shifts from the first metatarsal head to the second metatarsal, and possibly the third.[58,187] This weight transfer may result in the formation of a painful plantar keratosis, or a hammer toe or a crossover toe deformity of the second toe.[58]

The deformity results from a number of soft-tissue compromises and other factors including[26,240,411,412,413]

- Lateral subluxation of the FHL muscle, which transforms the FHL and brevis from flexors to adductors, which then pull the PIP medially and the DIP laterally.
- The abductor hallucis muscle slides underneath the metatarsal head and brings about pronation of the great toe, approaching 70–90% of pronation in severe cases.
- Failure of the lateral ligaments particularly the longitudinal plantar aponeurosis and MTP plantar plates and intervening deep transverse intermetatarsal ligaments (also referred to as the tie bar system).
- First-ray axis alignment. A more vertically oriented first metatarsal joint axis is highly correlated with a decreased arch height which in turn allows the first metatarsal to adduct with less anatomical resistance, which tilts the first metatarsal axis more vertically, making the first MTP joint more susceptible to repetitive loading.
- Footwear. Hallux valgus occurs almost exclusively in populations that wear shoes, although there are also some predisposing anatomic factors.
- Gender. Women are more likely than men to have hallux valgus (a ratio of 9:1),[414] and the condition has been reported to affect 22–36% of adolescents.[412,413,415–418]
- Anatomical factors. These include metatarsus primus varus (medial deviation of the first metatarsal), pes planus, forefoot pronation, and joint hyperlaxity.

Hallux valgus may also be hereditary.

A compensated bunion is a mild deformity without MTP joint subluxation and without marked lateral sesamoid subluxation.[419] A decompensated bunion is a moderate-to-severe deformity characterized by hallux valgus angle greater than

25 degrees, an intermetatarsal angle greater than 15 degrees, lateral sesamoid subluxation, and great toe pronation.

The intervention for hallux valgus begins conservatively and the intervention for the bunion includes advice on wearing wider shoes or an orthotic prescription.[412,413,416] A silicone bunion pad placed over the bunion may be helpful in alleviating direct pressure on the prominence.[58] Other interventions are based on the causative factors:

- Achilles stretching is used in cases of Achilles contracture.
- A simple toe spacer can be used between the first and second toes if they require separating.
- Joint mobilizations. These include first MTP joint glides, emphasizing medial joint glides, proximal and distal sesamoid glides, and first metatarsal plantarflexion.
- In cases of pes planus associated with hallux valgus, a medial longitudinal arch support with Morton's extension under the first MTP joint can be used to help alleviate symptoms.[58]

If pain persists, however, structural realignment of the first metatarsal varus is usually necessary, as the bunion deformity becomes more severe and decompensated.

Turf Toe

The term "turf toe" is used to describe a hyperextension sprain of the first MTP joint with an axial load to the heel while in ankle plantarflexion.[420] Turf toe is more common in football, baseball, and soccer players. Football players are at higher risk of this injury if they are tackled while landing from a jump or if another player lands on the back of their heel, forcing the first MTP joint into hyperextension.[7,421] Soccer players tend to develop the sprain in the great toe of the nonkicking foot due to the forced dorsiflexion on the stance leg as the other leg kicks the ball. It was originally thought that the artificial grass surface on football fields caused athletes to stop more quickly during planting and cutting, thus, slamming the toe into the front of the shoe. However, it is more likely that the lighter flexible turf shoes that are designed for the surface are more responsible. This increase in shoe flexibility causes a repetitive hyperextension injury of the great toe. The tendency of artificial turf to become hard and stiff over time may be a contributing factor.[422] Hypermobility of the first ray reportedly leads to biomechanical problems. It has been theorized that during gait, the medial longitudinal arch collapses because of excess posterior (dorsal) motion of the first ray. This collapse decreases the ability of the foot to effectively propel the body forward during walking. The increased posterior (dorsal) excursion of the first ray causes the foot to roll inward (pronation), and the second metatarsal must support an excessive proportion of the body weight.[166] The resulting increased magnitude and duration of pronation significantly diminishes the ability of the fibularis (peroneus) longus muscle to stabilize the first metatarsal.[166] As a result, ligamentous tissues that usually limit the end-range dorsiflexion movement of the first metatarsal undergo increased stress, and joint laxity occurs.[166] Because of these mechanical consequences, hypermobility of the first ray has been implicated in numerous conditions frequently accompanied by excessive or prolonged pronation, including lesser metatarsalgia, acquired flatfoot, posterior tibialis tendinopathy, plantar fasciitis, and shin splints.[166,423]

The mechanism of injury for turf toe can also involve hyperflexion and varus and valgus stresses of the first MTP joint.[7,421] With forced hyperflexion of the hallux, tearing of the plantar plate and collateral ligaments can occur. In the more severe injury, the capsule can actually tear off from the metatarsal head.[66] A fracture of the sesamoids can also occur, and posterior (dorsal) dislocation of the first MTP joint is possible.[62]

Clinically, patients with turf toe present with a swollen, stiff, and red, first MTP joint. They may have a history of a single dorsiflexion injury or multiple injuries to the great toe. The joint may be tender, both plantarly and posteriorly (dorsally). Players may have a limp and be unable to run or jump because of pain.

Turf toe typically develops into a chronic injury, and long-term results include decreased first MTP joint motion, impaired push-off, and hallux rigidus.[421] Fifty percent of athletes will have persistent symptoms 5 years later.[424]

Clanton and Ford[424] have classified the severity of turf toe injuries from grades I to III:

- Grade I: a minor stretch injury to the soft-tissue restraints with little pain, swelling, or disability.
- Grade II: a partial tear of the capsuloligamentous structures with moderate pain, swelling, ecchymosis, and disability.
- Grade III: a complete tear of the plantar plate with severe swelling, pain, ecchymosis, and inability to bear weight normally.

The intervention for turf toe in the acute phase is rest, ice, a compressive dressing, and elevation. NSAIDs are often prescribed, and the toe is taped with multiple loops of tape placed over the posterior (dorsal) aspect of the hallucal proximal phalanx and criss-crossed under the ball of the foot plantarly, to limit dorsiflexion.[62] Occasionally, a forefoot steel plate is used.[66] Passive ROM, and progressive resistance exercises are begun as soon as patient tolerance allows.[62,240] Return to normal activities is based on the initial severity:

- Patients with grade I sprains are usually allowed to return to sports as soon as symptoms allow, sometimes immediately.
- Patients with grade II sprains usually require 3–14 days' rest from athletic training.
- Grade III sprains usually require crutches for a few days and up to 6 weeks' rest from sports participation.

A return to sports training too early after injury could result in prolonged disability. Return to play is indicated when the toe can be painlessly dorsiflexed 90 degrees.[424]

Ankle Syndesmosis Sprain

An injury to the distal tibiofibular joint or syndesmosis often referred to as a "high-ankle" sprain, typically involves injuries to the interosseous tibiofibular ligament, anterior inferior tibiofibular, and posterior inferior tibiofibular ligaments. The most common mechanism of injury is excessive external rotation or forced dorsiflexion. Clinical findings include a lack of swelling, pain with weight bearing and heel raising, and

tenderness over the anterior aspect of the distal tibiofibular joint.[425] The following clinical tests can be used to help with diagnosis[11]:

- Cotton test.
- Kleiger (external rotation) test.
- Dorsiflexion compression test.
- Fibula translation (drawer) test.
- Heel-thump test.
- Squeeze test.

Once a fracture has been ruled out, the recommended conservative intervention includes rest, ice, compression, and elevation, bracing or boot and non weight bearing acutely.[11] Progressive ROM, proprioception, and strengthening exercises are introduced as appropriate. Return to sports can be considered when the patient can perform a one leg broad jump, vertical jump, and 10 crossover hop at 80% of the uninvolved joint.[426,427]

Lateral Ankle (Inversion) Sprain

A review of the Emergency Department records in the United States between 2002 and 2006 estimated the incidence rate of a lateral ankle sprain to be 2.15 per 1,000 person-years in the general population.[428] The incidence of lateral ankle sprains was highest in those between 15 and 19 years of age, but the overall incidence rate ratio for lateral ankle sprain did not differ between males and females. Nearly half of all lateral ankle sprains (49.3%) occur during athletic activity,[428] but many are work related, with those injured unable to attend work for more than 7 days post-sprain.[429] In the weeks following an ankle sprain, ADLs can be compromised, and, even though acute symptoms resolve, persistent symptoms are reported to occur in 30–40% of people.[430]

Risk factors for acute ankle sprain are categorized as being intrinsic or extrinsic[50]:

- Intrinsic factors include history of previous sprains, age, gender, physical characteristics (i.e., height, weight, and body mass index [BMI]) and musculoskeletal characteristics (i.e., balance, proprioception, ROM, strength, anatomic alignment, and ligament laxity).
- Extrinsic factors include the use of external support, sport, level of competition, and participation in neuromuscular training.

CLINICAL PEARL

Dynamic stability is provided to the lateral ankle by the strength of the fibularis (peroneus) longus and brevis tendons.

Stormont et al.[431] recently showed that ankle instability, and thus sprains, could only occur during systematic loading and unloading, but not while the ankle is fully loaded, due to the articular restraints. In the neutral position or dorsiflexion, the ankle is stable because the widest part of the talus is in the mortise. However, in plantarflexion, ankle stability is decreased, as the narrow posterior portion of the talus is in the mortise.[171] Thus, the most common mechanism of an ankle sprain is one of inversion and plantarflexion.[19,66] With eversion and external rotation, the deltoid and/or ligaments of the distal tibiofibular joint can be injured, producing the so-called medial and central sprains, respectively. Eversion injuries to the medial (deltoid) ligament of the ankles account for 5% of ankle sprains.[13,173,432]

If left untreated, ankle sprains can lead to chronic instability and impairment.[171] The prognosis for ankle sprains is inversely proportional to the severity and grade of the initial injury (Table 21-15),[430] the age of the patient (younger patients do not fair as well), and the rate of recurrence (the prognosis is worse when the ankle has been previously sprained).[19,167,433]

Sprains of the lateral ligamentous complex represent 77–83% of ankle ligament sprains.[434] In the younger population, serious ankle sprains are unusual in the skeletally immature, because the ligaments are usually stronger than the bone, necessitating a physeal fracture to be ruled out.[19,66]

The most common mechanism of injury for lateral ankle sprain occurs with forefoot adduction, hindfoot internal rotation, ankle inversion in plantarflexion, and external rotation of the leg beyond anatomical constraints. The sequence of lateral ligament tears is first the ATFL, then the anterolateral capsule, then the distal tibiofibular ligament, then the CFL, and finally the PTFL, the strongest of the lateral ligaments, ruptures[15,298], although injury to the PTFL rarely occurs in isolation with an inversion mechanism of injury. However, up to 73% of lateral ankle sprains involve isolated ATFL injuries.[434]

Following an excessive ankle inversion injury, structures other than the lateral ligaments can be injured and may include the lateral subtalar ligaments, fibularis (peroneal) tendon,

TABLE 21-15 The West Point Ankle Sprain Grading System

Criterion	Grade I	Grade II	Grade III
Location of tenderness	ATFL	ATFL and CFL	ATFL, CFL, and PTFL
Edema and ecchymosis	Slight and local	Moderate and local	Significant and diffuse
Weight-bearing ability	Full or partial	Difficult without crutches	Impossible without significant pain
Ligament damage	Stretched	Partial tear	Complete tear
Instability	None	None or slight	Definite

ATFL, anterior talofibular ligament; CFL, calcaneofibular ligament; PTFL, posterior talofibular ligament.
Data from Gerber JP, Williams GN, Scoville CR, et al. Persistent disability associated with ankle sprains: A prospective examination of an athletic population. Foot Ankle Int. 1998;19:653–660.

nerve injury, extensor brevis and fibularis (peroneus) longus retinaculum, inferior tibular ligament, osteochondral lesions of the talus or tibial plafond, and neuromuscular elements of the lower extremity.[50] T e high-ankle sprain, or syndesmotic sprain, which involves disruption of the ligamentous structures between the distal fibula and tibia, just proximal to the ankle joint, is a less-understood form of ankle sprain injury in comparison with the lateral ankle sprain. T e mechanisms of injury for syndesmotic ankle sprains include[250,253,435]

- forceful external rotation of the foot, resulting in widening of the ankle mortise, as the talus is driven into external rotation within the ankle mortise;
- forceful eversion of the talus, which widens the mortise;
- forceful dorsiflexion, which widens the mortise, as the wider anterior aspect of the talar dome enters the joint space.

With all of the above mechanisms, the distal fibula is pushed laterally away from its articulation with the distal tibia. Chronic instability of the syndesmosis may then result in increased shear stress and altered contact pressure patterns that might predispose the individual to degenerative articular cartilage changes in the ankle joint.[250,253,435]

In addition to ligamentous injury, a lateral ankle sprain may result in injuries to the lateral musculotendinous structures. T e dynamic stabilization of the ankle complex is dependent on the adjacent musculature and laterally includes the fibularis (peroneus) brevis. T e tibialis anterior and the EDL and brevis are thought to eccentrically control ankle plantarflexion.[50]

Although a physical examination is reliable for the diagnosis of an ankle fracture,[284] the reliability for detecting lateral ankle sprains may not be as definitive, especially if the examination is performed immediately after the injury.[264] T e place of a physical examination in diagnosis has been reviewed in a series of 160 patients,[264] comparing the accuracy within 48 hours of injury with that at 4–7 days. T e specificity and sensitivity of delayed physical examination for the presence or absence of a lateral ligament injury were 84% and 96%, respectively, indicating that a reasonably precise clinical diagnosis is possible if the examination is delayed for approximately 4 days postinjury.[438] Injuries to the foot and ankle may quickly be dismissed as ankle sprains, particularly in the adolescent population (Table 21-16). A clinician examining the foot and ankle needs to be aware of other potential pathologies to consider when an adolescent patient is referred to physical therapy with the diagnosis of ankle sprain. T ese pathologies include osteochondrosis, osteochondritis dissecans, accessory ossicle, anterior impingement syndrome, sinus tarsi syndrome, tarsal coalition, and epiphyseal fractures.[399]

T e mechanism of injury can afford some clues. As mentioned, a history of a forced dorsiflexion can result in a sprain of the distal tibiofibular syndesmosis. Distal tibiofibular syndesmosis sprains are usually accompanied by complaints

CLINICAL PEARL

Abnormal hip muscle activation has been found after ankle inversion movements in those with ankle hypermobility after injury.[436] It is theorized that local nerve damage can alter afferent cutaneous feedback receptors which may in turn involve central neuromuscular pathways.[437]

TABLE 21-16 Potential Pathologies Associated with Adolescent Ankle Injuries

Pathology	Def nition	Signs and Symptoms
Sever ostoechondrosis	Calcaneal apophysitis	Localized pain and tenderness at the Achilles attachment
Talocrural osteochondritis dissecans	Injury to articular cartilage and/or underlying bone	Catching, locking, and/or sudden sharp stabbing pains
Accessory ossicles at the distal tibia or fibula	Ossification centers that have not fused	Localized pain and tenderness Accessory bone with rounded edges on radiographs
Accessory os trigonum	Accessory ossicle on the posterior-lateral process of the talus	Pain posteriorly with maximum plantarflexion Accessory bone with rounded edges on radiographs
Anterior ankle impingement	Thickening of joint capsule with or without bone spurs at the anterior talocrural joint	Pain anteriorly with sudden dorsiflexion Decreased dorsiflexion ROM—a hard end-feel if bone spurs are present
Sinus tarsus syndrome	Injury to the structures contained within the sinus tarsus	Hindfoot instability Tenderness inferior and anterior to the anterior talofibular ligament
Tarsal coalition	Congenital union between two tarsal bones: usually calcaneonavicular or talocalcaneal coalition	Localized tenderness over the involved joint Rigid flatfoot and peroneal muscle spasm with inversion
Distal tibial epiphyseal fractures	Growth plate injury	Tenderness at the distal tibia Inability to weight bear

Data from Martin R. Considerations for differential diagnosis of an ankle sprain in the adolescent. Orthop Pract. 2004;16:21–22.

of pain that greatly exceed the amount of swelling and that increase with external rotation of the foot.[171] Forced plantarflexion can result in anterior capsular sprains. T ese are characterized by pain that worsens with passive plantarflexion and resisted dorsiflexion.[171]

No single symptom or test can provide a completely accurate diagnosis of a lateral ankle ligament rupture, but the collection of findings can be strongly indicative.[264]

- T e absence of swelling at the time of the delayed (after 4 days) physical examination suggests that there is no ligament rupture, whereas extensive swelling at this time is indicative of ligament rupture.[439]
- Pain on palpation of the involved ligament suggests involvement.
- T e presence of a hematoma suggests a rupture.
- Positive anterior drawer test suggests a rupture.
- Impairment of walking ability after injury suggests involvement.

One study[264] demonstrated that a combination of tenderness at the level of the ATFL, a lateral hematoma, discoloration, and a positive drawer test indicated a ligament rupture in 95% of cases, whereas the absence of these findings always indicated an intact ligament.

Lateral ankle sprains can be categorized as follows:

- Grade I: characterized by minimal to no swelling and localized tenderness over the ATFL. T ese sprains require on the average 11.7 days before the full resumption of athletic activities.[440]
- Grade II: characterized by localized swelling and more diffuse lateral tenderness. T ese sprains require approximately 2–6 weeks for return to full athletic function.[441,442]
- Grade III: characterized by significant swelling, pain, and ecchymosis and should be referred to a specialist.[443] Grade III injuries may require greater than 6 weeks to return to full function. For acute grade III ankle sprains, the average duration of disability has been reported to be anywhere from 4.5 to 26 weeks, and only 25–60% of patients are symptom free 1–4 years after injury.[444] In a summary of all prospective and controlled studies on grade III sprains, it was concluded that the long-term prognosis is good to excellent in 80–90% of patients with this injury, regardless of the type of intervention chosen.[445]

Intervention

For severe acute ankle sprains, surgical intervention may yield slightly better outcomes for function and instability compared with conservative treatment.[446] Conservative intervention has been found to be consistently effective in treating grades I and II ankle sprains,[447,448] and high-ankle sprains (Table 21-17). T e clinical course of acute lateral ankle sprains has been reported and indicate that a rapid decrease in pain and improved motion within the first 2 weeks after the injury can be expected.[447] It must be remembered that acute lateral ankle sprains can vary greatly in their presentation with respect to the amount of edema, pain, ROM limitation, and loss of function.[50]

TABLE 21-17 Summary of Conservative Treatment for Ankle Sprains

Phase/Criteria	Description of Intervention
Phase I	Pain and edema control: rest, ice, compression, elevation, electrical stimulation, toe curls, ankle pump, and cryotherapy Temporary immobilization/stabilization (i.e., short-leg cast, splint, brace, and heel lift) Nonweight bearing with crutches
Phase II Pain and swelling subside Partial weight bearing with assistive device	Patient can ambulate using partial weight bearing without pain. Lower-level balance training: bilateral standing activity or standing on a balance pad or several layers of towels Lower-level strengthening using theraband
Phase III Patient can ambulate full weight bearing without pain, possibly still needing protection from heel lift or ankle brace	Unilateral balance training Progress from double-heel raises to single-heel raises Treadmill walking or over ground walking Progress to fast walking
Phase IV Able to perform heel raises in unilateral stance	Fast pain-free walking without heel lift Jog to run progression Shuttle runs and cutting maneuvers Sport-specific training

The timeline for progression of an individual patient is dependent on the severity of the injury and the ability of the patient and the criteria listed in the table for progression to each phase.

Data from Lin CF, Gross ML, Weinhold P. Ankle syndesmosis injuries: Anatomy, biomechanics, mechanism of injury, and clinical guidelines for diagnosis and intervention. J Orthop Sports Phys Ther. 2006;36:372–384.

Intervention in the acute stage centers around aggressive attempts as follows:

- minimize effusion so as to speed healing;
- promote early protected motion;
- introduce controlled proprioceptive training.
- foster early supported/protected weight bearing as tolerated[449];
- foster protected return to activity; and
- prevent reinjury.

Early intervention incorporates cryotherapy, compression, and elevation to assist in the reduction of pain, swelling, and secondary hypoxic effects.[450] The clinician should use repeated intermittent applications of ice to reduce pain, decrease the need for pain medication, and improve weight bearing.[50] Although early motion and mobility rather than immobilization have demonstrated the stimulation of collagen bundle orientation and the promotion of healing,[451] it must be remembered that full ligamentous strength is not regained for several months or longer.[452–455]

Active ROM exercises, such as ankle pumping and toe curls (30 reps, four times/day each), are encouraged during this phase, but within pain-free limits.[181]

Protected weight bearing with an orthosis is permitted, with weight bearing to tolerance as soon as possible following injury. A systematic review by Kerkhoffs et al. involving 22 studies concluded there was a significant benefit to weight bearing as tolerated compared to non–weight-bearing cast immobilization.[449,21] The patient should be advised to use external supports and to progressively bear weight on the affected limb with the type of external support and gait assistive device based on the severity of the injury. As the healing progresses, and the patient is able to bear more weight on his or her ankle, there is a corresponding increase in the use of weight-bearing (closed-chain) exercises. A recommended activity during this phase is the "cross drill." The patient stands independently or with minimal assistance on the involved limb, with the other leg flexed. The patient then moves the uninvolved limb into hip flexion, hip extension, hip abduction, and hip adduction. The exercise is performed initially on a firm surface with the eyes open, and then, as the patient improves, the exercise is performed on a foam surface or balance board, first with the eyes open and then with the eyes closed.

In the subacute stages of the rehabilitation process (4–14 days), the patient begins dynamic balance and proprioceptive exercises. During the subacute phase, patients often experience stiffness, swelling, weakness, impaired balance response, decreased function, and instability. Proprioceptive[301] and postural control deficits[456] have been identified in those with acute ankle sprains.[50] A systematic review noted that balance is not only impaired on the injured extremity but may also be impaired on the uninjured extremity after an acute lateral ankle sprain.[457]

The external support may still be required during this phase. Using a balance board, the patient balances on the involved limb, while playing "catch" with the clinician. The intensity of this exercise can be varied by using balls of different sizes and different weights. The clinician may also make the exercises more challenging by throwing the ball to a variety of locations. This will require a shift in the center of gravity and an instantaneous adjustment of balance from the patient.

Manual therapy, including graded joint mobilizations, manipulations, and non–weight-bearing and weight-bearing mobilizations with movement can be used to improve ankle dorsiflexion proprioception and weight-bearing tolerance.[50]

Long-sitting gastrocnemius stretching with a strap or sheet can be introduced in this phase (six reps of 20 seconds each) to promote ankle dorsiflexion past the neutral position, enabling a closer to normal walking pattern.[181] Open-chain (nonweight bearing) progressive resistive exercises with elastic resistance are performed (two sets of 30 reps each) for isolated plantarflexion, dorsiflexion, inversion, and eversion. Stationary cycling can also be performed (at a comfortable intensity for up to 30 minutes), to provide cardiovascular endurance training and controlled ankle ROM.[188]

In the advanced healing stage (2–4 weeks postinjury), the goals are as follows:

- the restoration of normal AROM;
- normal gait without an assistive device;
- the pain-free performance of full-weight-bearing functional activities; and
- enhancement of proprioception.

Activities to help achieve these goals include heel-to-toe anterior–posterior walking (10 m for 20 reps), carioca drills, and mini-trampoline balancing exercises (unilateral stance with eyes open and then closed, and catching and passing activities with a medicine ball).

Plyometric activities are introduced during the functional challenge/return to activity phase. These can include two-foot ankle hopping, single-ankle hops, and then multidirection single-ankle hops. If appropriate, barrier jumps or hops may be introduced.

Recurrent Lateral Ankle Sprains

Five percent to 33% of patients with an ankle sprain continue to have pain for 1 year or longer follow-up, with 5–25% still experiencing pain after 2 years. Individuals with long-term symptoms and signs after acute lateral ankle injuries are commonly categorized as either having mechanical or functional ankle instability.[141,447] It is hypothesized that ankle instability may be an interaction between mechanical instability (laxity in both the talocrural joint and the subtalar joint), and functional instability (sensorimotor and neuromuscular deficits).[458] It has been suggested that patients with recurrent inversion ankle sprains frequently demonstrate dysfunction at the proximal tibiofibular, distal tibiofibular, talocrural, or subtalar joint.[459]

Recurrent ankle sprains may also be due to the following[19,167]:

- healing of the ligaments in a lengthened position;
- a weakness of the healed ligaments due to the inherent weakness of the scar;
- a weakness of the ankle inverters (the incompletely rehabilitated ankle sprain);
- hereditary hypermobility;

- loss of ankle proprioception demonstrated by increased sway with single-leg stance tested on a stable (eyes closed) or unstable surface[458];
- impingement by the distal fascicle of the anterior tibiofibular ligament, and/or impingement of capsular scar tissue (meniscoid tissue) in the talofibular joint; and
- undiagnosed associated problems such as cuboid subluxation or subtalar instability.

A systematic review by Hiller et al.[460] identified a larger talar curvature, inverted heel at heel strike of gait, decreased foot clearance when walking, prolonged time to stabilize after jumping, increased postural sway, and decreased concentric ankle inversion strength as characteristics associated with ankle instability.

T e associated complication of ankle sprains includes early degenerative changes.[258,461] Talar displacement of greater than 1 mm reduces the ankle's weight-bearing surface by 42.3%,[462,463,464] resulting in asymmetric load bearing of the articular surface.

Chronic lateral instability is manifested by recurrent injuries with pain, tenderness, and sometimes bruising over the lateral ligaments.[433,465–469] Many, approximately 30%,[433] may be asymptomatic between the events. Others may manifest with chronic lateral pain, tenderness, swelling, or induration with great difficulties in sports and daily activities.[433,466,469] A history of insecurity, instability, and giving way[467,470,471] is far more important in diagnosis than the physical examination in acute and recurrent sprains.[433,472]

In general, subjective complaints include

- frequent sprains[473,474];
- difficulty in running on uneven surfaces[474];
- difficulty in cutting and jumping in athletic events[469,474,475];
- feelings of "giving way."[473,476,477]
- Recurrent pain[469,473,476–478] and swelling.[473–475,477,478]
- Tenderness.[474,476,477]
- Inability to run.[479]
- Weakness.[469,479]

Recurrent ankle sprains are typically treated conservatively for 2–3 months[474,479–482] using a combination of some or all of the following: manual therapy techniques to restore or improve dorsiflexion, posterior talar glide, stride speed and step length, distribution of forces through the foot, and pain.[459] In addition, a lateral heel wedge, fibularis (peroneal) muscle strengthening, proprioceptive/coordination exercises, taping, elastic or thermoplastic ankle supports, and/or a short-leg brace can also provide benefit. It is worth mentioning that there is only limited evidence regarding the efficacy of neuromuscular training for ankle instability, although early indications are encouraging.[483]

If the conservative trial fails, late repair or reconstruction of the lateral ligaments is recommended.[433,484–489]

According to Hinterman,[23] a number of conditions can mimic ankle instability:

- Fibularis (peroneal) tendon subluxation.
- Instability of the Chopart's joint. Inversion and plantarflexion trauma of the foot may result in avulsion by the bifurcate ligament and, sometimes, additionally by the talonavicular ligament. Injuries at the Chopart's joint level are, however, frequently missed acutely and misdiagnosed as a lateral ankle sprain, if the clinical examination is not carefully carried out.
- Talocalcaneal and talonavicular coalition.
- Posterior tibial dysfunction.

Medial Ankle (Eversion) Sprain

It is unlikely that the clinician will encounter a sprain of the deltoid ligament as there is a greater likelihood of an avulsion from, or fracture of, the medial malleolus with an eversion stress. If the patient presents with an eversion sprain, the principles of treatment during the acute phase are the same as for any other ligament sprain:

- Minimize the swelling using a combination of compression, elevation, and ice
- Protect the injury site through immobilization and the use of an assistive device such as crutches
- Use gentle joint mobilization technique to maintain mobility and inhibit pain
- Train the patient on muscle setting techniques to assist with circulation and help maintain muscle integrity.

As the patient progresses, continued protection during weight bearing may be necessary as weight-bearing tolerance increases.

MIDFOOT SPRAIN

A sprain of the tarsometatarsal joint usually occurs from an indirect axial load on a plantarflexed and rotated foot, with or without abduction.[490] On examination, the patient will have tenderness to palpation directly over this area, and pain during passive midfoot pronation and supination while the hindfoot is stabilized.[490]

Radiographs of the foot should include weight-bearing AP and lateral and oblique views to rule out dislocation. T e metatarsals should be lined up with their respective cuneiforms.[66]

Conservative intervention can proceed if displacement of the metatarsals on a radiograph is less than 2 mm and includes an orthotic or a fracture boot if the patient is unable to bear weight comfortably.[66] A stiff shoe and orthotics to support the medial longitudinal arch are recommended for return to athletics.[491]

Sinus Tarsi Syndrome

T e sinus tarsi is located between the inferior neck of the talus and the superior aspect of the calcaneus. It is inferior and slightly anterior to the ATFL. Sinus tarsi syndrome is a sprain of the subtalar joint, with an injury to the talocalcaneal interosseous ligament. T e mechanism of injury involves an inversion sprain in a plantarflexed position that injures both the talocrural and subtalar joint and is sometimes difficult to distinguish from a routine ankle sprain.[66]

Symptoms can include a feeling of hindfoot instability when walking on uneven ground. Observation usually reveals swelling in the sinus tarsi. T ere is usually pain with palpation and pronation,[492] usually due to scarring in the soft-tissue elements of the sinus tarsi.[491]

T e intervention may include joint-specific mobilization and manipulation, followed by strengthening and proprioceptive exercises. An orthotic can be used to limit pronation and maintain the foot in a functional neutral position.

Selective cortisone injection into the subtalar joint can also be diagnostic and therapeutic.[492]

Cuboid Syndrome

As described in the "Anatomy" section, the cuboid is located in the lateral midfoot, surrounded by the calcaneus posteriorly, the fourth and fifth metatarsals anteriorly, and the navicular and lateral cuneiform medially. T e osseous configuration of the calcaneocuboid joint permits adduction, inversion, and some plantarflexion of the cuboid during closed-chain supination of the foot.[53] Cuboid syndrome (locked cuboid, cuboid fault syndrome, lateral plantar neuritis, and subluxed cuboid) is a common but poorly recognized source of lateral midfoot pain where the cuboid subluxes, commonly in a plantar and medial direction.[493] T e calcaneocuboid joint can be repetitively subluxed with strong forces, although the subluxation is usually a temporary occurrence. During excessive inversion and plantarflexion, the fibularis (peroneus) longus contraction may cause a forceful eversion causing the cuboid to sublux medially.[494] In addition, other etiologies have been proposed including overuse, excessive pronation, midtarsal instability, increasing body weight, training on uneven surfaces, or a lateral ankle or lateral foot sprain.[493,495]

T e cuboid syndrome usually presents with a gradual onset of lateral midfoot pain, which can mimic those of a ligament sprain. T e pain is usually localized to the lateral foot near the fourth and fifth metatarsals at the posterior (dorsal) aspect of the cuboid or the calcaneocuboid joint.[493] Often, the patient feels as if he or she is walking with a small stone in their shoe. Maximum discomfort is elicited by pressure directed over the fibular (peroneal) groove on the plantar surface of the calcaneus.[66] On occasion, the hook of the bone under the cuboid breaks or the short plantar ligament tears, producing heel pain.

Common findings in the physical examination are a tenderness along the fibularis (peroneus) longus tendon, a subtle forefoot valgus and a pronated foot, as well as a tight fibularis (peroneus) longus tendon.[493,496,497] T ere may also be tenderness at the cuboid groove, the dorsolateral and/or plantar cuboid, or the origin of the EDB muscle.[498] As the pronated foot produces an unstable transverse tarsal joint complex, careful gait analysis will often reveal that the pain is reproduced in terminal stance, at the onset of heel rise. Other findings include asymmetrical weakness of the fibularis (peroneus) longus muscle and decreased ROM of the lateral foot. Differential diagnosis should include fracture or dislocation of the cuboid, calcaneus, or fourth and fifth metatarsals, calcaneonavicular coalition, fibularis or EDB tendinopathy, plantar fasciitis, sinus tarsi syndrome, meniscoid of the ankle, gout, tarsitis, Lisfranc's injury, compression neuropathy of the sural nerve, lateral plantar nerve entrapment and anterolateral ankle impingement.[499,500]

Imaging studies, including radiography, computerized tomography, and MRI are usually not useful in determining the diagnosis.[495]

T e intervention for this condition includes a manipulation of the midfoot (see "Cuboid Whip" section) unless contraindicated, stretching the fibularis (peroneus) longus tendon, and strapping/plantar padding.[493,496]

Talocrural Joint Subluxation

T ere are essentially two types of subluxations at this joint, anterior and posterior, which result in a loss of plantarflexion and dorsiflexion, respectively.

- T e anterior subluxation is commonly caused by an inversion, plantarflexion force. T e clinical findings include a limitation of dorsiflexion, a decreased posterior talar glide, and/or conjunct external rotation of the talus.
- T e posterior subluxation may be from a compensatory or another type of flatfoot or from a dorsiflexion injury. T e clinical findings include a loss of the plantarflexion talar swing, anterior glide, and/or medial conjunct talar rotation.

T e intervention for this type of injury is usually a high-velocity thrust technique applied to the joint.

PREFERRED PRACTICE PATTERN 4E: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH LOCALIZED INFLAMMATION

T e list of potential pathology for soft-tissue injuries to the foot, accompanied by localized inflammation, is extensive.

Inflammation or Infection of the Nails and Skin

Subungual Hematoma

A subungual hematoma is also called "black toenails" or "runner's toe" and results from bleeding under the toenails due to chronic friction or bumping of the toe against ill-fitting shoes, or from overt trauma to the posterior (dorsal) aspect of the toe.[501] Due to the extreme sensitivity of the nail bed, significant pulsating pain is often associated with this problem, with or without palpation.

In the case of poorly fitting shoes, prophylactic treatment is recommended. Athletic shoes should be one size longer than street shoes in most cases.[198]

For an existing hematoma, the treatment of choice involves decompression of the hematoma using a red-hot paper clip or 18-gauge needle, heated in an alcohol burner, which is used to burn a hole through the nail.[502]

Subungual Exostosis

A subungual exostosis is a hypertrophic bone, usually affecting the medial border of the hallux, as the result of excessive

pressure, that produces pain on ambulation.[503] An accurate diagnosis of this condition requires a radiograph.[502]

Conservative intervention involves using a deep toe box and decreasing the width of hypertrophic nails.

Onychocryptosis

Onychocryptosis is more commonly referred to as ingrown toenails. It is commonly associated with a secondary pyogenic infection or paronychia. Onychocryptosis without paronychia is treated conservatively by removing the offending portion of the nail and then smoothing the nail border with a curette.[502]

Onychia

Onychia is an infection of one or both sides of the nail and nail plate, which can result from a number of factors including chronic pressure on the nail plate, allergies, nail polish, improperly cutting the nails, or certain soaps.[502]

Onychauxis

Onychauxis is an overgrowth of the nail that can be the result of microtrauma or macrotrauma, peripheral neuritis, old age, nutritional disturbances, or decreased circulation, producing future nail growth distortion.[501,502,504] The diagnosis is made by the hallmark characteristics of a hypertrophic, dystrophic, and discolored nail plate.[505]

The conservative intervention for this condition involves the mechanical or chemical debridement of the nail plate.[505]

Onychomycosis

Onychomycosis is a chronic fungal condition of the nails, which is often responsible for causing onychauxis.[506]

Tinea Pedis

Tinea pedis is more commonly known as athlete's foot. It usually presents with redness or itchiness but can also appear as dry and flaky skin.[502]

Treatment is simple and involves soaking the foot in one-half cup of vinegar in a pan of water once a day and applying a topical antifungal agent.[502]

Blisters

Blisters occur secondary to friction and shearing and can give the clinician valuable information as to where the stresses of the foot are occurring. Besides the obvious fact that tight shoes cause blisters, other causes include excessive motion such as pronation and supination.

Tendinopathy

Overuse of the ankle and foot tendons typically occurs as the result of training errors, abrupt changes in training patterns, muscle–tendon imbalances, anatomic malalignment, or improper footwear.[492]

CLINICAL PEARL

Training error is a vague term because it covers a broad range of flaws in the running regime including incorrect warm-up, excessive mileage, excessive speed, not stretching correctly, not resting sufficiently in between runs, a rapid change in intensity, and a sudden increase in running distance.

The overuse causes the tendons to break down, resulting in tendinopathy. Although more common in the adult population, tendinopathy can also be seen in the adolescent due to a sudden growth spurt or the resumption of play after a period of decreased training.[507] The intervention for tendinopathy/tenosynovitis includes identifying and removing the causative factor, an initial period of PRICEMEM followed by a program of stretching and strengthening of the tendon. On occasion, the intervention may require casting, orthotics, and/or prophylactic bracing.

Fibularis (Peroneus) Longus Tendinopathy

This form of tendinopathy is particularly common in young ice skaters and dancers, but can also be seen in any running athlete. A number of conditions are associated with fibularis (peroneus) longus tendinopathy including chronic lateral ankle instability due to repeated inversion strains, which stretch and inflame the sheaths of the fibularis (peroneus) longus and brevis tendons (runner's foot), or with instability between the fourth and fifth metatarsals.

The patient usually presents with pain behind and distal to the lateral malleolus.[507] There may be associated swelling in the acute phase. There will also be a pain with resisted foot eversion.

Fibularis (Peroneal) Longus Tendon Subluxation

Subluxation of the fibularis (peroneal) longus tendon is an infrequent but potentially disabling condition that mainly affects young athletes[508] In its early and later phases, the condition is often difficult to distinguish from a lateral ankle sprain, as the acute symptoms include pain at the posterior distal fibula, swelling, ecchymosis, and apprehension, or inability to evert the foot against resistance.[66,509] The chronic symptoms include lateral ankle pain, popping or snapping, and instability.[66] Confusing the issue is the fact that a chronic fibularis tendon subluxation can both mimic and coexist with chronic ankle instability.

One of the causes of this condition is that, in some individuals, there may be a number of anatomic anomalies that predispose the fibularis tendon to sublux including, an absent or shallow fibular groove,[104,492,510,511] probably combined with pes planus, hindfoot valgus, or lax/absent fibular retinaculum.[104,105,507,510,512] A subluxation can also occur from a traumatic rupture of the retinaculum as the result of a violently forced dorsiflexion of the ankle with reflex contraction of the fibularis muscles and subsequent dislocation.[104,105,492,512–515]

As with many tendon conditions, fibularis tendon subluxation can be an acute episode that turns into a chronic problem due to misdiagnosis.[66] Many of these subluxations are incorrectly diagnosed at the acute stage as simple ankle sprains.[516] The young patient may present acutely after a supposed ankle sprain, with pain and swelling over the posterolateral aspect

of the ankle. More commonly, though, the initial presentation may occur weeks to months after the injury.[515] T e adolescent may complain of recurrent inversion ankle sprains and lateral ankle instability, with a painful snapping across the ankle.[76] Chronic ankle instability can also contribute to chronic fibularis tendon subluxation, with the development of an incompetent superficial fibular retinaculum.[76,104] T is can also be confused with a rare isolated injury to the PTFL.[104,105,511,512]

On physical examination, subluxation may be provoked with forceful ankle dorsiflexion and eversion. T ere may be pain posterior to the lateral malleolus in an acute situation, as well as a negative anterior drawer test.[66]

A number of surgical procedures have been described for a chronic fibularis tendon subluxation, including tendon transfer, repair of the fibular retinaculum, groove deepening procedures, and tendon rerouting.[104,508,512,514,516]

Tibialis Posterior Tendinopathy

Tibialis posterior dysfunction is a complex disorder of the hindfoot that begins with synovitis, followed by tendinosis and elongation, and potentially culminating in rupture.[517] T e condition is often associated with a symptomatic progressive loss of medial longitudinal arch height in adults, which is known as adult acquired flatfoot deformity.[11] Early identification is essential for initiation of care that may prevent the development of a disabling condition. T e gradual development of tibialis posterior dysfunction can be described in four stages[146]:

CLINICAL PEARL

Controversy exists as to whether a persisting rotational instability after ankle sprain may cause tibialis posterior dysfunction or vice versa. Tibialis posterior dysfunction may cause ankle instability by overloading the ankle ligaments, especially the medial (deltoid) ligament of the ankle.[47]

Stage I. T is stage is characterized by tibialis posterior muscle weakness, mild swelling, and medial ankle pain, without rear foot or forefoot structural deformity. T e loss of strength may be progressive or sudden.

Stage II. T is stage is characterized by medial and lateral hindfoot pain and some degree of rear foot valgus and forefoot abduction (i.e., toe out) when bearing body weight, which results from tibialis posterior tendon elongation. T e deformity is flexible and correctable. T e excursion of the tibialis posterior tendon is estimated at 2 cm, and any deviation in the length can drastically affect the moment created by its action. Indeed, patients with tibialis posterior dysfunction have been found to have a marked reduction in inversion torque of 3–6 lb or approximately 20–40% of preserved torque.[518] T e valgus deformity of the hindfoot is due to the unopposed action of the fibularis (peroneus) brevis.

Stage III. T is stage is characterized by an uncorrectable rigidity of both the rear foot and forefoot (i.e., fixed rear foot valgus, combined with fixed forefoot varus and abduction), which is due to osteoarthritic degeneration in the subtalar joint and transverse tarsal joints. T e failure of the tibialis posterior to stabilize the medial column of the foot allows the gastrocnemius–soleus to become a deforming force as the hindfoot valgus deformity shifts the gastrocnemius–soleus insertion lateral to the subtalar joint axis.

Stage IV. T is stage is characterized by a complete rupture of the tendon and valgus at the talocrural articulation.

A decreased range of talocrural joint dorsiflexion in stages I and II appears to be an important factor that exacerbates tibialis posterior dysfunction, thereby increasing the likelihood of progression to stages III and IV.[146]

Tibialis posterior tendinopathy is seen relatively frequently in participants of dance and ice-skating who have a pronated foot and flattened longitudinal arch.[210] T e condition is also seen in running sports that require rapid changes in direction (basketball, tennis, and soccer) as abrupt changes in direction place increased stress on the tendon.[98] Other contributing factors include an adaptive shortening of the gastrocnemius–soleus complex, obesity, age-related degeneration, inflammatory arthritides, hypertension, diabetes mellitus, traumatic rupture, and general weakness of the posterior tibialis.[11]

T e symptoms associated with this condition are usually felt in one of three locations:

- Distal to the medial malleoli in the area of the navicular.
- Proximal to the medial malleoli.
- At the musculotendinous origin, or insertion.

T e primary patient complaint during stage I is typically aching discomfort on the medial aspect of the ankle and foot, which is exacerbated by weight-bearing activities and relieved by rest. Swelling may sometimes be seen. Discomfort may be elicited by manually resisted inversion of the subtalar joint, as well as patient performance of a single leg heel rise, and palpation of the portion of the tendon that lies between the posterior margin of the tibial malleolus and the navicular tuberosity. Sometimes pain may be secondary to an accessory navicular.[98] With a complete rupture, the navicular subluxes inferiorly, and the patient ambulates in a flatfooted position, as they are unable to produce any toe-off at terminal stance.

Plain radiographs are rarely helpful, although MRI or bone scan[519] may aid in the diagnosis.

Unfortunately, very little high-quality research evidence is available to guide conservative management of tibialis posterior tendinopathy. TFM has been advocated for the reduction of scar tissue and facilitation of tendon healing, but no high-quality research evidence is available to support its value for the treatment of tibialis posterior tendinopathy. As with other tendinopathies, any contributing biomechanical abnormality must be addressed. T is would include stretching of the adaptive shortened triceps surae, orthotics, taping, and strengthening of the tibialis posterior using eccentric exercises.

Tibialis Posterior Myofascial Tightness

Patla and Abbott[212] describe a condition called tibialis posterior myofascial tightness (TPMT) as a factor in heel pain. In contrast to tibialis posterior tenosynovitis, TPMT is not characterized by inflammation of the tendon sheath. T e patient with TPMT complains of immediate heel pain on weight bearing in the morning. T e pain is increased with increased load from activities but typically decreases during the day.

There is no specific injury or activity identified as the cause. Physical findings include[212]:

- depression of the medial arch with standing;
- neutral or inverted calcaneus in standing;
- flatfoot appearance and diminished push-off with gait;
- decreased full ROM of plantarflexion and calcaneal inversion with weight-bearing heel raising;
- full PROM of dorsiflexion and plantarflexion, with possible end-range discomfort; and
- the posterior tibialis length test (see "Special Tests" section) shows decreased extensibility and often produces pain.

The intervention for this condition is geared toward correcting the impairments of the tibialis posterior muscle. The same technique and contacts used in the test are used for treatment, except that the manual stretch is maintained for approximately 2 minutes and is repeated approximately four times, with slightly stronger pressure being used each time.

Tibialis Anterior Tendinopathy

Tibialis anterior tendinopathy is most commonly seen in runners, especially in those who participate in up or down hill training. The examination will show point tenderness over the tendon, as it crosses the ankle.

FHL Tendinopathy

As with the posterior tibialis, the FHL is lined by a tenosynovial sheath, which can become inflamed in areas where it changes direction. These areas of relative incongruence between the FHL tendon and the fibro-osseous tissue can cause a constriction of the tendon, particularly the position of extreme plantarflexion motion, which can put the tendon at risk.[11] FHL tendinopathy is common in ballet dancers and in individuals who jump or run. Thus, dancers who assume the repeated plantarflexed posture of demipointe or pointe are particularly susceptible to this condition,[496,520,521] although runners and gymnasts are also susceptible. The tendon sheath becomes inflamed due to forceful push-offs with the forefoot, where the FHL is stretched between the posterior talar tubercle and the sustentaculum tali. The tendon sheath can also be irritated with plantarflexion, where it is compressed over the posterior talar tubercle.[522]

FHL tendinopathy will usually present itself as pain with resisted great toe flexion in the young patient, as well as pain posterior and inferior to the medial malleolus, the latter of which is most often confused with posterior tibialis tendinopathy.[522] In fact, the diagnostic cluster for FHL tendinopathy is posterior medial ankle pain, medial arch pain, and/or a positive Tinel's sign.[11] Other findings may include:

- Palpable tenderness over the knot of Henry.
- Positive FHL resistance test.
- Positive FHL stretch test.

Achilles Tendinopathy

It is probably no accident that Homer decided that the heels of his Greek hero, Achilles, would be the one vulnerable area of the body.[523] This vulnerability of the heel continues to this day, with Achilles tendinopathy being the most common overuse syndrome of the lower leg,[88] accounting for 5–18% of the total number of running injuries.

The Achilles tendon is placed under extreme and rapid eccentric loading forces during such activities as running, standing up while cycling, ballet, gymnastics, soccer, and basketball.[524,525] For example, while running, the Achilles tendon loading exceeds 12.5 times the runner's body weight.[526]

The underlying mechanism of Achilles tendinopathy is not well understood, but a number of mechanisms have been proposed of which the biomechanical hypothesis is the most popular. Immediately after the foot makes contact with the ground in a supinated position, it pronates and then supinates again as the propulsion phase approaches.[48,151] The pronated foot imparts an internal rotation force through the tibia, whereas knee extension imparts an external rotation force through the tibia.[524] The overpronated foot places the medial aspect of the tendon under tension, generating an obligatory internal tibial rotation, which tends to draw the Achilles tendon medially.[527] Thus, excessive lateral heel strike and compensatory foot pronation can result in an uneven force generation from the gastrocnemius and soleus muscles that can overload certain areas of the Achilles tendon.[92] The rapid and repeated transitions from pronation to supination cause the Achilles tendon to undergo a "whipping" or "bow-string" action.[528] Moreover, if the foot remains in a pronated position after knee extension has begun, the external tibial rotation at the knee and the internal tibial rotation at the foot result in a "wringing" or twisting action of the tendon.[48]

Another proposed mechanism involves the eccentric contraction of the triceps surae during support. Maximal triceps sural contraction is associated with adduction and supination of the foot. At heel strike, the calf muscles undergo a rapid shortening before lengthening, as the tibia rotates forward over the foot. The calf muscles then shorten again during the forward propulsion phase.[529] These abrupt alternations in muscle action may cause microtears in the tendon.

In addition to those causes already described, a number of other factors appear to have some influence on the development of Achilles tendinopathy:

- Stretching. McCrory et al.[528] determined that injured runners were less likely to incorporate stretching into their regular training routines. However, whether stretching habits can be related to the incidence of overuse injuries remains uncertain.[530–533]
- *T*raining variables. Overuse injuries of the tendons have been strongly associated with a number of training variables including technique, inappropriate footwear, inconsistent surfaces, training at a faster pace, and hill training.[80,530,534]
- Fatigue. Overtraining has been found to correlate with muscle fatigue and microtears of a tendon.[48,151]
- Exercise variables. Muscular insufficiency has been proposed as a significant factor in the inability to eccentrically control dorsiflexion during the beginning of the initial contact phase of running.[528,534–536]
- Anthropometric variables. One study determined that 20% of the injured runners with Achilles tendinopathy had cavus feet.[151] Clement et al.[535] suggested that a

potential cause was compensatory overpronation resulting from the inflexibility of the cavus foot. A high-arched foot has also been found to be related to the incidence of various overuse syndromes by a number of other studies.[80,377,537,538]

- Age. Some studies have found a correlation between age and the pathogenesis of running injuries,[528,539] whereas others[532,538,540–542] have found no associations.
- Proximal structures. Altered knee kinematics and reduced proximal muscle activity (rectus femoris and gluteus medius, have been associated with Achilles tendinopathy).[543]
- Shoe type. Spiked running shoes, which provide minimal shock absorption and which lock the feet on the surface during the single support phase during running have been correlated with Achilles tendinopathy. Theoretically, this type of shoe transfers the lateral and vertical torque shear forces directly to the foot and ankle and through the Achilles tendon, thereby increasing the overloading of the tendon, and causing microtrauma and inflammation of the tendon.[527,544]
- Sacroiliac joint dysfunction.[527] The primary function of the pelvis appears to be as a shock absorber, transmitting the weight of the trunk and upper extremities to the lower limbs and distributing the ground reaction forces.[127,545] The ground forces, which tend to rotate the innominate posteriorly, and the trunk forces combine to provide a mechanism for stability.[127,545] Posterior dysfunction is reported to be the most common lesion of the sacroiliac articulation by several authors.[546–548] This is results in a functional shortening and external rotation of the involved leg,[549,550,551] both of which may influence the kinematic chain of the lower extremity in the following manner[527]:
  - The ankle and foot position will be in external rotation, instead of neutral, at heel strike.
  - Due to the transfer of body weight over the involved leg during the rest of the stance phase, the loading of the lateral aspect of the heel will be short, the following pronation prolonged, and the inversion delayed. This may decrease the amount of dorsiflexion in the ankle, thus minimizing the tension in the plantar soft tissues. This is, in turn, decreases the leverage of the Achilles tendon, and the truss mechanism[544] may not be activated due to insufficient hyperextension of the big toe.
  - Because of the relative ineffectiveness of the foot's truss mechanism at terminal stance, together with the decrease in leverage of the Achilles tendon, the triceps surae will have to activate more motor units to ensure continued performance, thus putting additional loading on the Achilles tendon.

Achilles tendinopathy typically occurs as one of two types of tendinopathy: insertional and noninsertional, with the former involving the tendon–bone interface and the latter occurring just proximal to the tendon insertion on the calcaneus in or around the tendon substance.[524]

Noninsertional tendinopathy can be referred to as peritendinopathy, peritendinopathy with tendinosis, or tendinosis.[524,552]

- Peritendinitis. The inflammation in peritendinitis is limited to the peritendon, and thickening can result.
- Peritendinitis with tendinosis. This is condition describes a second stage of inflammation, in which a portion of the Achilles tendon itself is involved in the disease process.
- Pure tendinosis. This is condition, which typically affects the weekend warrior, is characterized by microscopic and macroscopic mucoid degeneration of the tendon.

Clinical symptoms associated with Achilles tendinopathy consist of a gradual onset of pain and swelling in the tendon 2–3 cm proximal to its insertion, which is exacerbated by activity. Some patients will present with pain and stiffness along the Achilles tendon when rising in the morning or complain of pain at the start of the activity, which improves as the activity progresses. In fact, in the early stages of the condition, morning stiffness may be the only symptom whereas pain is felt even at rest in the advanced stages.[79]

The vast majority of symptomatic patients are runners who complain of pain in the posterior aspect of the heel, approximately 2 cm proximal to the superior margin of the calcaneus, which increases while running activities.[93] The pain typically worsens over time, until it inhibits the individual from running, at which point they usually seek medical attention.

The differential diagnosis for posterior heel pain includes retrocalcaneal bursitis,[93] metabolic diseases, arthritis and chondropathic diseases of the ankle joint, tibia vara, os trigonum, a calcaneal contusion, plantar heel pain, calcaneal stress fracture impingement syndrome and stress fractures of the fibula or tibia.[527,553]

The Achilles tendon and heel may be examined with the patient in sitting or prone. Upon observation, the patient will often be found to have pronated feet, and the presence of swelling around the tendon is common.

Systematic palpation is performed along the tendon, over the heel, along the posterior border of the calcaneus, and down to the heel pad. Localization of the tenderness is extremely important. Tenderness located 2–6 cm proximal to the insertion is indicative of noninsertional tendinopathy, whereas pain at the bone–tendon junction is more indicative of insertional tendinopathy.[524] If there is an area in the tendon itself, which is discrete and painful with side-to-side pressure of the fingers, this often indicates an area of mucoid degeneration or a small partial rupture of the tendon.[93] If the tenderness is in the area of the retrocalcaneal bursa, which is noted by side-to-side pressure in that area, this is the primary area of involvement.[93]

A lack of 20 degrees of dorsiflexion in knee extension signifies adaptive shortening of the gastrocnemius, and an inability to dorsiflex 30 degrees in knee flexion implicates the soleus as well.[93]

Analysis of gait may reveal an antalgic gait, with the involved leg held in external rotation during both the stance and swing phases. There is often pain with resisted testing of the gastrocnemius/soleus complex.

The intervention for Achilles tendinopathy in relation to exercise intensity varies according to the severity of the symptoms[89]:

- *T*ype I. Characterized by pain that is only experienced after activity. These patients should reduce their exercise by 25%.

- *Type II.* Characterized by pain that occurs both during and after activity but does not affect performance. These patients should reduce their training by 50%.
- *Type III.* Characterized by pain during and after activity that does affect performance. These patients should temporarily discontinue running.

The conservative intervention, which almost always involves modification of extrinsic factors (training errors), includes Achilles stretching, eccentric strengthening of the calf muscles, the correction of any lower chain asymmetries (low-back, pelvic, and hip flexor asymmetries; knee flexion contracture; femoral anteversion; and foot pronation),[554,555] electrotherapeutic modalities as appropriate, correct shoe wear, and orthotics—appropriately designed orthoses made from a mold of the foot held in subtalar neutral, and non-weight bearing can be of significant benefit.[79]

A 2005 literature review by Goodnite[556] that investigated the best intervention for a patient with recurrent Achilles tendinopathy, based on its validity and strength, recommended the 12-week eccentric program as outlined by Alfredson et al.[557] The Alfredson program of eccentric heel-drop exercises consists of two types of exercises—eccentrically loading the calf muscles with the knee bent and the knee straight and three sets of 15 repetitions using just body weight to start, with the patient instructed to continue unless the pain becomes disabling. The original protocol recommended completion of 180 eccentric repetitions a day, and the exercises are performed for 12 weeks. If only minor pain or discomfort is experienced, the patient is instructed to increase the load by using a backpack loaded with weight. However, there is no strong rationale currently for this repetition volume,[558] even though the 37-year-old patient in this study was compliant with the program and was able to successfully progress to marathon training within 3 weeks of beginning the program.[556] A more recent study[559] found that performing a program of eccentric heel drop exercises for 6 weeks as tolerated, compared to the recommended 180 repetitions per day, did not lead to lesser improvement for individuals with midportion Achilles tendinopathy.

Rupture of the Achilles Tendon

Rupture of the Achilles tendon was first described in 1575, and first reported in the literature in 1633.[560] Although the etiology of a spontaneous rupture remains incompletely understood, a number of theories have been proposed, including microtrauma,[561] inhibitor mechanism malfunction,[562] hypoxic and mucoid tendon degeneration,[563] decreased perfusion,[564] and systemic or locally injected steroids.[565] However, the fact that the peak incidence of Achilles' tendon rupture occurs in the middle age group rather than in the older population tends to lend credence to a mechanical etiology.[566] Three specific activities have been implicated in rupturing the Achilles tendon[567]:

- Pushing off on the forefoot while extending the knee.
- Sudden dorsiflexion with full weight bearing as might occur with a slip or fall.
- Aggressive dorsiflexion such as that occurs when jumping or falling from a height and landing on a plantarflexed foot.

The diagnosis of an Achilles tendon rupture is based almost solely on the history and physical findings. The classic history includes reports of sudden pain in the calf area, often associated with an audible snap, followed by difficulty in stepping off on the foot.[566] Physical examination reveals swelling of the calf as well as a palpable defect in the tendon (hatchet strike), as well as ecchymosis around the malleoli.[568] Perhaps, the most reliable sign of a complete rupture is a positive result on the Thompson squeeze test (see Fig. 21.52).[566,569]

Treatment options for an Achilles tendon rupture include surgical and nonsurgical approaches, although opinions are divided as to what is the best course of action. The conservative intervention of Achilles tendon rupture traditionally consisted of short- or long-leg cast immobilization in the gravity equinus position (10–20 degrees of plantarflexion). However, this approach was found to result in a high incidence of re-rupture (10–30%) [570–573] and a decrease in maximal function.[562,574,575] This is may be because it is impossible to restore the correct length of the Achilles' tendon with nonoperative treatment.[566] Recent studies have produced superior results with a much quicker rehabilitation using fixed or hinged boots.[452–455]

The results from the surgical approaches have varied with the recent studies reporting small, but statistically significant benefits from surgery.[456,457]

Sever's Disease (Calcaneal Apophysitis)

Sever's disease is a traction apophysitis at the insertion of the Achilles tendon and is a common cause of heel pain in the athletically active child, with 61% of cases occurring bilaterally.[576]

The calcaneal apophysis serves as the attachment for the Achilles tendon superiorly and for the plantar fascia and the short muscles of the sole of the foot inferiorly.[577] This os calcis secondary center of ossification appears at 9 years of age and usually fuses at 16 years of age.[66] The average age of onset for this condition is 8–13 years.[578]

Factors involved in the etiology of Sever's disease include beginning a new sport or season, foot pronation, and a tight gastrocnemius–soleus complex.[66,579] Young gymnasts and dancers are particularly susceptible to this condition because of their repetitive jumping or landing from a height.[579] The tight Achilles' tendon is usually associated with a recent growth spurt and is not related to a specific injury.[66]

Although radiographs are often normal, sclerosis or fragmentation of the apophysis may be seen on plain radiographs.[66]

The location of the pain differs from that of plantar heel pain in that its focal point is more posterior than it is plantar.

The intervention for Sever's disease begins with stretching the heel cord, using heel cups or heel wedges, and avoiding barefoot walking until becoming asymptomatic.[492]

Iselin's Disease

Iselin's disease is a traction apophysitis of the tuberosity of the fifth metatarsal, which is more commonly seen in athletically active older children and adolescents.[66] The secondary center of ossification appears as a small, shell-shaped fleck of bone oriented slightly oblique to the metatarsal shaft and is located on the lateral plantar aspect of the tuberosity of the

fifth metatarsal.[66] T is apophysis is located within the insertion site of the fibularis (peroneus) brevis tendon. T e center appears in girls at an average of 9 years and in boys at 12 years and usually fuses to the shaft by 11 and 14 years, respectively.

T e patient is usually involved in sports with running, cutting, and jumping. T ese activities may result in an inversion stress to this area. T ere is usually pain over the area, but no specific history of trauma. Resisted eversion typically reproduces the pain. A bone scan will usually be positive. Iselin's disease can be differentiated from an avulsion fracture of the base of the fifth metatarsal because the apophysis is located parallel to the long axis of the shaft, and an avulsion fracture is usually transverse in nature.[66]

T e intervention for Iselin's disease includes immobilization for acute pain and physical therapy for strengthening of the fibularis (peroneal) tendons.[580]

Plantar Heel Pain

Plantar heel pain, which is the term used to describe pain arising from the insertion of the plantar fascia, with or without heel spur, has been experienced by 10% of the population.[581–583] Plantar heel pain is usually unilateral, although, in 15–30% of people, both feet are affected.[73] T e condition, often referred to as plantar fasciitis, is an inflammatory process. Waugh[584] has recently proposed that previously accepted inflammatory conditions, such as epicondylitis and plantar fasciitis, may be more accurately referred to as chronic pain syndromes.[585]

A number of factors have been proposed for the etiology of this condition:

- Obesity.[586] Obesity has been shown to occur in 40% of men and 90% of women with plantar heel pain.[587,588] A BMI greater than 30 kg/m^2 increases the risk of developing plantar heel pain.[589]
- Occupational. T ere is an association between plantar heel pain and prolonged standing or walking ("policeman's heel"),[73] or a sudden change in the stresses placed upon the feet likening this condition to other repetitive stress disorders such as carpal tunnel syndrome and tennis elbow.
- Acute injury. Although less common, plantar heel pain may be associated with an acute injury to the heel. Some people recall stepping on a pebble, or other hard object, before the pain began ("stone bruise").[73]
- Anatomical. T e heel pad is specially constructed as an efficient shock absorber to attenuate peaks in dynamic forces and to dampen vibrations.[158] Part of the impact energy involved in displacement of the heel pad during ambulation is dissipated, and part of the energy is recovered in the subsequent elastic recoil. Two studies that examined the mechanical properties of the heel pad[590,591] found that thickness and compressibility index (CI; ratio of thickness of the loaded heel pad to that of the unloaded one) were greater in patients with plantar heel pain. T is finding implies that loss of elasticity of the heel pad may be a factor in plantar heel pain syndrome. In addition, impaired vascularity with subsequent metabolic disturbance is also been proposed as one of the anatomical causes. A moderate to marked increase in vascularity in the proximal plantar fascia has been observed in patients with plantar fasciitis.[592] Similar vascularization has been observed in patients with Achilles, patellar, and tendinopathy.[593]
- Biomechanical causes. People with high arches (pes cavus) or low arches (pes planus) are at increased risk because of the increased repetitive stress being placed on the fascia.[73] Likewise, adaptive shortening of the calf muscles and Achilles tendon, excessive hindfoot motion (especially overpronation), or a rigid varus hindfoot may also put the patient at risk, by placing excess stress on the plantar fascia.[377,594–596] Amis et al.[595] found that 78% of patients with painful heels had ankle dorsiflexion limitations of at least 5 degrees. Kibler et al.[596] noted that 90% of running athletes with plantar fasciitis had either a lack of 5 degrees dorsiflexion beyond neutral on the affected side or a lack of 10 degrees or more dorsiflexion compared with the noninvolved side. A weakness of the intrinsic foot muscles has also been cited as a cause. T ese factors may increase the moment of maximum tension in the fascia, which, even under normal circumstances, endures tension that is approximately two times body weight while walking at the moment when the heel of the trailing leg begins to lift off the ground. T us, an accurate history of footwear should be obtained: Often patients wear shoes with poor cushioning or inadequate arch support or they walk barefoot on hard floors.

Although more common in active individuals, plantar heel pain can also affect the sedentary although the reasons for this remain elusive. Despite the fact that modern shoes are designed with every conceivable type of heel cushioning, plantar heel pain continues to be a pervasive entity. Although more common in middle-aged individuals, plantar heel pain can occur in the younger individual, although it rarely exists alone in this age group and usually coincides with calcaneal apophysitis.[66] As the plantar fascia assists in the development of the push-off power during running and jumping, it is not surprising that plantar heel pain is particularly prevalent in joggers and tennis players, as well as in athletes participating in racquet sports, soccer, gymnastics, and basketball.[73]

T e role of the heel spur in plantar heel pain is controversial.[73] Half of patients with plantar heel pain have heel spurs,[587] whereas 16–27% of the population have heel spurs without symptoms.[201,597] T e greater pull of the plantar fascia was thought to lead to periosteal hemorrhage and inflammatory reaction and to laying down of new bone and heel spur formation,[598] but the heel spur is more often associated with the FDB muscle than the plantar fascia.[210,525,595,599–602]

Since chronic subcalcaneal heel pain is a common manifestation of many conditions, the following diagnoses must be excluded:

- Inf ammatory spondyloarthropathies. T ese disorders should be considered when multiple joints or areas are involved. Up to 16% of patients presenting with subcalcaneal pain will later be diagnosed with a systemic arthritic disorder.[43,73]
- Calcaneal stress *f*racture.[603] T e history for calcaneal stress fractures usually involves a sudden increase in

running activities, such as that seen in a military recruit at boot camp or a reservist.

- Nerve entrapment.[603,604,605] Heel pain was recently reported to involve the nerve to abductor digiti quinti, the first branch of the lateral plantar nerve.[606] In a fifth of cases of inferior heel pain, the pain may be caused by this nerve being trapped between the abductor digiti quinti muscle and the quadratus plantae muscle or affected by inflammation of the plantar fascia.[606] Positive percussion (Tinel's sign) on the medial aspect of the heel should lead to a suspicion of an entrapment of the nerve that supplies the abductor digiti quinti, or a TTS.[43]
- *T*umors. Tumors in this area, including a proximal plantar fibroma, are quite rare, presenting as palpable masses or bony erosions of the calcaneus.
- In*f*ections.[607] As with infections in other parts of the body, there will usually be some swelling and/or erythema and a history of malaise or fever.
- Neuropathy (diabetic, alcoholic).[603] A history of burning pain, numbness, or paresthesias can often be elicited in patients with neuropathic pain. A thorough neurologic examination will confirm the diagnosis.
- T e *f*at-pad syndrome.[42,608] Pain while hopping on the toes may help distinguish this entity from the fat-pad syndrome.

T e diagnosis of plantar heel pain is typically made on the basis of the history and clinical findings[609]:

- Reports of pain and tenderness on the plantar medial aspect of the heel, especially during initial weight bearing in the morning or after any period of inactivity. T is is thought to be due to the fact that the plantar fascia becomes contracted, or stiff.[610] T e patient may also report pain that radiates up the calf and toward the toes. In severe cases, the pain may have a throbbing or burning quality. Interference with daily activities is common.[73,611,612]
- T e heel pain often decreases during the day but worsens with increased activity (such as jogging, climbing stairs, or going up on the toes).
- Localized pain on palpation along the medial edge of the fascia or at its origin on the anterior edge of the calcaneus, although firm finger pressure is often necessary to localize the point of maximum tenderness.[43] T e main area of tenderness is typically just over and distal to the medial calcaneal tubercle, and usually there is one small extremely painful area. Tenderness in the center of the posterior part of the heel may be due to bruising or atrophy of the heel pad or to subcalcaneal bursitis.[587]
- Slight swelling in the area is common.[595]
- Abnormal Foot Posture Index Score
- Positive windlass test
- Negative tarsal tunnel tests
- Limited active and passive talocrural joint dorsiflexion ROM. A tightness of the Achilles tendon is found in 78% of patients.[587,595]
- High BMI in nonathletic individuals.

A recent review of the literature at the plantar heel pain interventions concluded that there was no quality information regarding the effectiveness of treatments of the heel pain.[582] T e interventions thus far attempted include the following:

- Night splinting. Night splints can be prescribed for a 1–3-month program for patients who consistently have pain with the first step in the morning. T ere is limited evidence for night splints to treat chronic symptoms.[613]
- Orthotics. Most of the orthotics are designed to correct biomechanical faults, especially over pronation. Foot orthoses, either prefabricated or custom fabricated/fitted can be used to support the medial longitudinal arch cushion the heel to reduce pain and improved function for short- (2 weeks) to long-term (1 year), especially in those individuals who respond positively to antipronation taping techniques.
- Heel cups/taping. Antipronation taping can be used for immediate the purposes (up to 3 weeks) pain reduction and improved function. Additionally, an elastic therapeutic tape can be applied to the gastrocnemius and plantar fascia for short-term (1 week) pain reduction.[609] Lynch et al.[614] performed an unblinded prospective trial of 103 subjects with plantar heel pain randomized into one of three groups of treatment: anti-inflammatory (NSAIDs and steroid injections), accommodative (viscoelastic heel cup), or mechanical (taping for 4 weeks followed by custom orthoses). At the end of 3 months, there was no significant difference in activity level and first step pain between the groups. However, the mechanical treatment group (taping) had significantly better VAS scores than the accommodative group (heel cup) and had a significantly better rate of fair or excellent outcomes. A randomized controlled trial by Hyland et al.[585] found calcaneal taping to invert the heel and raise the medial longitudinal arch to be a more effective tool for the relief of plantar heel pain than stretching, sham taping, or no treatment after 1 week. Taping can be considered as a means of reinforcing either the calcaneal fat pad and/or the medial longitudinal arch.[93] Prior to applying the tape, the patient should be relaxed and the heel and foot placed in neutral. Excessive tension through the strips will lead to complaints during activity. T e tension in the tape flow is critical if skin breakdown is to be avoided with repeated taping. T e patient should be in weight bearing throughout the foot before applying the final closing strips.
- Exercises. Some evidence exists for plantar fascia stretching to address chronic plantar fasciitis.[615] One study[616] demonstrated that the position of ankle dorsiflexion and MTP joint dorsiflexion stretch the plantar fascia more consistently than ankle or MTP joint dorsiflexion alone. T is would tend to suggest that the use of ankle dorsiflexion combined with the MTP joints dorsiflexed is an effective stretch of the plantar fascia. Other exercises typically involve strengthening exercises and movement training for muscles that control pronation and attenuate forces during weight-bearing activities. Furthermore, specific exercises (e.g., short foot exercises) are believed to selectively recruit the intrinsic muscles of the foot, which are typically found to be weak with plantar fasciitis.[26]

- Deep frictional massage. This can be applied manually VIDEO or through the use of a tennis ball VIDEO, or golf ball VIDEO.
- Physical agents. The only physical agents that have shown some efficacy include low-level laser, phonophoresis, and ultrasound.[609]
- Shoe modifications. A rocker bottom shoe construction in conjunction with a foot orthosis may be prescribed to reduce pain.
- Education and counseling. Education and counseling on exercise strategies to gain or maintain optimal lean body mass. In addition, the clinician may refer an individual to an appropriate health care practitioner to address nutrition issues.
- Casting. Recalcitrant or long-standing cases of plantar heel pain may require casting. This can take the form of a short-leg walking cast positioned in neutral (plantigrade) for 4–6 weeks. Patients with severe pain and marked limitation of activity are best treated with a molded, below-knee, walking cast for 3–4 weeks.[39] It provides a relative rest, reduces pressure on the heel at heel strike, provides arch support, and prevents tightening of the Achilles tendon. A night splint positioned in 5 degrees of dorsiflexion is worn for an additional 6 weeks once the cast is removed, and the patient can resume the stretching and strengthening program for an additional 6 weeks once the cast is removed.[73]

A number of clinical trials have attempted to examine the efficacy of intervention combinations for plantar heel pain. The University of Pittsburgh Medical Center Foot and Ankle Clinic has advocated nonsurgical treatment of insertional plantar heel pain using a standardized regimen since 1992.[617] The regimen is as follows:

- Take NSAIDs as directed for 4 weeks.
- Attend the University of Pittsburgh Sports Medicine Clinic for a one-time instructional home-exercise program of Achilles stretching (four exercises) and plantar fascia stretching (two exercises). The subject is instructed to continue the exercises for six sets, holding each for 30 seconds × 3/day.
- Wear a night splint every night to bed.
- Use an orthosis or heel cup at all times when wearing shoes.

The reported outcomes in this study were not as good as the average outcome reported in other published studies, with only 51% being asymptomatic after 4 months.[617] The authors cited that the reasons for this were that other studies may have included subjects with causes of subcalcaneal heel pain other than true plantar heel pain, making direct comparison difficult.

The lack of universal intervention for plantar heel pain, and the poor level of long-term success, likely stems from its many causes. A poor response to intervention may be due, in part, to inappropriate and nonspecific techniques or an inaccurate diagnosis. The etiological trauma for plantar heel pain occurs after the peak loads of initial contact are reached and as the center of mass advances beyond the ankle. This would tend to indicate that the forces associated with initial contact are not directly linked to the stresses that are applied to the plantar fascia. Indeed, the highest force loads on the foot during gait occur at the forefoot. These forces have been found to be 15–25% higher than those occurring during initial contact. Fortunately, the foot has a built-in mechanism to deal with these loads—the Windlass mechanism. As the heel rises about the rotating MTP joints, the plantar fascia, through its insertion into the bases of the digits, "winds" itself around the drum-like metatarsal heads. This creates a winch-like effect that pulls the proximal aspect of the heel closer to the ball of the foot and elevates the medial longitudinal arch, which, in turn, provides a stable platform upon which propulsion can occur. Critical to the efficiency of the Windlass mechanism is the ability of the first MTP joint to dorsiflex during the heel-raise phase of gait. An inability to dorsiflex the first MTP is called functional hallux limitus (see "Examination" section).

Given that plantar heel pain appears to be impairment based, an impairment-based physical therapy examination and intervention approach would appear to be logical.[613] Such an approach has been investigated in several randomized controlled trials. Pollard and So[618] reported full recovery in a 35-year-old male with a 3-month history of right inferior heel pain, using a combination of talocrural and talocalcaneal joint mobilization, stretching, strengthening, custom orthosis, and pain modalities. Patla and Abbott[212] reported restoration of pain-free functional activities with the use of manual posterior tibialis stretching in two patients with primary complaints of heel pain. Young et al.,[613] in a case series, treated four patients with plantar heel pain, using an impairment-based physical therapy approach, which emphasized manual therapy. All four patients demonstrated complete pain relief and full return to activities.[613]

On the basis of the above-mentioned studies, the intervention for plantar heel pain should include the following:

- Rest or at least avoidance of any activity that continually provides axial loading of the heel and tensile stresses on the fascia.
- A recommendation of shoes that provide good shock absorption at the heel and support to the medial longitudinal arch and plantar fascia.
- The identification of the cause of any tissue overloading that is occurring, as well as any functional biomechanical deficits (plantarflexor inflexibility and weakness) and functional adaptations (running on toes, shortened stride length, and foot inversion).
- Strengthening exercises. A number of strengthening exercises have been devised for plantar heel pain:
  - Towel curls. A towel is placed on a smooth surface, with the foot placed on the towel. The patient is instructed to pull the towel toward the body by curling up the toes, and then attempt to move the towel in the reverse direction VIDEO.
  - Marble pick-ups. A few marbles are placed on the floor near a cup. While keeping the heel on the floor, the patient uses the toes to pick up the marbles and drop them in the cup.
  - Toe taps. The patient is instructed to keep the heel on the floor and lift all of the toes off the floor. The patient is asked to tap the big toe to the floor while keeping the

outside four toes in the air. Next, the patient keeps the big toe in the air, while tapping the other four toes to the floor.

A regimen of stretching of the gastrocnemius and the medial fascial band, especially before arising in the morning and after sedentary periods during the day, as well as before and after exercise.[619]

- Gastrocnemius and soleus. Patients are taught how to stretch the gastrocnemius and soleus VIDEO components of the triceps surae independently while minimizing stress on the plantar fascia. After a warm-up, the patient stands against a wall, with his or her hands placed against the wall. With one foot forward and one behind, the patient leans his or her trunk toward the wall, shifting their weight over the front foot, while straightening the knee of the back leg. The heel of the back foot should remain on the floor while the front of the foot is internally rotated and supinated, to stabilize the medial longitudinal arch, putting the foot in the close-packed position and allowing for the stretch to be isolated to the Achilles tendon.[73] The stretch is then repeated on the other leg. A similar stretch can be done by standing on a stair step, with only the toes on the stairs and the back two-thirds of the feet hanging off the step. By leaning forward to balance, the heel, Achilles tendon, and calf will be stretched. The stretch can also be performed when standing, where the heel is on the floor, and the front part of the foot is on a wooden 2 × 4.
- Plantar fascia stretch. The plantar fascia stretch is performed with the patient sitting with their legs crossed, with the involved leg over the contralateral leg. Then, while using the hand on the affected side, the patient places his or her fingers at the base of the toes on the bottom of the foot (distal to the MTP joints) and pulls the toes back toward the shin until a stretch is felt in the arch of the foot. The correct stretch is confirmed by palpating the tension in the plantar fascia with the contralateral hand while performing the stretching. In a prospective randomized trial from DiGiovanni et al.,[615] 101 patients who had chronic proximal plantar heel pain for at least 10 months were randomized into one of two treatment groups. The mean age was 46 years. All patients received prefabricated soft insoles and a 3-week course of celecoxib, and they also viewed an educational video on plantar heel pain. The patients received instructions for either a plantar fascia tissue-stretching program (Group A) or an Achilles-tendon-stretching program (Group B). All patients completed the pain subscale of the FFI and a subject-relevant outcome survey that incorporated generic and condition-specific outcome measures related to pain, function, and satisfaction with treatment outcome. The patients were reevaluated after 8 weeks. Eighty-two patients returned for follow-up evaluation. With the exception of the duration of symptoms ($p < 0.01$), covariates for baseline measures revealed no significant differences between the groups. The pain subscale scores of the FFI showed significantly better results for the patients managed with the plantar fascia-stretching program with respect to item 1 (worst pain; $p = 0.02$) and item 2 (first steps in the morning; $p = 0.006$).[615] Analysis of the response rates to the outcome measures also revealed significant differences with respect to pain, activity limitations, and patient satisfaction, with greater improvement seen in the group managed with the plantar fascia-stretching program.

The stretches are performed twice daily, beginning with a sustained stretch for 1 minute and progressing to 3 minutes based on tolerance.[606] The rest period should involve gentle active dorsiflexion and plantarflexion exercises, while resting the Achilles tendon and calf on a hot pack to enhance the stretch.[73] Massage to the foot in the area of the arch and heel or rolling the foot over a tennis ball or a 15 oz can may also be helpful.

- Orthotics may be prescribed, but only after careful examination of the footwear to ensure a firm, well-fitting heel counter, good heel cushioning, and an adequate longitudinal arch support.[620] A wide variety of rigid, semirigid, and soft shoe inserts are commercially available, although rigid plastic orthoses rarely alleviate the symptoms and often aggravate the heel pain.[587] Orthoses made of softer materials provide cushioning by reducing the shock of walking by up to 42%.[43] Since the plantar fascia is stretched during flattening of the foot, orthoses should be designed to maintain the medial longitudinal arch during ambulation, and should be prescribed in full length or three-quarters length-accommodative inlays of medium-density plastazote.[43]

The type of orthotic prescribed depends on the findings[73]:

- Normal foot. Off-the-shelf heel cups should be used to cushion the heel. Cyriax recommended heel lifts to relieve the strain on the plantar fascia during early treatment,[175] and bilateral heel lifts of ¼–⅜ in are sometimes successful, but their use should be discontinued at the earliest possible time.[93]
- Pes planus (flat foot). For this foot type, the orthotic is used to stabilize the arch and thereby decrease the strain on the plantar fascia. A University of California-Biomechanics Laboratory (UC-BL) type of orthotic is indicated.
- Pes cavus (high arch). An excessively high arch or cavus foot can cause an inability to evert the foot to dissipate stress. In this situation, the orthotic of choice would be one that focuses on cushioning to increase the total contact area of the foot.

Bursitis

Retrocalcaneal Bursitis

Retrocalcaneal bursitis is a distinct entity denoted by pain that is anterior to the Achilles tendon, just superior to its insertion on the os calcis. This type of bursitis appears to be more common in older individuals and low-level recreational athletes.[94,621]

The bursa becomes inflamed, hypertrophied, and adherent to the underlying tendon, resulting in deep pain and visible swelling.[45,94] Characteristic findings include pain with a two-finger squeeze just superior and anterior to the Achilles insertion and pain with passive dorsiflexion.[66]

Retrocalcaneal bursitis is treated conservatively with shoe modifications (open backed if necessary) and a heel lift.[66] In rare cases, a bursectomy with associated resection of the posterior superior margin of the os calcis is necessary.

A small percentage of the population has an adventitious subcalcaneal bursa, which may become inflamed and cause heel pain.[597]

Anterior Ankle Bursitis

Anterior ankle bursitis is commonly seen in young figure skaters and ice hockey players.[66] T is condition can present with swelling over the anterior ankle or over either malleolus. A doughnut pad inside the skate over the irritable area will usually decrease the pressure at this point.[66]

Haglund's Deformity

Haglund's deformity[622] refers to an abnormal prominence of the posterior superior lateral border of the calcaneus. Because of its association with various shoe types, it is often referred to as a "pump bump,"[623] "high heel,"[624] and "winter heel."[625,626]

T e prominence is frequently a bony spur or osteophyte acquired as the result of poorly fitting of shoes in adolescent females, ice skaters, soccer players, and runners,[210] but is also thought to be a congenital variation.

Whatever the etiology of these various prominences, they frequently aggravate the retrocalcaneal bursa on the deep surface of the Achilles tendon, producing an associated retrocalcaneal bursitis or Achilles tendinopathy.[66]

On physical examination, a bump, which is 2–3 cm in diameter, is usually located more to the lateral side of the heel, and there is often an accompanying thickening of the overlying skin. Pain is often noted on palpation just proximal and slightly lateral to the insertion of the Achilles tendon.[619] Sometimes a varus hindfoot is found. A cavus or high-arched foot is believed to change the calcaneal position and increase the prominence of this ridge.[619]

Before intervention is initiated, the differential diagnosis must be considered, including systemic disease, Achilles tendinopathy, or intrinsic conditions of the calcaneus, such as infection and tumor.[66]

Intervention involves relieving the friction imposed by the shoe counter by using a softer heel counter, increasing shoe size by one-half, padding the prominence, or using a heel lift to actually raise the heel out of the shoe.[94,626,627] Achilles stretching and strengthening and the use of local modalities, such as ultrasound, are also recommended.[66]

Surgical excision of the deformity is reserved for persistent symptoms in the young athlete.[623,626,628]

Metatarsalgia

Metatarsalgia is defined as pain in the plantar aspects of the lesser metatarsal heads adjacent to the MTP joints due to repetitive high-pressure loading under the metatarsal head that causes pain.[58] During the normal gait cycle, the center of pressure progresses along the plantar aspect of the foot from the heel at initial contact to the toes at terminal stance. T e center of pressure is initially located in the central heel and then accelerates rapidly across the midfoot to reach the forefoot, where it is located under the second and the third metatarsal head, rather than under the first and the fifth metatarsal head and the calcaneus, as was once thought.[58,115,120] T is weight-bearing force is approximately equal to the body weight, which is more than twice the load carried by the other toes combined.

Any biomechanical intrinsic or extrinsic condition that increases stress on the metatarsal heads may result in metatarsal head pain and the development of painful plantar keratoses or calluses.[202] Plantar keratoses may be diffuse and large or small and discrete.

- A Morton's foot with a short first metatarsal and a relatively long second metatarsal may result in increased loading of the second metatarsal head and the development of a painful callus.[629]
- Patients with abnormally lax first metatarsal–cuneiform joints, resulting in a hypermobile first ray, can experience increased weight bearing under the second and third metatarsals, which often results in painful diffuse calluses.[58]
- A prominent lateral condyle of a lesser metatarsal can result in a smaller discrete plantar keratosis, which can be exquisitely tender to palpation.
- A tight Achilles tendon can increase the forefoot load in late-stance phase and may result in metatarsalgia.[58]
- T e use of high-heeled shoes extrinsically increases forefoot load and may lead to diffuse metatarsalgia.

T e intervention for metatarsalgia involves the use of a metatarsal pad that is placed proximal to the painful metatarsal heads. Adhesive-backed metatarsal pads of different shapes and sizes are available to unload one or several metatarsal heads. Custom orthotics may also be molded specifically for the cavus foot to decrease load on the plantarflexed first and second rays, to distribute weight evenly across the forefoot. A patient with a hypermobile first ray will benefit from a custom longitudinal arch support with medial forefoot post. A trial of Achilles stretching is helpful in the initial treatment of metatarsalgia. T e wearing of high heels should be discouraged in patients with metatarsalgia.

If unresponsive to conservative intervention, surgical plantar condylectomy may be required for resolution of a discrete plantar keratosis. More generalized diffuse painful calluses such as those seen under the first and second metatarsal heads in the cavus foot may require posterior (dorsal) closing wedge osteotomies of the metatarsal bases to achieve pain relief.[202]

Idiopathic Synovitis

Idiopathic synovitis of the second or third MTP joint is another cause of metatarsalgia. T is condition results in painful distension of the joint, swelling of the second toe, warmth, and limited MTP joint motion.[630] Second MTP joint synovitis probably occurs as a result of attrition of the plantar plate due to a long second metatarsal.[631] Posterior (dorsal) instability of the MTP joint may develop with joint subluxation or dislocation. A hammer toe or claw toe deformity is common.

Initially, the patient develops pain on palpation in the plantar and posterior (dorsal) aspects of the MTP joint. Joint instability can be diagnosed with passive articular mobility testing.

Conservative intervention includes NSAIDs, a metatarsal pad, taping the toe in a plantarflexed position, and an accommodative shoe. An intraarticular corticosteroid injection in combination with a rocker-sole modification has been shown to result in improvement in 93% of 15 cases.[632] Persistent pain in the second MTP joint despite conservative measures may necessitate operative synovectomy to avert toe dislocation or deformity.

Metatarsalgia of the Fifth Toe

This is usually due to overwork of the fibularis (peroneus) longus/brevis secondary to an unstable ankle. The overwork of the brevis leads to an instability of the fifth metatarsal at the intermetatarsal or cubometatarsal joints. The patient will point to the tubercle of the fifth metatarsal and complain of pain in the proximal part of the fibularis (peroneus) muscle. Conservative intervention involves taping a strip of tape over the posterior aspect of the foot and then one strip on the medial aspect, going proximally to distal. These two strips are then connected with strips of tape under the foot, across the sole.

Anterior Ankle Impingement

Anterior ankle impingement can be bony or soft tissue related. Patients with this problem usually present with anterior ankle pain exacerbated by extreme dorsiflexion.[19,66]

A bony impingement can be seen in young ballet dancers who exercise in extreme ankle dorsiflexion, irritating the periosteum on the talar neck, and leading to an exostosis and discomfort with pliés.[579]

A soft-tissue impingement can be secondary to generalized synovitis or capsulitis that can develop after an acute or recurrent episodes of an inversion ankle sprain. It can also occur in adolescent gymnasts who sustain repeated forced dorsiflexion in landing and dismount.

Chronic anterolateral ankle impingement due to a thickened and scarred joint capsule is a frequent sequela of recurrent ankle sprains. Wolin et al.[633] reported in 1950 that recurrent pain and swelling after injury to the lateral ligaments without instability in patients with a history of previous ankle sprains was due to hyalinized connective tissue arising from the anteroinferior portion of the talofibular joint capsule. They believed that the symptoms resulted from this connective tissue becoming pinched in the talofibular joint with motion. As this mass of tissue and synovium increases in size, impingement of the tissue mass between the talus, tibia, and fibula causes further irritation and pain. This has since been confirmed arthroscopically and by MRI.[634–641]

Bassett et al.[642] reported a cause of chronic pain in the ankle after inversion sprain in seven patients as being due to talar impingement by a distal fascicle of the anterior–inferior tibiofibular ligament.

On physical examination, there is usually pain to palpation anteriorly, with no palpable swelling.[407] Plain ankle radiographs can be helpful in determining a bony problem, but a bone scan is usually necessary for a definitive diagnosis. MRI may also be diagnostic.

The intervention for the soft-tissue impingement variety includes discontinuing landing temporarily, icing,[525] antiinflammatories, and exercises to stretch the Achilles tendon and strengthen the dorsiflexors. Occasionally, a pad taped over the anterior ankle may provide temporary relief.[407] Arthroscopy may be indicated if conservative treatment fails. A partial synovectomy[643] or excision of osteophytes is successful but must be followed by exercises to prevent recurrence.

Posterior Ankle Impingement

Posterior ankle impingement or talar compression syndrome[69] is seen most often in young female dancers, ice skaters, or gymnasts.[66] These sports require excessive plantarflexion of the ankle, compressing the posterior structures of the ankle.[69,522]

On physical examination, the patient will have pain on palpation of the posterior ankle, dramatically increased with forced plantarflexion.[66]

Plain radiographs of the ankle can be taken to rule out a bony etiology (i.e., os trigonum).[69] Soft-tissue etiology includes FHL irritation, a thickened or invaginated posterior capsule, synovitis, and calcific debris.[522,644,645]

Sesamoiditis

This condition has been defined as inflammation and swelling of the peritendinous structures of the sesamoids. The tibial (medial) and fibular (lateral) sesamoids are situated under the first metatarsal head. These sesamoids are prone to injury in repetitive high-impact and contact sports.[58] Since the tibial sesamoid bears most of the force under the first metatarsal head, it is most commonly injured.[58]

Although direct trauma or forced dorsiflexion of the great toe can acutely fracture the sesamoids, most sesamoid injuries are overuse injuries. Twelve percent of injuries to the great toe complex are sesamoid injuries.[60]

The etiologies of sesamoid injuries include stress fracture (40%), acute fractures (10%), chondromalacia, synovitis, sesamoiditis (30%), osteochondritis (10%), arthritis (5%), and bursitis (5%).[60] Bipartite or multipartite sesamoids occur in 5–33% of the population and are bilateral in 25%.[63,646]

The diagnosis of sesamoiditis is one of exclusion.[647] Sesamoiditis is associated with local trauma, pain on weight bearing, and plantar soft-tissue swelling.[648] Passive dorsiflexion of the MTP joint while palpating the sesamoids exacerbates the pain. Sesamoidal bursitis presents with swelling, erythema, and tenderness with a side-to-side pinch. A plantar fullness or fluid-filled bursal cyst may be palpated under the sesamoids.

Conservative intervention involves rest from the offending activity, NSAIDs, and low-heeled shoes with a soft metatarsal support proximal to the metatarsal head, to decrease the load on the involved sesamoid.[649] One or two injections of corticosteroids into the region of the sesamoids may be helpful.[58] Failure of several months of conservative care may result in the need for surgical excision of the offending sesamoid to alleviate symptoms.[649]

MEDIAL TIBIAL STRESS SYNDROME

Exercise-induced anterior and medial leg pain has been reported to account for 60% of all injuries causing leg pain in

athletes.[650] A number of generic terms such as "medial tibial syndrome," "tibial stress syndrome," "shin splints," "posterior tibial syndrome," "soleus syndrome," and "periostitis" have evolved over the years to describe exercise-related leg pain. Of all these terms, MTSS is the most appropriate.

MTSS was originally thought to involve a periostitis caused by abnormal traction by the deep flexor and/or soleus muscles.[651] However, a 2009 study[652] reported that the cause was due to a mismatch between bony resorption and formation with resultant overloading of the tibial cortex. T e anatomic site of the abnormality has been fairly well localized to the fascial insertion of the medial soleus.

T e characteristic complaint in these patients is a dull aching pain in the middle or distal posteromedial tibia. Early in this process, the pain usually occurs at the beginning of a run, resolves with continued exertion, only to recur toward the end or after a workout.[653] At this stage, the pain typically subsides quickly with rest.[653] With continued training the pain usually becomes more severe, and persistent, and with increasing chronicity, the pain may be present with ambulation or at rest.[653]

MTSS is associated with an imbalance of foot pressure (greater on the medial foot), excessive pronation, a sudden increase in intensity and/or duration of training, and an uneven training terrain.[92] T ese factors increase soleus strain by eccentric contraction to resist pronation. Other findings associated with MTSS include decreased hip internal rotation, increased ankle plantarflexion, and a positive navicular drop test.[654] In contrast, overuse or weakness of the tibialis anterior, EDL, or EDB may be the causative factors in anterior shin splints, as are excessive or abnormal pronation, restricted ankle joint dorsiflexion, training errors, and inadequate footwear.[110]

With the exception of pain and point tenderness at the anteromedial aspect of the tibia, which is increased with active dorsiflexion and passive stretching into plantarflexion, there are few objective findings. However, the pain is usually provoked by activity and relieved with rest.

As with most overuse injuries, the intervention for MTSS involves rest and cross-training using low-impact activities such as stationary biking and underwater running. Once symptoms resolve, a gradual return to sports is recommended using a slow acceleration (10–25% every 3–6 weeks), while making sure to identify and correct any training errors or abnormal foot biomechanics.[655] Surgical options include a release of the deep posterior compartment, including the soleus sling and removal of a strip of posteromedial tibia periosteum.[92]

PREFERRED PRACTICE PATTERN 5F: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM, OR REFLEX INTEGRITY SECONDARY TO PERIPHERAL NERVE INJURY

An entrapment neuropathy is characterized by an entrapment of a peripheral nerve by fascia, a ligament, a bony groove, or a tendinous arch of a muscle origin. Sural nerve neuropraxias and fibular (peroneal) nerve palsies are an infrequent complication of lateral ligamentous injuries of the ankle but are quite problematic.[19,167] EMG evaluation of patients with ankle sprains reveals that up to 80% of patients with severe ankle sprains have some evidence of fibular (peroneal) nerve injury.[19,167]

Interdigital Neuroma

An interdigital neuroma, which is also referred to as a Morton's neuroma, is a mechanical entrapment neuropathy of one of the interdigital nerves in the forefoot.[11] T e name of the condition is a misnomer, as a true neuroma does not exist. Rather, there is a thickening of the tissues around the nerve due to perineural fibrosis, fibrinoid degeneration, demyelination, and endoneural fibrosis.[58,656] In a study of 91 patients with interdigital neuromas, the male: female ratio was 1:9.[657]

Although a common cause of this condition is chronic compression of the interdigital nerve, it can also occur due to an acute dorsiflexion injury to the toes, with an associated injury to the collateral ligaments of the MTP joint.[58,199]

Symptoms are usually aggravated with weight bearing and somewhat relieved by rest and forefoot.[58,199] Incorrect shoe selection, such as wearing a cross-training or racket shoe for long-distance running, may increase the impact forces on the forefoot and contribute to the symptoms.[58] Narrow shoes and high-heeled shoes have also been implicated.

Physical examination reveals tenderness in the webspace plantarly between the metatarsal heads.[58] Squeezing the forefoot with one hand, while carefully palpating the involved interspace with the thumb and index fingers of the other hand, will usually elicit marked discomfort.[58] T is compression may produce a painful audible click, known as Mulder's sign.[658] Careful palpation of the MTP joint, metatarsal head, and proximal phalanx should be performed to rule out localized joint or bone pathology such as MTP joint synovitis, stress fracture, or Freiberg's disease, which can also cause symptoms of forefoot pain.[58] A positive Tinel's sign over the tarsal tunnel or multiple symptomatic webspaces should alert the clinician to the possibility of a more proximal nerve compression or underlying peripheral neuropathy.[58] Electromyography (EMG) studies and nerve conduction velocity (NCV) testing should be performed in these cases.[199]

T e intervention initially involves an avoidance of the offending activity, cross-training using lower-impact sports, and a modification of footwear—a switch to wider, more accommodating shoes with soft soles and better shock absorption[58] In addition, a metatarsal pad, placed proximal to the symptomatic interspace, may prove helpful.[58] T e metatarsal pad can also be incorporated into a custom-made full-length semirigid orthotic.[58] A trial of NSAIDs is indicated in an attempt to decrease inflammation around the interdigital nerve.[58] A trial of vitamin B6 has been used successfully in the treatment of carpal tunnel syndrome and may also be useful in the treatment of interdigital neuritis.[659]

Recalcitrant cases that fail to respond after 2–3 months of the above conservative measures may benefit from an injection of corticosteroids.[58] One to two injections can be tried, but multiple injections should be avoided, as corticosteroids

may cause atrophy of the plantar fat pad.[58] Surgery is the intervention of last resort.

Deep Fibular (Peroneal) Nerve Entrapment/Anterior TTS

Entrapment of the deep fibular (peroneal) nerve was first reported in 1963[660] and was given the name anterior TTS in 1968.[661]

At the ankle level, both motor and sensory branches of the deep fibular (peroneal) nerve are present.

Anterior tarsal syndrome[662] occurs when there is a contusion to the terminal branch of the deep fibular (peroneal) nerve, as it travels beneath the posterior tibialis and EHB tendons, and above the first and second cuneiforms, where it is relatively unprotected.[663] T e compression usually results from tight boots or from the shoe straps of high heels, a ganglion, pes cavus, or from direct trauma.[662,664] A partial anterior TTS[665] occurs when either the motor branch to the EDB or only the sensory branch of the deep fibular (peroneal) nerve is compressed beneath the inferior extensor retinaculum.[663]

Patients with anterior TTS complain of a deep aching pain in the medial and posterior (dorsal) aspect of the foot, burning around the nail of the great toe, and pins and needles at the adjacent borders of the great and second toes that are exacerbated with plantarflexion and improved with rest.[663,664,666,667]

T e examination reveals weakness or atrophy of the EDB muscle and diminished movement with toe extension.[663]

Conservative intervention for these patients involves an alteration of daily and sports activities, alteration in footwear, orthotics, and if necessary NSAIDs.[663]

Surgical intervention, reserved for those who do not respond to conservative measures within 3 months, involves decompression of the nerve.[663]

Superficial Fibular (Peroneal) Nerve

Although injuries to the superficial nerve at the level of the ankle are relatively rare, the nerve can be stretched with lateral (inversion) ankle sprains or can become entrapped as it pierces the deep fascia to become subcutaneous approximately 4–5 in above the lateral malleolus.[199,668–672]

Patients complain of diminished sensation on the posterior aspect of the foot, which is exacerbated by activity.

Tarsal Tunnel Syndrome

TTS is an entrapment neuropathy of the posterior tibial nerve, or one of its branches (medial calcaneal nerve to the heel, and medial and lateral plantar nerves to the sole of the foot and toes), which usually occurs at the level of the ankle. T is relatively rare syndrome was first described by Keck[673] and Lam[674] in two separate reports in 1962.

T e posterior tibial nerve often is entrapped as it courses through the tarsal tunnel, passing under the deep fascia, the flexor retinaculum, and within the abductor hallucis muscle.[675] T e most common site of entrapment is at the anterior–inferior aspect of the tunnel, where the nerves wind around the medial malleolus.[676]

T e onset of TTS may be acute or insidious. T e etiology is multifactorial and may be posttraumatic, neoplastic, inflammatory,[677] the result of rapid weight gain,[678] a space occupying lesion, fluid retention,[678] talocalcaneal coalition, accessory muscles, abnormal foot or ankle mechanics (flatfoot syndrome),[679–684] TTS has a high incidence in the athletic population.[685]

T e diagnosis is based on history, physical examination, electrodiagnostic tests, and imaging. T e typical patient reports a poorly localized burning sensation or pain along the pathway of the nerve, medial ankle pain and paresthesia at the medial plantar surface of the foot, with the distribution correlating with the level of entrapment of the medial or lateral plantar nerve as they join to form the posterior tibial nerve.[381] T e symptoms may also radiate to the toes. Some patients have cramps in the longitudinal foot arch. Discomfort is worse after activity and typically is accentuated with prolonged standing or walking.[675] Resting pain is reported infrequently but can disturb sleep.[381] Differential diagnosis includes plantar heel pain (plantar fasciitis), chronic heel pain syndrome, and FHL tenosynovitis.

T e physical examination can reveal any one, or all, of the following:

- Positive Tinel's sign, sometimes with pain radiating distally toward the midsole, along the posterior branch of the nerve.[686] Percussion should be performed with and without weight bearing.[619]
- Pain with passive dorsiflexion combined with eversion.
- Decreased two-point discrimination on the plantar aspect of the foot.[686]
- Varus or valgus deformity of the heel.[678,682,684,686]
- A weakness of the foot intrinsics with sustained plantarflexion of the toes.
- Normal results from the neurologic examination.[687]

EMG and NCV can be employed to assist with the diagnosis.

T e most effective conservative interventions for TTS are to decrease pressure, pain and inflammation through the use of local corticosteroid injections,[684,688] strengthening of the foot intrinsics to restore the medial longitudinal arch,[681] weight loss for obese patients,[681] joint mobilizations, a heel lift to decrease tension on the tibial nerve, and an orthoses for foot deformity when excessive pronation is present.[677] Specifically, a medial longitudinal arch with a hindfoot varus post can limit excessive pronation. In cases of early excessive hindfoot pronation and subtalar joint pronation at heel strike, an orthosis with a deepened heel cup can help to control hindfoot motion. In cases of severe hyperpronation, a hindfoot wedge may be helpful.

Surgical intervention, which typically occurs after a trial course of conservative measures, involves decompression of the nerve.[682,683] T e overall results from early surgical decompression are beneficial in most patients.[678]

Peripheral Neuropathy

Peripheral neuropathy is characterized by a progressive loss of nerve fibers that predisposes the patient to painful or

insensitive extremities, vascular compromise, and neuropathic ulceration.[689,690] In more severe cases, uncontrolled peripheral neuropathy can result in amputation. Affected nerve functions associated with peripheral neuropathy include reduced NCV, decreased temperature sensation, decreased tendon reflex response, alterations in autonomic function, and a decreased ability to detect vibration and touch. Peripheral neuropathy is a complication of both insulin-dependent (type 1) and noninsulin-dependent (type 2) diabetes mellitus.[689,690]

A loss of sensation in the legs and feet prevents the patient from detecting minor cuts or trauma, which can become infected, placing these patients at high risk of developing a neuropathic ulcer. Motor neuropathy may cause muscle atrophy and imbalances, which can lead to foot deformity and increased pressure on the plantar aspect of the foot. T is is particularly true with the diabetic patient who participates in sports, where the forces acting on the sole of the foot can be significant. Autonomic dysfunction may lead to decreased perspiration and sebaceous oil production, which can cause dryness, cracking, and, eventually, fissures in the skin. Good foot care is thus essential for these patients. It is recommended that the clinician regularly assess the general skin condition of the patient's foot and leg (dryness, cracks, and fissures) and the skin temperature. Red and warm skin may indicate the presence of infection, cellulitis, or an undetected bone infection or fracture. Cold skin and pallor may indicate decreased blood flow. Other signs of vascular compromise can include diminished pulses and toe pressures, dry and shiny skin with no hair growth, and thickened flaky nails. Skin rashes and foul odor may be indicative of a fungal infection. Callus and corn formation, blisters, and bunions may highlight the presence of an ill-fitting shoe or a deformity (equinus contracture, claw toes, and charcot arthropathy). Charcot (rocker-bottom) foot occurs when the bones at the plantar aspect are prominent, resulting in a diminished longitudinal arch and an increased potential for fracture. Other conditions to observe for include plantar warts and ingrown toenails.

Sensation of the foot can be tested using Semmes–Weinstein filaments, which are calibrated nylon monofilaments with increasing stiffness indicated by increasing numbers (see Chapter 3).[689,690] Protective sensation of the foot has been defined as the ability to sense a 5.07 monofilament, whereas absent sensation is defined as the inability to sense a 6.10 monofilament.[689]

T e primary focus of intervention with this patient population is patient education regarding proper foot and nail inspection and care.

T e following advice should be given:

- T e feet should be washed every day in warm, not hot, water. Hot water dries the skin and can easily burn the foot. T e water temperature can be tested using a thermometer. T e feet should not be soaked to avoid skin maceration.
- T e skin should be inspected at least once a day for cuts, bruises, blisters, swelling, and calluses. A mirror can be used where necessary. If the skin is dry, lotion can be applied to the tops, bottoms, and sides of the feet, but not between the toes, which can create a moist environment for fungal and bacterial infections.
- Toenails should be trimmed straight across with a nail clipper once a week. Rounding off the corners of the nails increases the potential of ingrown toenails and increases the potential for cutting the skin. If the patient has retinal neuropathy and poor eyesight, the nails are best trimmed by a family member or by a professional.
- T e patient should avoid walking barefoot or wearing sandals.
- T e feet should be protected from hot or cold temperatures.
- T e patient should exercise a little every day. Appropriate nonimpact exercises include cycling or swimming. Gait training may be appropriate to maintain mobility and alter gait patterns to decrease abnormal plantar pressures.[689]
- If possible, the patient should stop smoking. Smoking causes the blood vessels to constrict.

Appropriate footwear and orthotics should be prescribed where appropriate to reduce plantar pressures and increase the weight-bearing area of the foot.[110] T e total contact cast is considered the gold standard for ambulating patients, due to its ability to reduce pressure on the midfoot and forefoot by distributing pressure over the total foot surface.[110] Alternatively, the patient may be prescribed a prefabricated walker boot or a bivalved ankle foot orthosis.

In the presence of a diabetic wound, frequent sharp debridement of nonviable tissue has been shown to be an effective method to speed wound healing.[691] T is can be performed with a scalpel and tweezers. Enzymatic and autolytic debridements can be used as adjuncts to sharp debridement.[691] Enzymatic debridement uses ointments that contain papain-urea or other enzymes that help break the bonds between necrotic tissue and wound bed. Autolytic debridement uses moisture-retentive secondary dressings (hydrogels and hydrocolloids) to provide a moist environment, which helps to keep the wound fluids in contact with the wound bed.

Complex Regional Pain Syndrome

T e more classic patient with complex regional pain syndrome will present with severe regional pain, swelling, dysesthesia to light touch (allodynia) and vasomotor instability, and the subjective report will be one of pain out of proportion to the degree of injury (see Chapter 5).[692]

Myofascial Pain Syndrome

Ankle or foot pain can arise, and trigger points in the tibialis anterior, extensor digitorum, or fibularis (peroneus) longus muscle are the most likely causes.[693]

Tibialis Anterior

Trigger points of this muscle can refer pain, tenderness, and stiffness deep into the anterior ankle and the great toe. T ese trigger points can be activated due to excessive pronation of the foot and excessive dorsiflexion.[693]

Extensor Digitorum

Trigger points of this muscle can refer pain and tenderness over the posterior aspect of the foot and into the middle three toes.

Fibularis (Peroneus) Longus

Trigger points of this muscle can refer to just posterior to the lateral malleolus. T is muscle is usually strained on inversion sprain injuries of the ankle and can, therefore, be the source of residual pain at the lateral ankle.[693]

PREFERRED PRACTICE PATTERN 4G: IMPAIRED JOINT MOBILITY, MOTOR FUNCTION, MUSCLE PERFORMANCE, AND ROM ASSOCIATED WITH FRACTURES

Bone Stress Injuries

A bone stress injury (BSI) represents the inability of a bone to withstand a repetitive mechanical loading, which results in structural fatigue and localized bone pain and tenderness. Bone stress injuries occur along a pathology continuum beginning with a stress reaction, which can progress to stress fractures and, ultimately, complete bone fracture. T e pathophysiology of a BSI remains somewhat speculative, but it probably involves an imbalance between load-induced microdamage formation and its removal.[694] Initially, mechanical loading causes the bone to deform, with the amount of deformation depending on the load magnitude and the ability of the bone to resist deformation (strain) (see Chapter 2). A number of extrinsic factors can produce mechanical loading including running on hard surfaces, improper running shoes, or sudden increases in jogging or running distance. Biomechanical factors, including malalignment of the lower extremity, particularly excessive pronation. A strain that is below the level required for a fracture is still capable of generating microscopic damage, referred to as microdamage. Microdamage formation is threshold dependent which is a factor of the strain rate-–the magnitude of the strain and the speed at which the strain is introduced. T ese areas of microdamage serve as a stimulus for targeted remodeling of the bone. While remodeling normally removes damage approximately as fast as it occurs, it is a time-dependent process, so, if insufficient time is given to adapt to the mechanical stimulus, progressively more damage may form, which eventually results in a localized reduction in the energy absorbing capacity of the bone and thus an escalation of the damage. If the escalation of damage is significant, a stress fracture results. T e exact location of BSI development depends on how an individual loads his or her skeleton during repetitive weight-bearing activities. For example, long-distance runners typically use a rear foot strike pattern, whereas sprinters use a forefoot strike pattern. Consequently, long-distance runners are at a greater risk of developing long-bone BSIs, whereas sprinters are more prone to BSIs of the tarsals and metatarsals.[694] Ideally, a BSI is diagnosed early before it progresses to a stress fracture—an astute clinician may be able to diagnose the pathology at the stress reaction stage; however, some patients may not present until the pathology has progressed to a stress fracture.[694] Clearly, the earlier in the continuum that a diagnosis is made, the more likely it is that the pathology will respond quickly and favorably to conservative management.[694] In most instances, an individual with a BSI has a consistent and predictable history that centers on pain and which is usually described as a mild, diffuse ache that occurs after a specific amount of repetitive activities such as running or at specific times during the gait cycle. T e pain does not tend to dissipate as the activity continues and only abates once the activity has ceased. Over time, the pain may become more severe and localized, and occur at an earlier stage in the activity, and it may also persist for longer periods following the completion of the activity and/or begin to be present during activities that involve the lower levels of bone loading such as walking in the case of runners. T e most obvious feature of a BSI during a physical examination is localized bony tenderness. A number of studies have found BSIs to be more common in women, older individuals, and Caucasians.[695,696] Amenorrhea is present in up to 20% of robustly exercising women and may be as high as 50% in elite runners and dancers. Patients with amenorrhea for more than 6 months experience the same bone loss as postmenopausal women, predisposing them to BSI.[697] Muscular fatigue of the foot may also play a role in the etiology.[698] In longer standing BSIs there may be periosteum or thickening and callous formation. Confirmation through imaging can only be provided by MRI because of its superior contrast resolution, lack of exposure to ionizing radiation, and combined high sensitivity and specificity.[699] Conservative intervention includes activity modification (utilizing a forefoot landing rather than a heel or rear foot landing), identification and removal of potential risk factors, maintenance of physical conditioning, and attempts to accelerate tissue level healing. While there are no proven conservative methods to accelerate bone healing, there are a number of promising possibilities:

- Low-intensity (less than 0.1 W/cm^2) pulsed ultrasound therapy. It has been effective in stimulating union in 98% and 94% of BSI's displaying delayed union and nonunion, respectively.[700]
- Extracorporeal shock wave therapy and electromagnetic and capacitive coupled electric fields.[701]

Tibial and Fibular BSI

A tibial BSI is a common cause of shin soreness and a very common cause of exertional leg pain. Tibial stress fractures account for nearly 50% of all stress fractures in athletes,[702] whereas a fibular stress fracture occurs less frequently and represents 4.6–21% of all athletic stress fractures.[703]

- *Tibial.* T e tibia accounts for 25.9–49.1% of all stress fractures, particularly in long-distance runners.[704] A tibial stress fracture usually occurs on the compression side and involves the posterior and medial cortex in a transverse orientation, although longitudinal fractures do occur.[705] T e mechanism of injury may be repetitive ankle plantarflexor contractions.[702] Although it is difficult to determine risk factors in male runners for developing tibial stress fractures, menstrual imbalance,

low bone mineral density and lean mass in the lower limb, and low-fat diet are associated with stress fractures in female runners.[706] Recognition of anterior tibial stress fractures is important because these fractures are prone to nonunion and avascular necrosis. In the high risk anterior tibia, radiography can reveal the dreaded black line along the anterior tibial cortex.[707] Anterior tibial stress fractures are also at greater risk of becoming displaced than are posterior tibial stress fractures. T is increased susceptibility to complication has been attributed to a predominance of tensile forces along the anterior diaphysis rather than compressive forces along the posterior diaphysis.

- Fibular. Fibular stress fractures account for 5.1–9.3% of all stress fractures.[704] Stress fractures of the fibular typically occur within the distal third of the shaft, 5–6 cm proximal to the lateral malleolus.[92] As with tibial stress fractures, the mechanism of injury may be repetitive ankle plantarflexor contractions.[702] Unlike tibial stress fractures, these fractures are low risk. Fibular and low-risk tibial stress fractures often respond to a period of rest ranging from 4 to 8 weeks.[702] Progressive return to sport is initiated with cross-training followed by higher-impact activities.

Metatarsal BSI

T e second and third metatarsals are the most frequently injured.[708]

Although numerous studies have attempted to correlate foot shape, footwear, and orthotics to the incidence of metatarsal BSIs, none have conclusively shown a direct relationship,[372,709–711] although one study showed a decrease in the incidence of metatarsal fractures in low-arched feet by using a semirigid orthotic.[117]

T e typical clinical findings with this type of BSI include reports of mild forefoot discomfort, which may initially be relieved by rest, but which occurs while walking and even at rest as the BSI worsens.[58] Occasionally, there is point tenderness over the involved metatarsal, swelling, and a palpable mass.[708,712] In the case of a stress fracture of the metatarsal, A-P, lateral, and oblique radiographs of the foot may not show a fracture for 3–6 weeks, although a technetium bone scan is positive as early as 48–72 hours after onset of symptoms.[58]

T e intervention for metatarsal BSIs includes rest from the offending activity and cross-training in a low-impact sport.[58] Weight bearing to tolerance may be allowed in comfortable shoes of choice or a wooden shoe. If weight bearing is painful, or the a fracture is present, a short-leg cast or hard-soled shoe is worn for 4–6 weeks until healing callus is seen radiographically.[708,712]

Proximal Second Metatarsal. T is type of metatarsal BSI differs from other metatarsal BSIs since it can be difficult to heal. T e anatomy in this area tends to encourage an abnormal amount of stress, particularly in young ballet dancers.[713–716]

Other predisposing factors can include amenorrhea, anorexia nervosa, cavus foot, and anterior ankle impingement with resulting hyperpronation.[713]

On physical examination, there will be pain in the first webspace, usually accompanied by proximal second metatarsal pain.[717]

Initial foot radiographs will most often be negative; hence, a bone scan is usually necessary. T e bone scan may be nonspecific, with synovitis, stress reaction, and stress fracture as differential.[717]

T e intervention for a BSI of the second metatarsal that has progressed to a stress fracture usually consists of 6–8 weeks of rest in a hard shoe or cast,[713,717] with gradual return to activities when the tenderness resolves.

Navicular BSI

A navicular BSI typically presents with an insidious onset or with a history of acute flexion and inversion.[7] T e patient complains of chronic pain that is vague in nature but tender to palpation on the posterior aspect of the foot and/or medial aspect of the midfoot.[708]

T is condition is most commonly seen in basketball players, hurdlers, and runners, in whom repeated cyclic loading results in fatigue-failure through the relatively avascular central portion of the tarsal navicular.[66,515,718] T e cyclic loading across the navicular may be exacerbated due to a short first metatarsal, metatarsus adductus, or limited dorsiflexion or subtalar motion.[66]

To confirm a diagnosis of fracture if suspected, a bone scan or CT scan may be necessary, as plain films are rarely diagnostic.[718]

T e intervention varies according to severity. If fractured but nondisplaced, treatment involves a short-leg non–weight-bearing cast for 6–8 weeks.[492,718] If the fracture fails to heal or is displaced, the operative intervention of fixation with compression screw, and additional bone grafting where necessary, is used.[492,718] Return to sport may take as long as 16–20 weeks.[708]

Sesamoid BSI

T e young patient with a sesamoid BSI will present with the insidious onset of pain and swelling over the plantar aspect of the first MTP joint.[515,719] Pain is usually aggravated by activity and relieved by rest. Differential diagnosis includes metatarsalgia, bursitis, sesamoiditis, stress fracture, and bipartite sesamoid.[719]

T e intervention for a sesamoid BSI is initially rest from the offending high-impact activity. An alternative treatment is the use of a "C" or "J" pad, which unloads the injured sesamoid. Pads with adhesive backing may be fixed to the insole of the shoe or may be incorporated into a custom-molded orthotic to unload the sesamoid. If a fracture is present, a wooden-soled shoe or a short-leg cast is prescribed for 6–8 weeks. If cast, a CT scan is performed at 8 weeks to detect signs of avascular necrosis. If avascular necrosis is present, and the young patient has persistent symptoms, resection may be necessary.[61] Surgical choices include excision of the involved sesamoid or bone grafting, in an attempt to achieve union and preserve the sesamoid.

Fractures

Ankle Fractures

Ankle fracture (i.e., fracture of the distal tibia or fibula) is among the most common traumatic injuries requiring

orthopaedic management, with an incidence rate of 13–28 per 10,000 persons per annum in young men, 16–20 per 10,000 persons per annum in older women, and at least 5 per 10,000 persons per annum across all ages.[720,721] However, despite their high incidence, ankle fractures have been the subject of less empirical research in comparison to other fracture types.[226] Treatment of ankle fracture typically involves surgical or nonsurgical intervention, followed by a period of immobilization. A systematic review and meta-analysis of longitudinal studies by Beckenkamp et al.[721] reported that adults typically experience a rapid initial recovery of physical function after ankle fracture (approximately 80% function at 6 months), but on average, recovery remains incomplete 24 months after injury. In addition to the uncertainty surrounding the frequency of poor outcomes for patients following ankle fracture, a Cochrane systematic review found limited available evidence to inform specific rehabilitation protocols for the management of ankle fracture.[722] A limiting factor when evaluating the effectiveness of ankle fracture rehabilitation interventions is the absence of a suitable ankle fracture-specific, patient-reported outcome measure with robust content foundation.[227]

Unimalleolar Fractures

Unimalleolar fractures are the most common fractures of the ankle.[7] The degree of stability of these fractures is dependent on their location, with those located below the tibiotalar joint tending to be stable.[7] Approximately 85% of lateral malleolar fractures occur without damage to the medial aspect of the ankle joint and do not cause abnormal displacement of the talus.[723,724]

Medial malleolar fractures are often seen in conjunction with other fractures.

Bimalleollar and Trimalleolar Fractures

These fractures, as their name implies, involve two or three malleoli. The bimalleolar fracture usually results from a severe pronation/abduction/external rotation force, which shears the lateral malleoli and avulses the medial malleolus. The trimalleolar fracture involves a fracture of the medial, lateral, and "posterior" malleolus, which typically results from an abduction and severe external rotation force so strong that the talus moves sufficiently posteriorly to shear off the posterior margin of the tibia.

The intervention for bimalleolar fractures remains controversial, whereas it is generally agreed that trimalleolar fractures require open reduction and internal fixation.[725]

Pilon Fractures

These fractures result from an axial compression force, where the tibia is driven inferiorly into the talus, splitting and shattering the distal end of the tibia and completely disrupting the ankle joint, resulting in long-term morbidity in the majority of cases.[726]

Talar Dome Fractures

These are the most common chondral fractures and are also known as osteochondritis dissecans, transchondral fractures, or flake fractures.[7]

These injuries, which present with persistent swelling, pain with walking, locking of the ankle, and crepitus, tend to present as a "sprained ankle that did not heal."[7]

Intervention varies from none to casting, to arthroscopy for larger fragments.[7]

Talar Fractures

Major fractures of the talar head, neck, and body are associated with high-energy mechanisms, with one-half of major talar injuries involving fractures of the talar neck, 15–20% involving talar body fractures, and the remainder involving talar head fractures.[7] The mechanism of injury usually involves an axial load with the foot positioned in plantarflexion or excessive dorsiflexion, resulting in compression of the talar head against the anterior aspect of the tibia.[727]

The intervention varies according to location and severity, with nondisplaced fractures treated with a short-leg non–weight-bearing cast for 6–8 weeks and displaced fractures involving immediate reduction.[7]

Calcaneus

The calcaneus is the most frequently fractured tarsal, accounting for over 60% of foot fractures,[728] and one that can be a frequent and often misdiagnosed cause of heel pain.[729] With the increasing number of middle-aged and elderly people involved in active recreational pursuits, sports medicine has had to incorporate the way these conditions are related to these different age groups.[66] Jumping activities or unaccustomed activities may precipitate crushing of the fragile architecture of an osteoporotic calcaneus, leading to fractures.[66]

Tenderness on M-P compression of the heel (squeeze test) should lead to a suspicion of a stress fracture of the calcaneus.[43]

Conservative intervention of calcaneal fractures has shown poor long-term clinical results with a significant loss of ankle function.[730,731]

Fifth Metatarsal Fractures

All fractures of the proximal fifth metatarsal have been arbitrarily labeled a "Jones fracture." The most common fifth metatarsal base fracture is an avulsion fracture of the tuberosity caused by traction of the fibularis (peroneus) brevis and lateral band of the plantar fascia during hindfoot inversion.[732]

The proximal fifth metatarsal has a poor blood supply and is at significant risk for delayed union or nonunion. These fractures should be treated with non–weight-bearing short-leg cast immobilization for 6–8 weeks or until healing is seen radiographically. If an established nonunion develops, screw fixation and/or bone grafting may be required.[733]

THERAPEUTIC TECHNIQUES

Techniques to Increase Joint Mobility

Joint Mobilizations

With some slight variations, the same techniques that are used to examine the joint glides described in the test and measures section can be used to mobilize the joints, with the clinician

varying the intensity of the mobilizations based on the intent of the technique, the patient's response, and the stage of tissue healing. T e purposes for the various mobilizations include the following:

- A posterior glide of the talocrural joint can be used to increase ankle joint dorsiflexion, whereas an anterior glide of the talocrural joint can be used to increase ankle joint plantarflexion.
- A medial gapping of the subtalar joint can be used for increasing ROM into subtalar joint eversion, whereas lateral gapping of the subtalar joint can be used for increasing ROM into subtalar joint inversion.
- A posterior glide of the intermetatarsal joints can be used to assist flattening of the transverse arch of the foot, whereas an anterior glide can be used to help increase the transverse arch of the foot.
- A posterior glide of the MTP joint can be used to increase ROM into MTP joint extension, whereas an anterior glide of the MTP joint can be used to increase ROM into MTP joint flexion.
- A posterior glide of the IP joint can be used to increase ROM into IP joint extension, whereas an anterior glide of the IP joint can be used to increase ROM into IP joint flexion.

Intervention following successful manual treatment should consist of strengthening of the plantarflexors, particularly the fibularis (peroneal) muscles. If the patient has a history of recurrent ankle sprains, then appropriate proprioceptive retraining should be instituted. Pain relief and improved function should be immediate and long lasting; however, if the condition reoccurs, follow-up care could include foot taping (e.g., using the Low-dye technique), use of arch supports or foot orthoses (over the counter or custom made), stretching and/or soft-tissue mobilization of the fibularis (peroneus) muscles, and adjustment to any asymmetrical training or daily habitual usage patterns.

CASE STUDY

BILAt er AL HeeL PAIn

HISTORY

History of Current Condition

A 54-year-old female presents with insidious onset of a constant dull ache in both heels, which is worse in the morning, especially when first putting her feet on the ground and at the end of the day. The patient denies numbness or tingling in either foot or ankle area or any history of trauma. Pain has increased this past week, prompting her to see an MD who prescribed physical therapy and an anti-inflammatory medication.

Past History of Current Condition

Bilateral heel pain of approximately 2 months duration a few years ago, which resolved spontaneously.

Past Medical/Surgical History

Unremarkable.

Medications

NSAIDs are prescribed for pain relief and decreasing the inflammation.[469]

Other Tests and Measures

Radiographs showed the presence of a heel spur in both heels.

Social Habits (Past and Present)

Sedentary lifestyle.

Growth and Development

Overweight as a child.

Living Environment

Lives in a ranch-type home with carpeting throughout, except for a tiled bathroom.

Occupational/Employment/School

Works in a warehouse stacking boxes of tissues and has been working there for 6 years.

Functional Status/Activity Level

Soreness occurs first hour in morning, especially when she initially bears weight, and again at the end of the day after working. Walking on the concrete floor at work is reported to aggravate the condition.

Health Status

General good health, but feels her pain interferes with tasks at home and at work.

Questions

1. List all of the structures that could be at fault with complaints of bilateral heel pain of an insidious onset.
2. Does the history of heel pain with initial weight bearing in the morning give the clinician any clues as to the diagnosis?
3. Why do you think the patient's symptoms are worsened with weight bearing?
4. What additional questions would you ask to help rule out referral from the hip, knee, or lumbar spine?
5. Do you have a working hypothesis at this stage? List the various tests you would use to rule out each of the possible causes.
6. Does this presentation/history warrant a scan? Why or why not?

CASE STUDY

Heel PAIn

HISTORY

History of Current Condition

A 34-year-old female complains of insidious onset of pain in the posterior aspect of the right ankle, which began approximately 3 months ago when she began a jogging program but which had not worsened significantly until last week. The pain is worse in the morning and after prolonged positions.

The patient denies numbness or tingling in the foot or ankle area. The increase in pain this past week had prompted the patient to visit her MD, who prescribed physical therapy and gave her a heel lift to wear in each of her shoes.

Past History of Current Condition

Similar right posterior heel pain of approximately 1-month duration a few years ago, which resolved spontaneously.

Past Medical/Surgical History

Unremarkable.

Medications

Naproxen (daily).

Functional Status/Activity Level

Soreness occurs first hour in the morning.

Health Status

In good health but feels the pain interferes with tasks at home and at work.

Questions

1. List the structure(s) and differential diagnoses that may be involved with complaints of unilateral heel pain related to running.
2. What does the history of no significant worsening of the pain tell the clinician?
3. Why do you think the patient's symptoms are worse after rest?
4. What additional questions would you ask?
5. What is your working hypothesis at this stage? If you have a number of hypotheses, which tests would you use to rule out each one?
6. Does this presentation/history warrant a lower quarter scanning examination? Why or why not?

SECTION V

THE SPINE AND TMJ

CHAPTER 22 Vertebral Column

The design specification for the human vertebral column is the provision of structural stability affording full mobility as well as protection of the spinal cord and axial neural tissues.[1] While achieving these seemingly disparate objectives, the spine also contributes to the functional requirements of gait and to the maintenance of static weight-bearing postures (see Chapter 6).[1]

At the component level, the basic building block of the spine is the vertebra. The vertebra serves as the weight-bearing unit of the vertebral column, and it is well designed for this purpose. Although a solid structure would provide the vertebral body with sufficient strength, especially for static loads, it would prove too heavy and would not have the necessary flexibility for dynamic load bearing.[2] Instead, the vertebral body is constructed with a strong outer layer of cortical bone and a hollow cavity, the latter of which is reinforced by vertical and horizontal struts called trabeculae.

The term vertebral column describes the entire set of vertebrae excluding the ribs, sternum, and pelvis (Fig. 22-1). The normal vertebral column is made up of 29 vertebrae (7 cervical, 12 thoracics, 5 lumbar, and 5 sacral) and three or four coccygeal segments. The adage that "function follows form" is very much applicable when studying the vertebral column. Although all vertebrae have similar characteristics, each has specific details that reflect its unique function. The overall contour of the normal vertebral column in the coronal plane is straight. In contrast, the contour of the sagittal plane changes with development. At birth, a series of primary curves give a kyphotic posture to the whole spine. With the development of the erect posture, secondary curves develop in the cervical and lumbar spines, producing a lordosis in these regions. The curves in the spinal column provide it with increased flexibility and shock-absorbing capabilities.[2]

Functionally, the vertebral column consists of anterior and posterior columns. The anterior column is the hydraulic and weight-bearing portion that provides the vertebral column with its shock-absorbing capability and consists of the vertebral bodies and intervertebral disks (IVD).[3] The posterior column consists of the structures that provide the gliding mechanism for movement, the articular processes, and the zygapophyseal (facet) joints.[3] A motion segment in the vertebral column is defined as two adjacent vertebrae and consists of three joints. One joint is formed between the two vertebral bodies and the IVD of the anterior column. The other two joints are formed by the articulation of the superior articular processes of the inferior vertebra and the inferior articular processes of the superior vertebra (Fig. 22-2) of the posterior column.

The vertebral column contains 24 pairs of zygapophyseal joints, which project from the neural arch of the vertebrae. The regional characteristics of the zygapophyseal joints are described in the relevant chapters. Mechanically, zygapophyseal joints are classified as plane joints as the articular surfaces are essentially flat.[4] The articular surfaces are covered with hyaline cartilage and, like most synovial joints, have small fatty or fibrous synovial meniscoid-like fringes that project between the joint surfaces from the margins.[5] These intra-articular synovial folds act as space fillers during joint displacement and actively assist in the dispersal of synovial fluid within the joint cavity.[1] The articular processes act as a mechanical barricade, particularly against excessive torsion and shear, permitting certain movements while blocking others[4]:

- Horizontal articular surfaces favor axial rotation.
- Vertical articular surfaces (in either sagittal or frontal planes) act to block axial rotation.

Most zygapophyseal joint surfaces are oriented somewhere between the horizontal and vertical planes. In the cervical spine, the zygapophyseal joints are relatively horizontal while progressively increasing toward 45 degrees to the horizontal from the upper to the lower segments.[6–9] In the thoracic region, the joints assume an almost vertical direction while remaining essentially in a coronal orientation, which facilitates axial rotation and resists anterior displacement.[10] In the lumbar spine, the zygapophyseal joints are vertical with a curved, J-shaped surface predominantly in the sagittal plane, which restricts rotation and also resists anterior shear.[1] Understanding the variable structure and function of the human zygapophyseal joints and their relationship with the other components of the vertebral

column is an important requirement for the examination and intervention of individuals with mechanical spinal pain disorders.[1]

The IVDs of the vertebral column lie between the adjacent superior and inferior surfaces of the vertebral bodies from C2 to S1 and are similar in shape to the bodies (Fig. 22-3). The IVD forms a symphysis or amphiarthrosis between two adjacent vertebrae and represents the largest avascular structure in the body. Each disk is composed of an inner nucleus pulposus (NP), an outer annulus *fi*brosus (AF), and limiting cartilage end plates. The annulus and end plates anchor the IVD to the vertebral body. In cervical and lumbar regions, the IVDs are thicker anteriorly, and this contributes to the normal lordosis. In the thoracic region, each of the IVDs is of uniform thickness. Phylogenetically, the IVD is a relatively new structure. In the human spinal column, the combined heights of the IVDs account for approximately 20–33% of the total length of the spinal column.[11] The presence of an IVD not only permits motion of the segment in any direction up to the point that the disk itself is stretched, but also allows for a significant increase in the weight-bearing capabilities of the spine.[12] A normally functioning disk is extremely important to permit the normal biomechanics of the spine to occur and to reduce the possibility of mechanical interference among any of the neural structures. Although the disk is incapable of independent motion, movement of the disk does occur during the clinically defined motions of flexion–extension, side bending, and axial rotation.[13] The major stresses that must be

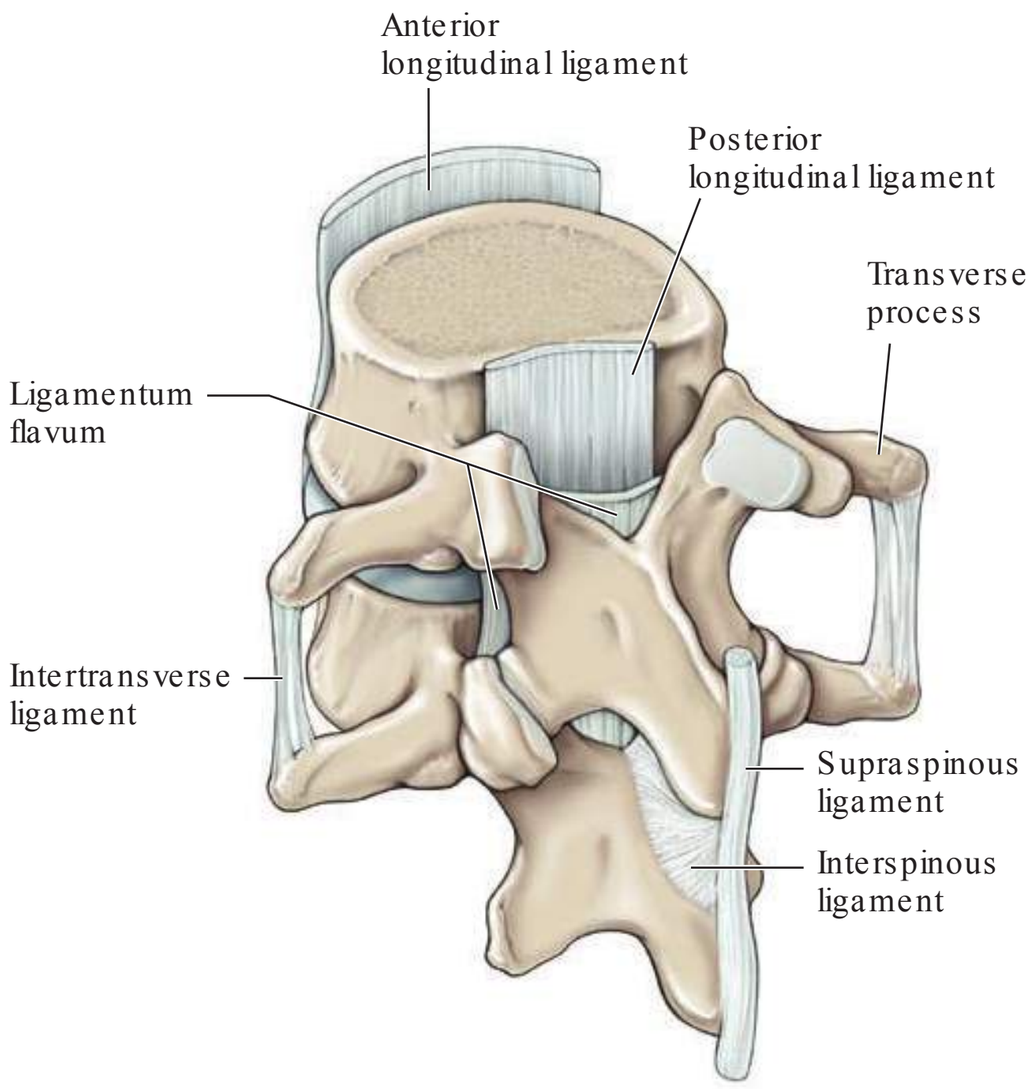

FIGURE 22-3 The intervertebral disk and ligamentous structures. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

withstood by the IVD are axial compression, shearing, bending, and twisting, either singly or in combination with each other.

T e role of the IVD is unique because it operates as an osmotic system, holding neighboring vertebral bodies together while simultaneously pushing them apart. As such, the IVD is a dynamic structure that responds to stresses applied from vertebral movement or from static loading.

T ere are regional differences within the spine, each with its own specific demands and function. As discussed, all vertebral disks have traditionally been described as being composed of three parts: the AF, the vertebral end plate, and a central gelatinous mass, called the NP (Fig. 22-1). However, this description is based on the anatomy of a lumbar disk, the region where most research has occurred and for which many authors have extrapolated the anatomy to all IVDs.[14] An appreciation of the differing anatomy of the IVDs, throughout the spine, which are described in the separate chapters, is important when developing clinical examination and intervention models.[14]

SPINAL JUNCTIONS

T e spine contains four junctions, each of which is different in posterior element orientation and spinal curvature. Transitional vertebrae can occur at any of the junctions. T e transition can be "complete" but is more commonly partial. T ese junctions, described by Schmorl and Junghanns[15] as ontogenically restless, are of en rich in anomalies[16]:

- T e craniovertebral junction is located between the cervical spine and the atlas, axis, and head. T is region is covered in Chapter 23.
- T e cervicothoracic junction represents the region where the mobile cervical spine and the relatively stiffer superior segments of thoracic spine meet, and where the powerful muscles of the upper extremities and shoulder girdle insert. T e cervicothoracic junction is described in Chapters 25 and 27.
- T e thoracolumbar junction is located between the thoracic spine, with its large capacity for rotation, and the lumbar spine, with its limited rotation. T is region is described in Chapter 27.
- T e lumbosacral junction is located between the lumbar spine, with its ability to flex and extend, and the relative stiffness of the sacroiliac joints. T is region is described in Chapters 28 and 29.

Although highly variable, the line of gravity acting on a standing person with ideal posture passes through the mastoid process of the temporal bone anterior to the second sacral vertebra, posterior to the hip, and anterior to the knee and ankle (see Chapter 6).[4] In the vertebral column, the line of gravity is on the concave side of the apex of each region's curvature. As a consequence, ideal posture allows gravity to produce a torque that helps maintain the optimal shape of each spinal curvature.[4]

SPINAL MOTION

T e movements of the vertebral column occur in diagonal patterns as a combination of flexion or extension with a coupled motion of side bending and rotation. Since the spine can move from top-down or bottom-up, the motion at a functional unit is defined by what is occurring at the anterior portion of the vertebral body of the superior vertebra. For example, at the L3–4 segments, flexion involves an anterior motion of the L3 vertebra relative to the L4 vertebra, and extension involves a posterior motion of the L3 vertebra relative to the L4 vertebra. Movements of the spine, like those elsewhere, are produced by the coordinated action of nerves and muscles. Agonistic and synergistic muscles initiate and perform the movements, whereas the antagonistic muscles control and modify the movements. T e amount of motion available in each region of the spine is a factor of a number of variables. T ese include the following:

- Disk–vertebral height ratio
- Compliance of the fibrocartilage
- Dimensions and shape of the adjacent vertebral end plates
- Age
- Disease
- Gender

T e type of motion available is governed by:

- T e shape and orientation of the articulations
- T e ligaments and muscles of the segment, and the size and location of its articulating processes

Although the range of motion (ROM) at each vertebral segment varies, the relative amounts of motion that occur at each region is well documented[11,17] Although various motion patterns have been proposed for the sacroiliac joint,[18–21] the precise model for sacroiliac motion has remained fairly elusive (see Chapter 29).[22–24] Postmortem analysis has shown that until an advanced age, small sacroiliac movements are measurable under different load conditions.[25,26] Including translations and rotations around three different axes, the spine is considered to possess 6 degrees of freedom. T ese include flexion/extension, side bending, rotation, compression/distraction, anterior/posterior shear, and lateral shear.

Flexion/Extension

At the segmental level, flexion produces a combination of an anterior roll and an anterior glide of the vertebral body in the sagittal plane. T e anterior portion of the vertebral bodies approximate, and the spinous processes separate. T e reverse occurs with extension.

Side Bending

Side bending, which occurs in the frontal plane, is a complex and highly variable movement involving side bending and

rotatory movements of the interbody joints and a variety of movements at the zygapophyseal joints.[27] During side bending, the lateral edges of the vertebral bodies approximate on the side toward which the spine is bending, compressing the IVD, and separate on the opposite side, distracting the IVD.

Rotation

Irrespective of whether the movement occurs from the pelvis upward, or from the head down, rotation to the lef results in a relative movement of the body of the superior vertebra to the lef , and its spinous process to the right. T e opposite occurs with rotation to the right. During rotation, torsion of the IVD occurs.

Compression/Distraction

Compression (approximation) or distraction (separation) occurs with a longitudinal force.

Anterior/Posterior Shear

An anterior shear occurs when the body of the superior vertebra translates anteriorly on the vertebra below. A posterior shear occurs when the body of the superior vertebra translates posteriorly on the vertebra below.

Lateral Shear

A lateral shear occurs when the body of the superior vertebra translates sideways on the vertebra below. T is commonly occurs during side bending.

In general, the human zygapophyseal joints of the spine are capable of only two major motions: gliding upward and gliding downward. If these movements occur in the same direction, flexion or extension occurs. If the movements occur in opposite directions, side bending occurs. Although rotation does occur as a motion component within intervertebral segments, it is always coupled and never an isolated motion.[28] Indeed during functional rotation of the spine, the actual motion occurring at any given zygapophyseal joint is a linear glide. Because the orientation of the articular facets of the zygapophyseal joints does not correspond exactly to pure planes of motion, pure motions of the spine occur very infrequently.[29] In fact, most motions of the spine occur three-dimensionally because of the phenomenon of coupling. Coupling involves two or more individual motions occurring simultaneously at the segment and has been found to occur throughout the lumbar, thoracic, and cervical regions. Descriptions of the types of coupling that occurs in these regions are provided in the respective chapters. All normal motions in the cervical, thoracic, and lumbar regions involve both sides of the segment moving simultaneously around the same axis. T at is to say, a motion on the right side of a segment produces an equal motion on the lef side of that same segment. If both sides of a vertebral segment are equally impaired (equally hypomobile or hypermobile), there is no change in the axis of motion except in the case where it ceases to exist, as in a bony ankylosis. Where a symmetric impairment of motion exists, there is no noticeable deviation from the path of flexion or extension (impaired side bending and rotation), but rather, the path is shortened with a hypomobility (producing decreased motion) or lengthened with a hypermobility (producing increased motion).

An alteration of the structures of the motion segment can result in a loss of motion, a loss of segment integrity (instability), or a loss of function. T ese changes result mainly from injury, developmental changes, fusion, fracture healing, healed infection, or surgical arthrodesis.[17] T e loss of motion segment integrity, which can be measured with flexion–extension roentgenograms, is defined as an anteroposterior motion of one vertebra over another that is greater than 3.5 mm in the cervical spine, greater than 2.5 mm in the thoracic spine, and greater than 4.5 mm in the lumbar spine.[11]

Fryette's Laws of Physiologic Spinal Motion

Although listed as laws, Fryette's[30] descriptions of spinal motion are better viewed as concepts because they have undergone review and modifications over time. T ese concepts serve as useful guidelines for the evaluation and intervention of spinal dysfunction and are cited throughout many texts describing spinal biomechanics.

Fryette's First Law

"When any part of the lumbar or thoracic spine is in neutral position, side bending of a vertebra will be opposite to the side of the rotation of that vertebra."

T e term neutral, according to Fryette, is interpreted as any position in which the zygapophyseal joints are not engaged in any surface contact, and the position where the ligaments and capsules of the segment are not under tension. T is law describes the coupling for the thoracic and lumbar spines. T e cervical spine is not included in this law because the zygapophyseal joints of this region are always engaged. When a lumbar or thoracic vertebra is side bent from its neutral position, the vertebral body will turn toward the convexity that is being formed, with the maximum rotation occurring near the apex of the curve formed.

Dysfunctions that occur in the neutral range are termed by osteopaths as type I dys*f*unctions.

Fryette's Second Law

"When any part of the spine is in a position of hyperextension or hyperflexion, the side bending of the vertebra will be to the same side as the rotation of that vertebra."

Put simply, when the segment is under load, the coupling of side bending and rotation occurs to the same side. T e term non-neutral, according to Fryette, is interpreted as any position in which the zygapophyseal joints are engaged in surface contact, the position where the ligaments and capsules of the segment are under tension, or in positions of flexion or extension. T is law describes the coupling that occurs in the C2–T3 areas of the spine.

Dysfunctions occurring in the flexion or extension ranges are termed by osteopaths as type II dys*f*unctions.

Fryette's Third Law

Fryette's third law tells us that if motion in one plane is introduced to the spine, any motion occurring in another direction is thereby restricted.

CLINICAL PEARL

While it is commonly believed that coupled motions in the lower cervical spine occur toward the same side (a side bend to the right is accompanied by rotation to the right), it is important to remember that results from numerous studies are inconsistent regarding the specific spinal motions that are coupled with one another in the upper cervical, lumbar, and thoracic spine.[31]

Combined Motions

It would appear that, irrespective of the coupling that occurs, there is a great deal of similarity between a motion involving flexion followed by lef side bending, and a motion involving lef side bending followed by flexion. However, although both motions have the same end result, they use different methods to arrive there. T e same could be said of the following combined motions:

- Flexion and right side bending followed by right side bending and flexion
- Extension and right side bending followed by right side bending and extension
- Extension and lef side bending followed by lef side bending and extension

By using combined motions, the clinician can of en reproduce a patient's symptom that was not reproduced using the planar motions of flexion, extension, side bending, and rotation.[32–34] However, care should be taken when utilizing combined motions, especially with the acute and subacute patient, when a reduction of symptoms through modalities and gentle exercise might be preferable to exacerbating the patient's condition through a comprehensive movement examination.

Using a biomechanical model, a restriction of extension, side bending, and rotation to the same side of the pain is termed a closing restriction, whereas a restriction of the opposite motions (flexion, side bending, and rotation to the opposite side of the pain) is termed an opening restriction. Motions that involve flexion and side bending away from the symptoms tend to invoke a stretch to the structures on the side of the symptoms, whereas motions that involve extension and side bending toward the side of the symptoms produce a compression of the structures on the side of the symptoms.[32–34] An example of a stretching pattern would be a pain on the right side of the spine that is increased with either flexion followed by a lef side-bending movement or a lef side-bending motion followed by a flexion movement. A compression pattern would involve pain on the right side of the spine that is increased with a movement involving either extension followed by right side bending or right side bending followed by the extension.

T e symptom reproduction that occurs with combined motions usually follows a logical and predictable pattern. However, there are situations in which illogical patterns are found. Because the vertebral column consists of many articulating segments, movements are complex and usually involve several segments resulting in restrictions that may be complex and apparently illogical. An example of such a pattern would be a pain on the right side of the spine that is increased with a flexion and right side bending combination but decreased with an extension and right side bending combination. T e movements just described involve a combination of stretching and compression movements. T ese illogical patterns typically indicate that more than one structure is involved.[32–34] Of course, they could also indicate to the clinician that the patient does not have a musculoskeletal impairment.

SPINAL STABILITY

Spinal stability is characterized by the behavior of the spinal column and the coordination of muscles that surround the spine. T ere are two types of stability:

- Static. T is type of stability refers to a state of equilibrium where the velocity of the object or body is zero. When a person is standing perfectly still with no swing back and forth, the person said to be in static equilibrium.
- Dynamic. T is type of stability implies a change over time, but the velocity is constant. T eoretically, if a perturbation is applied to the spine, and the spine behaves as it did in its undisturbed state, it is said to be stable, whereas if the spine's kinematic behavior changes as a result of the disturbance, it is unstable.[35] States requiring dynamic stability are far more common than those requiring static stability. T us, from the mechanical point of view, the spinal system is inherently unstable. Panjabi[36,37] indicates that there are three subsystems that contribute to spinal stability:
  - Passive system. T e spinal column, which includes the vertebrae, IVDs, zygapophyseal joints, joint capsules, and ligaments (Fig. 22-4) are the load-bearing units and the source of passive stiffness for stabilizing the spine. Passive stiffness of the ligaments and joint capsules is mainly a factor at the extremes of the ROM. T e effectiveness of the passive support system is a factor of the ability of its structures to resist the forces of translation, compression, and torsion.
  - Active system. Muscles, which serve to reduce or prevent movement and are the source of active stiffness (i.e., muscles act like stiff springs) by using stored elastic energy and the level of activation or force.[36,38] Because the passive stiffness is mainly engaged at the extremes of range, the primary source of stiffness for stability during movements in healthy individuals is from the active stiffness of the trunk muscles and not the passive stiffness of ligaments. A large number of muscles have a mechanical effect on the spine and pelvis, and all muscles are required to maintain optimal control.[38] T is muscle activity must be coordinated within a hierarchy of interdependent levels: control of intervertebral translation and rotation, control of spinal posture/orientation, and control of the body

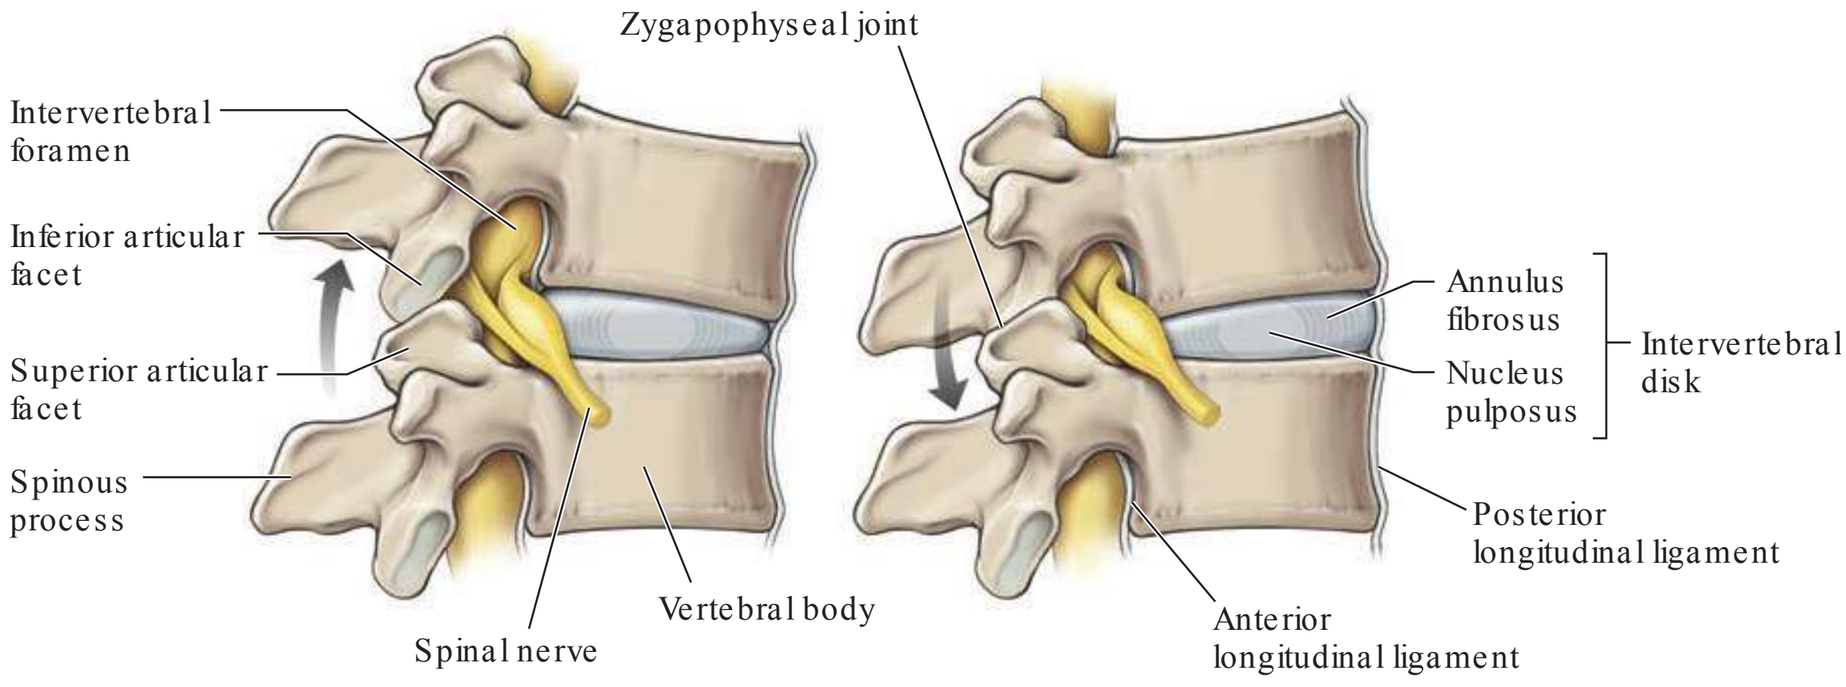

FIGURE 22-4 The passive system of the spine. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

with respect to the environment, in addition to maintaining a number of homeostatic functions such as respiration and continence.[38–40] The concept of different trunk muscles playing differing roles in the provision of dynamic stability to the spine was proposed by Bergmark[41] and later refined by others.[42–47] The specific muscles that provide stability and their interactions are described in the relevant chapters.

- Central nervous system (CNS), which utilizes feedforward (anticipatory) control to generate active muscle stiffness and uses the feedback (reflex) control to augment the stiffness.[48] The CNS must continually interpret the status of stability, plan mechanisms to overcome predictable challenges, and rapidly initiate activity in response to unexpected challenges.[38]

CLINICAL PEARL

Although trunk muscles must have sufficient strength and endurance to satisfy the demands of spinal control, the efficacy of the muscle system is dependent on its controller, the CNS.[36,38]

The neutral zone is a term used by Panjabi[36] to define a region of laxity around the neutral resting position of a spinal segment. The neutral zone is the position of the segment in which minimal loading is occurring in the passive structures (IVD, zygapophyseal joints, and ligaments) and the active structures (the muscles and tendons that control spinal motion), and within which spinal motion is produced with minimal internal resistance.[2] Panjabi et al.[49] have studied the effect of intersegmental muscle forces on the neutral zone and ROM of a lumbar functional spinal unit subjected to pure moments in flexion–extension, side bending, and rotation. Simulated muscle forces were applied to the spinous process of the mobile vertebra of a single motion segment using two equal and symmetric force vectors directed laterally, anteriorly, and inferiorly. The simulated muscle force maintained or decreased the motions of the lumbar segment for intact and injured specimens, with the exception of the flexion ROM which increased.[49]

CLINICAL PEARL

Mechanoreceptors throughout the spine play an important role in spinal stability. For example, the mechanoreceptors can provide excitatory or positive feedback control during rapid elongation of the ligaments.[50] For example, when large unexpected perturbations caused the spine to flex rapidly, the quick stretch to the posterior ligaments of the spine leads to a rapid activation of the trunk extensor muscles.[51] In addition, the mechanoreceptors can become desensitized when exposed to tissue creep, leading to impaired muscle responses.[52]

The interaction between the passive and active systems of the spine changes when there has been prolonged tension or cyclic loading of the passive system resulting in a change to the muscle responses in the form of a delayed response. Furthermore, it is hypothesized that these changes in muscle activation may lead to increased spinal compression forces, which have been recognized as a risk factor for vertebral end-plate fracture, especially if applied repetitively.[53,54] An alternate consequence is that muscle insufficiency resulting from fatigue may shift the loading to the passive tissues,[55,56] which may put the spine at increased risk of injury.

CLINICAL PEARL

Activities such as acute repetitive loading have been shown to have a significant effect on reducing the stiffness of the passive tissues of the spine because of the viscoelastic nature of the muscles, tendons, ligaments, and IVDs.[57,58]

Under normal circumstances, when large perturbations are expected, preparatory coactivation of the spinal muscles enhances active stiffness, and reflexes augment the stiffness at the appropriate time.[59] These anticipatory postural adjustments and corrective responses are part of a motor control strategy executed by the CNS that was learned from previous experience when performing similar movements or activities.[60–63]

The emphasis on spinal stability exercises should be to:

- Strengthen the trunk muscles so that they are able to produce sufficiently large forces and active stiffness. The timing and sequencing of muscle activity, coupled with the appropriate magnitude of muscle activation, produces smooth, accurate, and efficient movement behavior that is adjusted to the immediate demands and consequences within the environment.[48]
- Increase the endurance of the trunk muscles so that the force output of the muscles does not deteriorate.
- Incorporate sound motor learning principles to address impaired motor control strategies.

The various strategies to incorporate into the intervention for spinal instability are addressed in the appropriate chapters.

EXAMINATION OF THE VERTEBRAL COLUMN AND PELVIS

The examination of the spine is complicated by the number of conditions that can cause pain in this region of the body. In addition, there is little scientific evidence for the establishment of many of the diagnostic labels attributed to spinal pain, such as instability, degenerative disk disease, and subluxation.[64]

The purpose of the examination is to identify correctly those patients who will benefit from a physical therapy intervention. The correct identification of a diagnosis requires the use of evidence-based measuring tools that are valid, specific, and sensitive. There are numerous methods for examining and evaluating the spine, and each of these results in a conclusion that determines the course of the intervention.[65,66] Unfortunately, many of the procedures that are used today to examine the spine demonstrate methodologic shortcomings.[64–66] The interventions for spinal conditions fair no better. Despite the ever-increasing numbers of randomized controlled trials evaluating interventions for low back pain (LBP),[67] treatment outcomes remain less than optimal.[68] One reason for this may be the fact that many trials test interventions in a heterogeneous population of patients with LBP and such a diverse group of patients may not correspond to the one-treatment approach.[69] This is hypothesis has led to the design of classification systems to identify subgroups of patients who may respond preferentially to certain treatments.[70]

Use of Traditional Classification Systems

In recent years, attempts have been made to use a variety of methods to classify spinal pain, particularly LBP, into syndromes. The term syndrome implies that the specific diagnosis is unknown. A syndrome is a collection of signs and symptoms that, collectively, characterizes a particular condition. In the spine, where determining a specific diagnosis has historically been proven to be extremely difficult, syndromes have become popular. By classifying syndromes, it is proposed that a patient is more likely to respond to a type of intervention unique to that syndrome. The criteria that have thus been used to categorize a syndrome include the following:

- Pathoanatomy.[71,72] This is strategy involves using correlations to produce categories. The disadvantage of using pathoanatomy is the difficulty in identifying a relevant pathoanatomic cause for most patients.[73]
- Presence or absence of radiculopathy.[74,75]
- Location and type of pain.[76]
- Duration of the symptoms (acute, subacute, or chronic).[77]
- Activity and work status.[75,78]
- Impairments identified during the physical examination.
- Direction of motion that reproduces, peripheralizes, or centralizes the symptoms.[79]

The more common classifications are outlined next. The use of such classification systems may have some prognostic value and can direct clinicians to specific interventions.[80]

Osteopathic System

Osteopaths rely on the results of the active motion tests and position tests to determine their intervention approach. Note: Osteopaths use the term "side flexion" instead of "side bending."

Position Testing

Position testing involves palpation of the soft tissues over paired transverse processes of the spine, to detect palpable positional irregularity and altered tissue tension at a segmental level when the spine is positioned in flexion or extension compared with neutral. To locate the transverse process in the lumbar spine, the clinician first locates the spinous process to determine the level and then moves slightly laterally and superiorly by placing the thumbs on either side of the spinous process. Thus, the clinician must be very familiar with so-called layer palpation to be sure that the palpating fingers are monitoring the positions of the transverse processes at a particular segmental level. Vertebral dysfunctions occur as a combination of movements in the three planes. The key movement is the rotation. Theoretically, the rotational dysfunction, which is a result of the altered axis of rotation produced by the stiffer of the two sides of the segment, will be palpated as a much firmer end-feel to the palpation on that side. The direction of the rotation is named after the more posterior of the two transverse processes, and the positional name is an osteokinematic one having no established relationship with any joint.

Position Testing in Extension

If a marked segmental rotation is evident at the limit of extension, this would indicate that one of the facets is unable to complete its inferior motion (i.e., it is being held in a relatively flexed or superior position). The direction of the resulting rotation (denoted in terms of the anterior part of the vertebral body) informs the clinician as to which of the facets is not moving. For example, if the segment is rotated to the left when palpated in extension, the right zygapophyseal joint is not moving normally. This is impairment can be described in one of the following three ways:

1. The right zygapophyseal joint cannot extend or "close."
2. The right zygapophyseal joint is flexed (F), rotated (R), and side-flexed (S) left (L) around the axis of the right zygapophyseal joint.

3. T e right zygapophyseal joint is unable to perform any motions that require an inferior glide, such as extension, right side bending, and right rotation.

FRS or extension impairments are more evident in the positional tests than ERS impairments (described next) because there is less overall motion available into extension.

Position Testing in Flexion

If a marked segmental rotation is evident in full flexion, this indicates that one of the facets cannot complete its superior motion. For example, if the segment is found to be lef -rotated when palpated during flexion, the lef zygapophyseal joint is not moving normally.

T is impairment can be described in one of the following three ways:

1. T e lef zygapophyseal joint cannot flex or "open."
2. T e lef zygapophyseal joint is extended (E), rotated (R), and side-flexed (S) lef (L).
3. T e lef zygapophyseal joint is unable to perform any motion that requires a superior glide such as flexion, right rotation, and right side bending.

Position Testing in Neutral

Positional testing is performed in the neutral spine position for three reasons as follows:

1. If a rotational impairment of a segment exists only in neutral and is not evident in either full flexion or full extension, the cause of the impairment is probably not mechanical in origin but rather neuromuscular. T ese neuromuscular impairments are usually found at the spinal junctions, particularly the thoracolumbar and cervicothoracic junctions.
2. If a marked rotation is evident at a segment and this rotation is consistent throughout flexion, extension, and neutral, then the cause is probably an anatomic anomaly (e.g., scoliosis) rather than an articular problem.
3. If the cause of the rotational impairment is articular (zygapophyseal joint), the positional testing in neutral gives the clinician an idea as to the starting position of the corrective technique.

T e terminology used to describe the rotational disruption of the pure spinal motions (ERS or FRS) describes the positional and kinetic impairments only. It does not indicate what the pathology might be. Reasons for these impairments, other than movement dysfunctions, may include bony anomalies such as a deformed transverse process, compensatory adaptation, structural scoliosis, or a hemivertebra.

T e analysis of the change in the rotational impairment between full flexion and full extension theoretically gives clues as to the pathology. T us, in conjunction with other tests, such as active motion testing, this analysis can assist in ascertaining a biomechanical diagnosis.

Position testing has been found to be very reliable when used by experienced clinicians to identify segmental levels based on the relative position of spinous processes.[81] T e results for interrater reliability have been mixed when clinicians are asked to determine lumbar segmental abnormality using position testing,[82,83] and poor when attempting to determine the segmental level of a marked spinous process.[84]

CLINICAL PEARL

The clinician should be aware that position testing is insensitive to symmetric impairments and thus can give false negatives.

McKenzie System

T e McKenzie mechanical diagnostic and classification approach is a noninvasive and inexpensive method of assessing patients with cervical and LBP that uses physical signs, symptom behavior, and their relation to end-range test movements to determine appropriate classification and intervention.[79]

T e McKenzie approach focuses on the following four components:

- Providing a mechanical diagnosis.
- Providing a mechanical treatment, which is based on the mechanical diagnosis.
- Prevention of recurrence which is achieved by emphasizing the patient's responsibility for their own recovery
- Fully exploring the patient's self-generated forces before progression to externally applied forces.

According to McKenzie, symptoms of lumbar and/or cervical pathology can demonstrate a phenomenon of centralization and peripheralization.[79]

- Centralization of symptoms is the immediate or eventual abolition of the most distal extent of referred or radicular pain toward the midline of the spine in response to therapeutic loading strategies. Centralization occurs more commonly with extension, especially with end-range repeated movements. Although centralization of the symptoms can be associated with an increase in spinal pain, it normally indicates improvement in the patient's condition and provides the clinician with a directional preference.
- Peripheralization of symptoms indicates movement in the opposite direction and is usually associated with a poorer prognosis.

T e history taking is an integral component of the McKenzie approach. T e purpose of the history is to provide the clinician with information regarding

- an overall impression of the clinical presentation;
- the site of pain;
- the stage of the disorder;
- the status of the presenting condition; the severity of problem is used to guide the vigor of the examination;
- the identification of red flags;
- the baseline of symptomatic/mechanical presentation against which improvements can be judged;

- any aggravating/relieving factors (especially the role of posture); this helps the clinician to develop a hypothetical diagnosis by syndrome; and
- functional limits on the patient's quality of life.

During the initial observation, the patient's sitting and standing postures are noted to reveal how the spine is habitually subjected to static loading by the patient. In addition, the patient is asked to perform a single movement of each movement plane direction (see below) while the clinician notes the quantity and quality of movement—the ability of the patient to achieve end-range with spinal curve reversal and without deviating from the intended movement plane.[85] The accurate assessment of the effect of repeated movements/sustained positions on the patient's pain patterns is a key component of the McKenzie examination (Table 22-1). The movement plane directions evaluated for both the cervical and lumbar spines are those within which the clinically presenting antalgic postures occur.[85]

- Cervical spine. The movements observed include protrusion, flexion, retraction, extension, side bending right, side bending left, rotation right, and rotation left.
- Lumbar spine. The movements observed include flexion, extension, side gliding to the right, side gliding to the left.

After the quantity and quality of movement is assessed by the performance of single movements in each movement plane direction, dynamic and static tests are performed.[85] The effects of loading in a certain movement plane direction are highlighted best by repetition (dynamic) or sustained (static) loading. Static loading tests are generally used when dynamic tests do not provide a clear preferred loading strategy. With both the static and dynamic tests, loading in a sagittal movement plane direction is typically explored first, unless the patient has significant antalgia in a coronal movement plane direction, in which case, the coronal movement plane is explored first.[85] Should loading in the coronal plane not provide satisfactory answers, the transverse movement plane is explored.

- Dynamic tests. These tests involve performing a single motion within the movement plane direction being studied, followed by repetitive motion in the same movement plane direction while the clinician closely monitors how mechanics and symptoms respond to motion, at end-range, and after the dynamic loading. The testing progression applied includes the following[85]:
- Cervical spine. Flexion in sitting, retraction in sitting, retraction-then-extension in sitting, retraction in lying, and retraction extension in lying. If required, the following tests are also performed: protrusion in sitting, retracted side bending right in sitting, retracted side bending left in sitting, retracted rotation right in sitting, and retracted rotation left in sitting.
- Lumbar spine. Flexion in standing, extension in standing, flexion in lying, and extension in lying. If required, the following tests are also performed: side gliding right in standing or prone extension with right lateral shift and side gliding left in standing or prone extension with a left lateral shift.

Static tests. These tests are often used as ancillary tests to confirm dynamic testing or to explore further the effects of loading when dynamic testing yields no definitive conclusion.[85]

- Cervical spine. Protrusion, flexion, retraction (sitting or supine), retraction and extension (sitting, prone, or supine), retracted side bending right or left, and retracted rotation right or left.
- Lumbar spine. Sitting slouched, sitting erect, standing slouched, standing erect, lying prone in extension, long sitting, lateral shift right or left, and rotation in flexion.

The clinical reasoning intrinsic to the McKenzie method classifies mechanical and symptomatic responses to loading into three main syndromes: postural, dysfunction, and derangement (Table 22-2).

The posture syndrome is proposed to result from sustained loading of the tissues during end-range positions/postures. The pain associated with the postural syndrome is of a gradual onset, dull, local, midline, symmetric, and never referred. Prolonged postures worsen the pain, whereas movement abolishes it. On examination, the patient demonstrates no spinal deformity or loss of range and repeated movements do not produce the symptoms. The onset of symptoms, which is time-dependent (usually occurring after more than 15 minutes), is provoked with sustained end-of-range positions.

The dysfunction syndrome is proposed to result from an adaptive shortening of some soft tissues and an overstretching of others. The intermittent pain associated with this syndrome is local, adjacent to the midline of the spine, and not referred. The exception occurs in the case of an adherent nerve root (ANR) where the pain may be felt in the buttock, thigh, or calf (Table 22-3). The ANR represents the only time when the distal pain is experienced in the dysfunction syndrome,

TABLE 22-1 Various Effects of Test Movements

Term	Definition
Produce	No symptoms at rest but are created with movement
Increased	Symptoms present are increased
Decreased	Symptoms present are decreased
Abolished	Movement eliminates those symptoms that occur with rest
Worse	Symptoms increase or remain worse
No worse	Symptoms increase with movement (don't remain worse)
No better	Symptoms reduced/abolished with movement (do not remain)
Better	Presenting symptoms decreased/abolished/remain better
Pain during movements	Pain during movements
End range pain	Pain occurs at end ranges
No effect	Movement has no effect on symptoms

| | f | | |

TABLE 22-3 Characteristics of the Adherent Nerve Root

The ANR syndrome usually presents following the resolution of a derangement syndrome or postsurgically (6–12 weeks).

History
- Sciatic or surgery in the few months that has improved but is now unchanging
- Intermittent leg symptoms, thigh/calf (tightness)
- Consistent activity produces symptoms: touching toes, long sitting, walking
- Pain in leg does not persist upon ceasing movement or when changing position

Examination
- Flexion in standing clearly restricted—consistently produces concordant pain/tightness at end range
- No rapid reduction/abolition of symptoms produced; no lasting distal symptoms
- Moderate/major loss of flexion (may demonstrate deviation)
- Flexion movement will improve if knee is flexed
- FIL has no effect
- No rapid change in mechanical presentation with repeated movement testing

Intervention
- Flexion in sit with increasing knee extension
- Flexion in stand
- Flexion step stand (opposite leg on chair)
- End the session with EIL/EIS
- Monitor mechanical response to extension; should remain unchanged following repeated flexion

FIL, flexion in lying; EIL, extension in lying; EIS, extension in standing.

and the only time when distal symptoms are repeatedly reproduced as part of its management. Activities and positions at the end of range worsen the pain of the dysfunction syndrome, whereas activities that avoid end-ranges lessen the symptoms. On examination, the patient demonstrates a loss of motion or function that distinguishes this syndrome from the posture syndrome. Repeated movements do not alter the symptoms, and the loss of motion, or function may be symmetric or asymmetric.

The derangement syndrome is thought to result from a displacement or an alteration in the position of joint structures. The joint structure most commonly involved is the IVD, and McKenzie divides these disturbances into either a posterior disk or an anterior disk derangement. The posterior derangement can be subdivided further into seven derangement categories. Derangements 1 through 6 describe posterior derangements, whereas derangement 7 describes the anterior derangement (Table 22-4).

The pain of a derangement syndrome, which is usually of a sudden onset and is associated with paresthesia (or numbness), is dull or sharp and can be central, unilateral, symmetric, or asymmetric. The symptoms, which can vary in both intensity and distribution, may be referred to the buttock, thigh, leg, or foot. Bending, sitting, or sustaining positions worsen a posterior derangement, whereas walking and standing worsen an anterior derangement. Patients with a posterior derangement often feel better when walking and lying, whereas patients with an anterior derangement usually feel better in sitting and other flexed positions. With an examination, a lateral shift may be noted. There is always a loss of motion and function. Certain motions produce, increase, or cause the symptoms to peripheralize (move away from the spine), whereas other motions decrease, abolish, or centralize the symptoms. McKenzie

TABLE 22-4 Comparison of the Lumbar and Cervical McKenzie Derangement Syndromes

Lumbar Derangements	Cervical Derangements
Derangement 1 Central or symmetrical pain across low back; rarely buttock and/or thigh pain; no deformity	Derangement 1 Central or symmetrical pain about C5–7; rarely scapular and/or shoulder pain; no deformity
Derangement 2 Central or symmetrical pain across low back with or without buttock and/or thigh pain; deformity of lumbar kyphosis	Derangement 2 Central or symmetrical pain about C5–7 with or without scapular, shoulder, or upper arm pain; deformity of cervical kyphosis
Derangement 3 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain; no deformity	Derangement 3 Unilateral or symmetrical pain about C3–7 with or without scapular, shoulder, or upper arm pain; no deformity
Derangement 4 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain; deformity of lumbar scoliosis	Derangement 4 Unilateral or symmetrical pain about C5–7 with or without scapular, shoulder, or upper arm pain; with deformity or acute wry neck or torticollis
Derangement 5 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain with sciatica extending below knee; no deformity	Derangement 5 Unilateral or symmetrical pain about C5–7 with or without scapular or shoulder pain and with arm symptoms distal to elbow; no deformity
Derangement 6 Unilateral or asymmetrical pain across low back with or without buttock and/or thigh pain with sciatica extending below knee; deformity of lumbar scoliosis	Derangement 6 Unilateral or symmetrical pain about C5–7 with arm symptoms distal to the elbow with deformity of cervical kyphosis, acute wry neck or torticollis
Derangement 7 Symmetrical or asymmetrical pain across low back with or without buttock and/or thigh pain with deformity of accentuated lumbar lordosis	Derangement 7 Symmetrical or asymmetrical pain about C4–6 with or without anterior/anterior-lateral pain; no deformity

advocates a variety of loading principles for the reduction of the derangement.

- Extension
- Flexion
- Lateral movement
- Force progression
  - Start position: loaded versus unloaded
  - Positioning to mid-range
  - Positioning at end-range
- Dynamic patient-generated forces
  - Patient motion to mid-range
  - Patient motion to end-range
  - Patient motion to extreme ranges using patient overpressure (sag).
- Clinical generated forces
  - Patient motion to mid-range with clinician's overpressure
  - Patient motion to end-range with clinician's overpressure
- Clinician mobilization
- Clinician high-velocity thrust technique
- Force alternatives
- Static patient-generated forces
- Strategy: sagittal/frontal or combination
- Time factor: sustained/repeated
- Frontal plane angle during combined procedures

Once the subjective history and mechanical evaluation has been performed on the initial visit, the clinician should have an idea regarding which mechanical category the patient may belong. Depending upon the syndrome, a specific self-treatment program is prescribed for home use, and the patient is encouraged to accept responsibility for the intervention and recovery. The specific programs relative to the cervical and lumbar spine are described in the respective chapters.

The interrater reliability of the McKenzie method in performing clinical tests and classifying patients with LBP into syndromes has been investigated in a number of studies.[65,86–94]

Repeated movements have been found to be a reliable part of the examination of the spine in a number of studies.[93,95]

In one study,[93] intertester reliability between two therapists trained in the McKenzie method seemed to be high for classifying patients with LBP into McKenzie syndromes, and excellent for judging pain status change, including the centralization phenomenon, during examination of the lumbar spine.[91,93] The results from a study by Kilpikoski also suggested that intertester reliability in performing clinical tests and classifying patients with LBP into the main McKenzie syndromes is high when the clinicians have been trained in the McKenzie method.[94]

Donahue et al.[86] suggested that the McKenzie method was unreliable for detecting the presence of a lateral shift, but that a relevant lateral component could be reliably detected using symptom response to repeated movements. In contrast, Tenhula et al.[90] noted a significant relation between positive results on a contralateral side-bending movement test and a lumbar lateral shift, indicating that the former is a useful clinical test for confirming the presence of a lateral shift in patients with LBP.

Kilby et al.[92] found the "McKenzie algorithm" (Fig. 22-5) to be reliable in the examination of pain behavior and pain response with repeated movements but unreliable in the detection of end-range pain and lateral shift.

Riddle and Rothstein[65] found that the McKenzie approach was unreliable when physical therapists classified patients into McKenzie syndromes. They suggested that a potential source of unreliability was in determining whether the patient had a lateral shift and, if so, in which direction and whether the patient's pain centralized or peripheralized during test movements.[65]

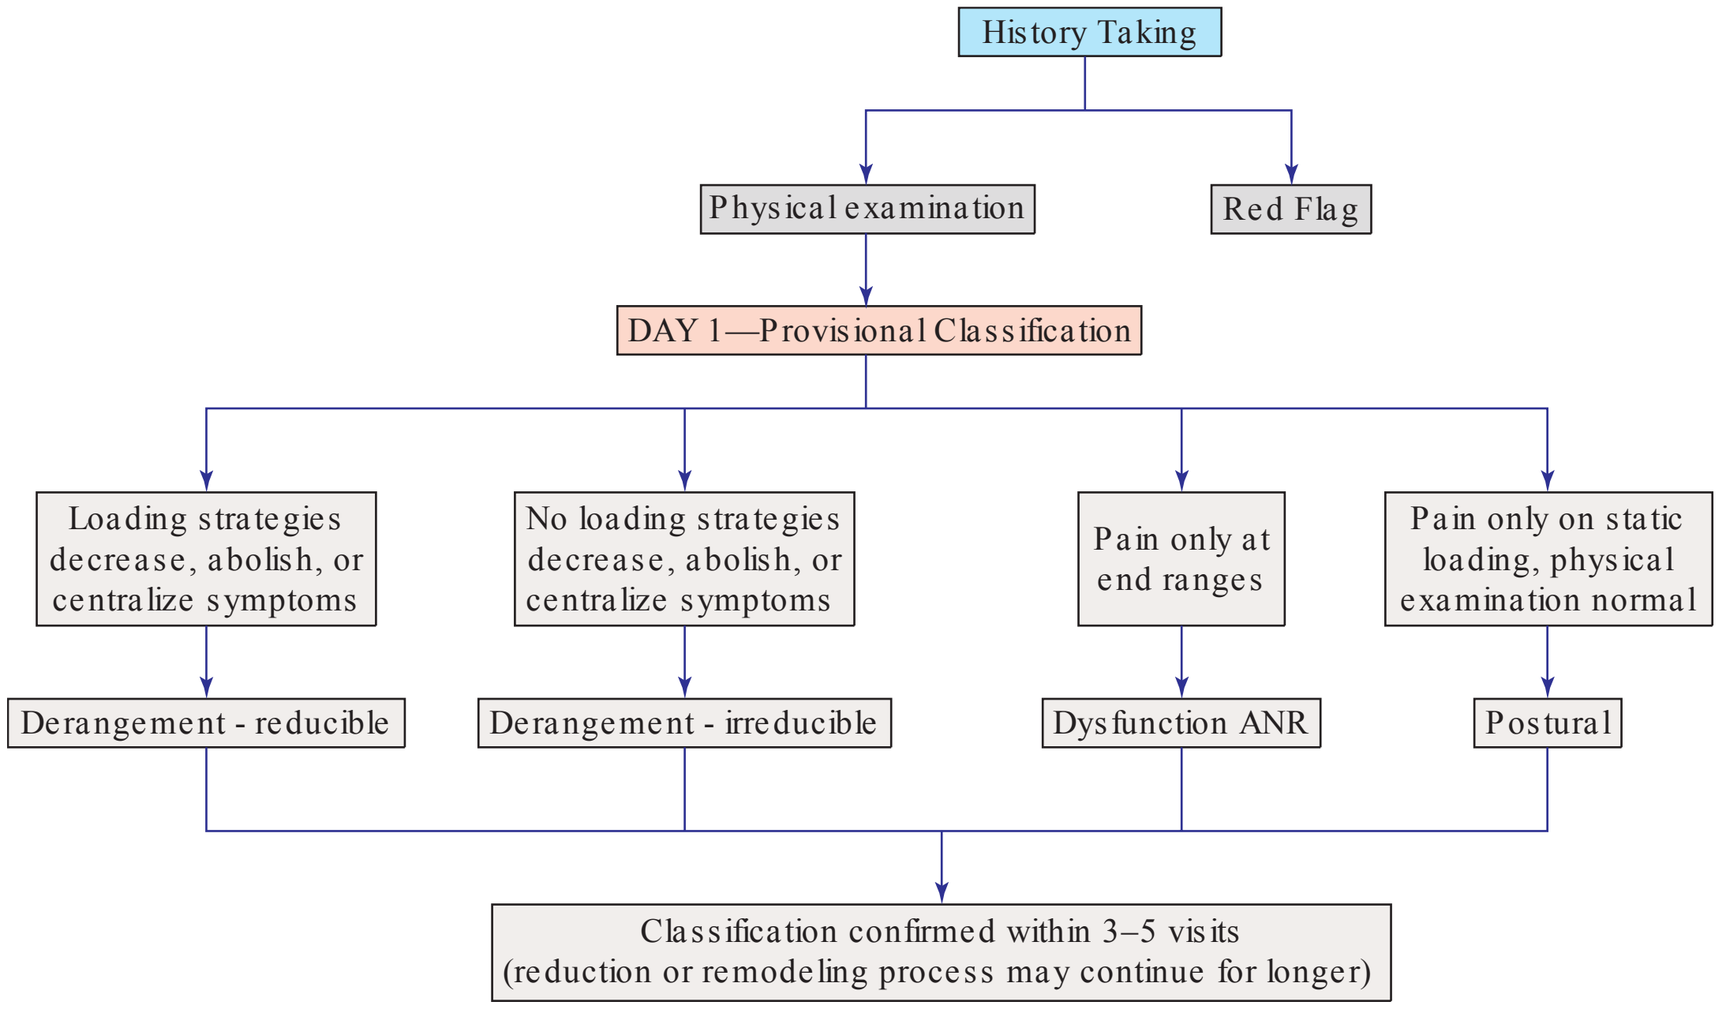

FIGURE 22-5 McKenzie classification algorithm.

Treatment-Based Classification System

T is system, originally proposed by Delitto et al.,[96] uses information gathered from the physical examination and from the patient's self-reports of pain (pain scale and pain diagram) and disability (modified Oswestry questionnaire) to classify the patient with LBP.[96,97] T e classification determines whether the patient's condition is amenable to physical therapy or whether care from another practitioner is required. T e treatment-based classification (TBC) system is designed for patients judged to be in the acute stage, with the determination of acuity based on the alignment of various body structures, the effect of movements on symptoms, the nature of the patient's symptoms, the degree of disability, and the goals for management, instead of strictly on the elapsed time from injury.[97]

Patients in the acute stage are those with higher levels of disability (modified Oswestry scores generally greater than 30), who report substantial difficulty with basic daily activities such as sitting, standing, and walking. Intervention goals are to improve the ability to perform basic daily activities, reduce disability, and permit the patient to advance in his or her rehabilitation.[97] Modifications to improve this algorithm have since been suggested in an attempt to improve treatment success.[70,98]

T e opening question for the algorithm asked whether the patient has symptoms distal to the buttock and signs of nerve root compression.

If the answer is YES (the patient has symptoms distal to the buttock and signs of nerve root compression), the clinician determines whether the patient has a peripheralization of those symptoms with an extension movement, OR has a positive crossed straight-leg raise (SLR) test. If the answer is YES to either, the patient is placed in the *T*raction classification.

- If the answer is NO to both, the clinician determines whether the patient experiences centralization with two or more movements in the same direction (i.e., flexion or extension), OR experiences centralization with movement in one direction and peripheralization with an opposite movement. If the answer is YES to one or both, the patient is placed in the Spec*if*ic Exercise classification.

  If the answer is NO (the patient does not have symptoms distal to the buttock and signs of nerve root compression), the clinician determines whether the patient experiences centralization with two or more movements in the same direction (i.e., flexion or extension), OR experiences centralization with movement in one direction and peripheralization with an opposite movement.

- If the answer is YES to one or both, the patient is placed in the Spec*if*ic Exercise classification.
- If the answer is NO to these questions, the following two questions are considered:
  a. Does the patient have a recent onset of symptoms (less than 16 days) AND
  b. Does the patient have no symptoms distal to the knee?

If the answer is YES to both these questions, the patient is placed in the Manipulation/Mobilization classification.

If the answer is NO to both these questions, a further determination is made by determining whether the patient has at least three of the following:

a. Average straight leg raise > 91 degrees
b. Positive prone instability test
c. Positive aberrant movements
d. Age < 40 years

If the patient has at least three of the above, they are placed in the Stabilization classification.

Despite these refinements, in a 2012 study[99] it was noted that almost a quarter of the patients were difficult to categorize with the classification decision-making associated with the TBC system and the study concluded that additional refinement is needed to reduce rater disagreement that persists in the use of this algorithm, particularly in the stabilization category.[99] To address this issue, a cross-sectional study by Stanton et al.[100] suggested that those individuals with an unclear classification may have a condition that would benefit from a treatment approach not included in the current algorithm. Instead, those individuals should be excluded, and provided with different interventions to help improve outcomes.

Mobilization/Manipulation

T e mobilization classification includes patients believed to have indications for either sacroiliac or lumbar region mobilization or manipulation. Mobilization of the sacroiliac region is indicated by asymmetries of the pelvic landmarks (anterior superior iliac spines, posterior superior iliac spines, and iliac crests) with the patient in the standing position and by positive results in three of four tests as follows:

1. Asymmetry of posterior superior iliac spine heights with the patient seated.
2. T e standing flexion test.
3. T e prone knee flexion test.
4. T e supine to long-sitting test.

Acute-stage intervention for this category involves a manipulation technique proposed to affect the sacroiliac joint region, muscle energy techniques, and ROM exercises for the lumbosacral spine.

Lumbar mobilization is believed to be indicated by the presence of the following:

- Unilateral paraspinal pain in the lumbar region.
- Asymmetric amounts of lumbar side-bending ROM with the patient standing in either an "opening" pattern (limited and painful flexion and side-bending ROM to the side opposite the pain) or a "closing" pattern (limited and painful extension and side-bending ROM to the same side as the pain).

T e intervention for this category consists of lumbar mobilization or manipulation techniques and ROM exercises for the lumbosacral spine.

Stabilization

T e stabilization classification is purported to identify patients with lumbar segmental instability. Key examination findings are typically gleaned from the history and include a history of frequent episodes of symptoms precipitated by minimal perturbations, frequent use of manipulation with

short-term relief of symptoms, trauma, or reduced symptoms with the prior use of a corset.[96]

The intervention for this category focuses on strengthening exercises for the back extensor and abdominal exercises as well as stabilization exercises designed to improve dynamic control of the lumbar spine.[97]

Specific Exercise

The key examination finding that places patients in a specific exercise classification is the presence of centralization with lumbar spine movement based on the McKenzie method.[79] When either lumbar flexion or extension is found to produce centralization, the patient is treated with specific exercises in the direction that produces the centralization. Patients are also educated to avoid positions found to peripheralize symptoms during the examination.

The primary examination findings that lead to a classification of a lateral shift, in which the shoulders are offset from the pelvis in the frontal plane, are a visible frontal plane deformity and asymmetric side-bending ROM in standing. If correction of the deformity produces centralization, the patient is taught specific exercises designed to correct the lateral shift (i.e., pelvic translocation).[79]

Traction

The traction classification is reserved for patients with signs and symptoms of nerve root compression who are unable to centralize with any lumbar movements. The acute-stage intervention involves the use of mechanical traction or autotraction[101] in an attempt to produce centralization.

Under the TBC, patients judged to be in a more chronic stage are treated with a conditioning program designed to improve strength, flexibility, and conditioning, or with a work-reconditioning program.[96]

A recent cross-sectional study[70] to evaluate the TBC algorithm found that approximately one-half of patients with acute or subacute LBP met the criteria for only one treatment subgroup. In addition, although approximately 25% of the patients met the criteria for more than one subgroup, 25% of the patient's did not meet the criteria for any of the treatment subgroups. This latter finding suggests that further research is needed to refine the algorithm.

Canadian Biomechanical Model

The Canadian model is an eclectic approach founded upon an amalgam of doctrines and techniques that incorporate the biomechanical concepts of the Norwegians,[102–106] the selective tissue tension principles of Cyriax,[76,107] the muscle energy concepts of the American osteopaths,[108–110] the combined movement testing of Edwards,[34] the manipulative techniques of Stoddard,[111] the various approaches to stabilization therapy,[43,112–114] the exercise protocols of McKenzie,[79] the muscle balancing concepts of Janda, Jull, and Sahrmann,[115–117] and the movement re-education principles of the neurodevelopment and sensory integrationist clinicians.[118,119]

The basic tenet of the Canadian approach is that, given an understanding of the anatomy and biomechanics of a joint, segment, or region, the pathologic mechanisms can be extrapolated using a series of testing procedures. These tests include the Cyriax upper and lower quarter scanning examinations for differential diagnosis (see Chapter 4), uncombined (plane) and combined movement testing, passive physiological intervertebral motion (PPIVM) tests, passive accessory intervertebral motion (PAIVM) tests, and segmental stability tests.

Following the active motion tests, the clinician should be able to determine the planar motions (flexion, extension, and side bending and rotation to both sides) that provoke symptoms. However, the clinician cannot yet determine whether a joint or soft tissue is responsible for the pain. Two tests are used to help determine the presence of articular involvement: the PPIVM tests and the PAIVM tests.

Passive Physiologic Intervertebral Mobility Testing

The PPIVM tests are used to determine the amount of segmental mobility available in the spine. The PPIVM tests assess the ability of each segment to move through its normal ROM. The adjacent spinous processes of the segment are palpated simultaneously, and movement between them is assessed as the segment is passively taken through its physiologic range. If both spinous processes move simultaneously, there is no movement occurring at the segment and a hypomobility exists. If the movement between adjacent spinous processes appears excessive when compared with the level above or below, a hypermobility or instability may be suspected.

Thus, once the physiologic range has been assessed, it can be categorized as either normal, excessive, or reduced compared with the neighboring segment. Other positive findings for a hypomobility would be a reduced range in a capsular or noncapsular pattern in the active motion tests, a reduced joint glide, and a change in the end-feel from the expected norm for that joint. The end-feel and joint glide are both tested in the PAIVM tests (discussed next).

Therefore, one of three conclusions may be drawn from the PPIVM tests:

1. The joint motion is determined to be normal. If the PPIVM test of a spinal joint has a normal range and end-feel, the joint can usually be considered normal because in the spine, instability will invariably produce a hypermobility. However, in a peripheral joint, it is possible to have a normal range in the presence of articular instability. Thus, if a peripheral joint demonstrates a normal physiologic range, the stability of the joint needs to be tested using the segmental stability tests (see later discussion) before the clinician can deem the joint to be normal.
2. The joint motion is determined to be reduced (hypomobile). A hypomobility can be painful, suggesting an acute sprain of a structure, or painless, suggesting a contracture or an adhesion of the tested structure. If the motion is determined as being reduced (hypomobile), PAIVM testing is performed to determine, using the joint glides, whether the reduced motion is a result of an articular or extra-articular restriction.
3. The motion is determined to be excessive (hypermobile). If the motion is determined to be excessive, segmental

stability tests are performed to determine whether a hypermobility or an instability is present (see later discussion).

It is worth noting that the judgments of joint stiffness made by experienced physical therapists examining patients in their own clinics have been found to have poor reliability in a number of studies. In two separate studies,[95,120] manual therapy tests that provoke patient's symptoms were found to be more reliable than judging stiffness in the spine. Smedmark et al.[121] investigated the interexaminer reliability of passive intervertebral motion testing. In their study, the passive intervertebral motion of the cervical spine was assessed independently by two physical therapists whose backgrounds (education and clinical experience) were equal. Sixty-one patients seeking care for cervical problems at a private clinic were included in the study, in which three segments of the cervical spine and the mobility of the first rib were graded as stiff or not stiff. Data analyzed by percentage agreement and κ coefficient indicated an interexaminer reliability that was greater than expected by chance. Results demonstrated interexaminer reliability of between 70% and 87% and κ coefficients ranging between 0.28 and 0.43, considered to be only fair to moderate.

However, in a study by Gonnella et al.[122] the performance of five physical therapists in evaluating passive mobility of the vertebral column of five asymptomatic endomorphic subjects was assessed for the reliability within and between therapists, the criteria for grading, and the subjects themselves. Intratester reliability was found to be reasonable to good; there was no intertester reliability. Reliability was highest at L1–L3 and lowest at L5–S1. Problems identified were idiosyncratic behaviors that may develop with experience, subject characteristics, and the instrument itself.

Passive Accessory Intervertebral Mobility Testing

In the PAIVM tests, the clinician assesses the joint glides or accessory motions of each joint and determines the type of end-feel encountered.

Accessory motions are involuntary motions. With few exceptions, muscles cannot restrict the glides of a joint, especially if the glides are tested in the loose-pack position of a peripheral joint and at the end of the available range in the spinal joints.[123] T us, if the joint glide is restricted, the cause is an articular restriction such as the joint surface or capsule. If the glide is normal, then the restriction must be from an extraarticular source such as a periarticular structure or muscle.

Determining the type of end-feel is very important, particularly in joints that only have very small amounts of normal range such as those of the spine. To execute the end-feel, the point at which resistance is encountered is evaluated for quality and tenderness. Additional forces are needed from the clinician as the end-range of joint motion is reached. T is space, termed as the end-play zone, requires a force of overpressure to be reached and when that force is released, the joint springs back from its elastic limits. Because pain generally does not limit movement in specific and deliberate passive tests, the PAIVM tests are better for gauging the reliability of the limitation based on tissue resistance, rather than patient willingness, and are better at determining the pattern of restriction than the active tests. If the pain is reproduced with end-feel testing, it is useful to associate the pain with the onset of tissue resistance to gain an appreciation of the acuteness of the problem. A normal end-feel indicates a normal range, whereas an abnormal end-feel suggests an abnormal range, either hypomobile or hypermobile. If the articular restraints are irritable, the range will be about normal but will be accompanied by a spasm end-feel because a reflex muscle contraction can prevent the motion into an abnormal and painful range.[123,124] If nonirritable, the physiologic range will be increased, and the end-feel will be sof er than the expected capsular one, suggesting a compromise of the structure under examination. A hard, capsular end-feel indicates a pericapsular hypomobility, whereas a jammed end-feel indicates a pathomechanical hypomobility.

T e PAIVM tests can be performed symmetrically or asymmetrically. T ese tests are described in the relevant chapters of this text. Generally speaking, the symmetric tests are used when planar motions have produced pain in the active motion tests, whereas the asymmetric techniques are used when the combined motions have produced pain in the active motion tests.

Caution must be taken when basing clinical judgments on the results of accessory motion testing alone because few studies have examined the validity and reliability of accessory motion testing of the spine or extremities and little is known about the validity of these tests for most inferences.[125]

Hayes and Peterson[126] examined two physical therapists who used standardized positions to evaluate two knee motions and five shoulder motions. Evaluators did not interview subjects and were blinded to previous test results. Evaluators applied overpressure and noted the end-feel while subjects identified the moment their pain was reproduced. Following testing, subjects rated their pain intensity. Analyses included percentage of agreement κ, weighted κ, and maximum κ coefficients and confidence intervals. Analyses were repeated for subjects whose pain intensity during testing did not change between examinations. Intrarater κ coefficients varied from 0.65 to 1.00 for end-feel, and intrarater weighted κ coefficients varied from 0.59 to 0.87 for pain-resistance sequence. Most coefficients remained stable or improved for the unchanged subjects. Interrater κ coefficients for end-feel and weighted κ coefficients for pain resistance sequence varied from − 0.01 to 0.70. T e authors concluded that the reliability of end-feel and pain-resistance judgments at the knee and shoulder was generally good, especially af er accounting for subject change and unbalanced distributions. Interrater reliability, however, was generally not acceptable, even af er accounting for these factors.[126]

In a separate study by the same authors,[127] the relationship between pain and normal and abnormal (pathologic) end-feels during passive physiologic motion assessment at the knee and shoulder were examined. Physical therapists examined subjects with unilateral knee or shoulder pain, and each subject was examined twice. Passive physiologic motions, two at the knee and five at the shoulder, were tested by applying an overpressure at the end of ROM, using standardized positions. Subjects reported the amount of pain (0–10) immediately af er the evaluator recorded the end-feel. T e authors concluded that abnormal (pathologic) end-feels were associated with more pain than normal end-feels during

passive physiologic motion testing at the knee or shoulder. Dysfunction should be suspected when abnormal (pathologic) end-feels are present.[127]

Based on review of the literature of the MEDLINE and CINAHL databases for the period of 1980 through 2000, using the keywords motion palpation, accessory motion, and intervertebral motion, Huijbregts[128] performed a review of 28 reliability studies. T e following conclusions were made from this study:

- Intra-rater agreement varied from less than chance to generally moderate or substantial agreement.
- Interrater agreement only rarely exceeded poor to fair agreement.
- Rating scales measuring absence versus presence or magnitude of pain response yielded higher agreement values than mobility rating scales.

Segmental Stability Tests

T ese are tests for movements that should not exist to an appreciable degree. T e tests include maneuvers that induce nonphysiologic rotational, anterior, posterior, and transverse shears to the segment. T e limitation in the clinical diagnosis of segmental instability lies in the difficulty of accurately detecting excessive intersegmental motion, because even conventional radiologic testing is of en insensitive and unreliable.[129,130] Instability should be suspected in the presence of a positive stability test in conjunction with other clinical findings and symptoms of instability. A positive stability test in the absence of other clinical findings is probably irrelevant. Hypermobility is clinically manifested by the presence of increased physiologic range in one or more directions, or normal range with pain and spasm at the end of that range.

Research indicates that skilled clinicians can distinguish subjects with symptomatic spondylolysis from LBP based on the finding of increased intersegmental motion at the level above the pars defect.[131,132]

T e various stability tests are described in the specific chapters of this book.

CHAPTER 23

The Craniovertebral Region

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the craniovertebral segments.
2. Describe the biomechanics of the craniovertebral joints, including coupled movements, normal and abnormal joint barriers, and kinesiology.
3. Perform a comprehensive history and systems review for the craniovertebral region.
4. Perform a detailed examination of the craniovertebral musculoskeletal system, including palpation of the articular and soft-tissue structures, specific passive mobility tests, passive articular mobility tests, and stability tests.
5. Evaluate the total examination data to establish a diagnosis.
6. Apply appropriate manual techniques to the craniovertebral joints, using the correct grade, direction, and duration.
7. Describe intervention strategies based on clinical findings and established goals.
8. Evaluate intervention effectiveness in order to progress or modify intervention.
9. Plan an effective home program and instruct the patient in this program.
10. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

The craniovertebral region is a collective term that refers to the occiput, atlas, axis, and supporting ligaments, which accounts for approximately 25% of the vertical height of the entire cervical spine. Injuries to this region have the potential to involve the brain, brain stem, and spinal cord, resulting in a myriad of symptoms ranging from headache and vertigo to cognitive and sympathetic system dysfunction.[1] Craniovertebral injuries that involve cognitive and sympathetic system dysfunction demonstrate a poorer prognosis and a lengthy recovery.

ANATOMY

The craniovertebral region is considered as a separate entity from the rest of the cervical spine because of its distinct embryology and anatomical structure. Kapandji[2] notes that the occiput, atlas, and axis actually form a primary kyphotic curve and that this curve serves as a delineation between the craniovertebral region and the cervical spine proper.

Foramen Magnum

The general shape of the foramen magnum is oval, with the longer axis oriented in the sagittal plane.[3] The margin of the foramen is relatively smooth and serves as the most superior attachment for a variety of the ligaments of the vertebral column. The smaller anterior region of the foramen magnum is characterized by a pair of tubercles to which the alar ligaments attach. The posterior portion of the foramen magnum houses the brain stem–spinal cord junction.

On either side of the anterolateral aspect of the foramen magnum are two ovoid projections, called occipital condyles. The long axis of these paired occipital condyles is situated in a posterolateral to anteromedial orientation. The occipital condyles articulate with the first cervical vertebra.

Atlas

The atlas is a ring-like structure that is formed by two lateral masses, which are interconnected by anterior and posterior arches (Fig. 23-1A). The demarcation of the two regions is marked by a pair of tubercles to which the transverse ligament of the atlas attaches. Although the atlas has a smaller vertical dimension than any other cervical vertebrae, it is considerably wider. Because this vertebra does not have a spinous process, there is no bone posteriorly between the occipital bone

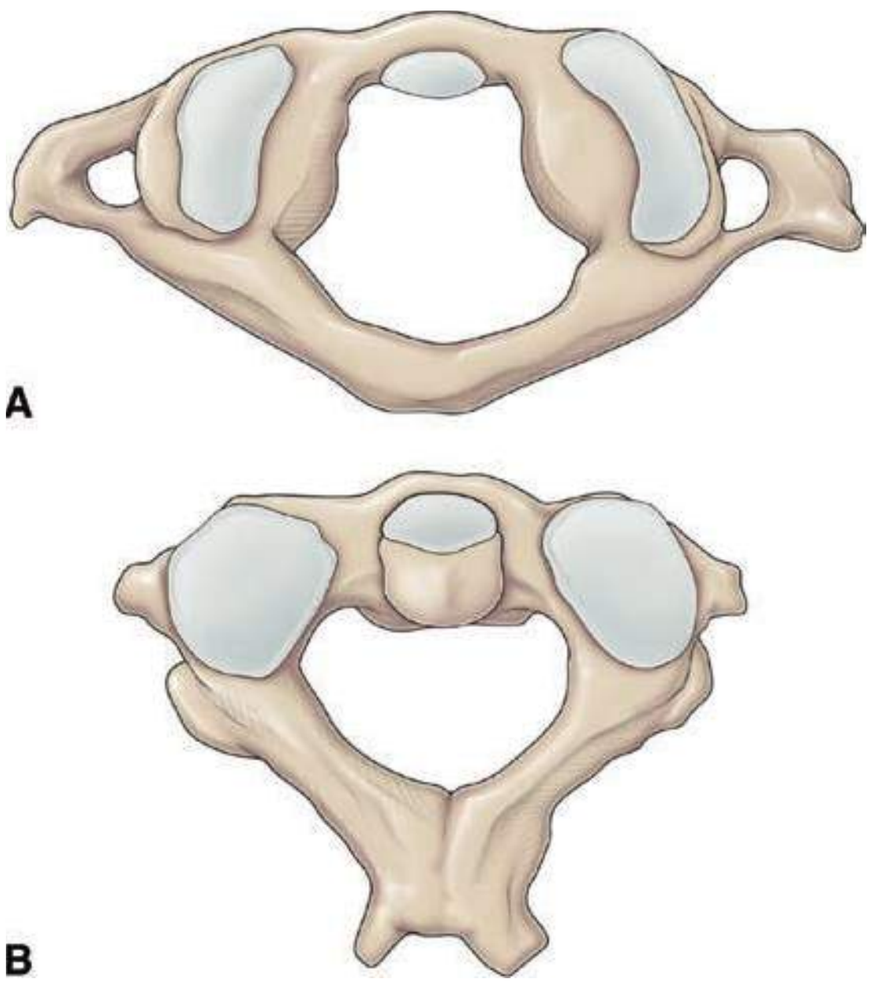

FIGURE 23-1 Bony structures of the craniovertebral joints. A. The atlas (C1). B. The axis.

and the spinous process of C2. T is results in an increase in the potential for craniovertebral extension.

T e superolateral aspect of each of the posterior arches has a transverse foramen to accommodate the vertebral artery (see Chapter 24). T e articular surface of the inferior facet is circular and relatively flat and slopes inferiorly from medial to lateral. T e upper articular facets of C1 are elongated from anterior to posterior, with the anterior ends closer together and more upwardly curved than their posterior counterparts.[3] T is arrangement results in much more extension than flexion being available at the articulation between the occipital condyles and the atlas—the occipitoatlantal (O-A) joint.[4]

O-A Joint

T e O-A joint represents the most superior zygapophyseal joint of the vertebral column and the only vertebral level that has an articulation characterized by a convex surface (occipital condyle) moving on a concave joint partner (articulating facet of the atlas).[5]

Axis

T e axis serves as a transitional vertebra (Fig. 23-1B) because it is the link between the cervical spine proper and the craniovertebral region.

T e dimensions of the axis are significantly different from those of the atlas. T e atlas is considerably wider than the axis, but because of the long spinous process, the axis extends much farther posteriorly and is the first palpable midline structure below the occiput.[6] Like the atlas, the transverse process of the axis has a transverse foramen to allow passage of the vertebral artery (not shown).

A unique feature of the axis is the odontoid process, or dens (Fig. 23-2B). T e dens, which develops with age, extends superiorly from the body to just above the C1 vertebra, before tapering to a blunt point (Fig.23-2). Very dense, thick trabecular bone is present in the center of the tip of the dens, and the cortical bone at the anterior base of the body of C2 (where the anterior longitudinal ligament attaches) is uniformly thick.[7] Hypodense bone, however, is present consistently beneath the odontoid process at the upper portion of the body of C2.[8] T is area of hypodense bone is susceptible to fracture. T e anterior aspect of the dens has a hyaline cartilage-covered mid-line facet for articulation with the anterior tubercle of the atlas (the median atlantoaxial (A-A) joint). T e posterior aspect of the dens usually is marked with a groove where the transverse ligament passes. T e dens functions as a pivot for the upper cervical joints and as the center of rotation of the A-A joint. T e most variable dimension of the axis is the dens angle in the sagittal plane, which can range from –2 degrees (leaning slightly anterior) to 42 degrees (leaning posterior).[9] T is extremely variable angle can make assessment of fracture reduction challenging.[7]

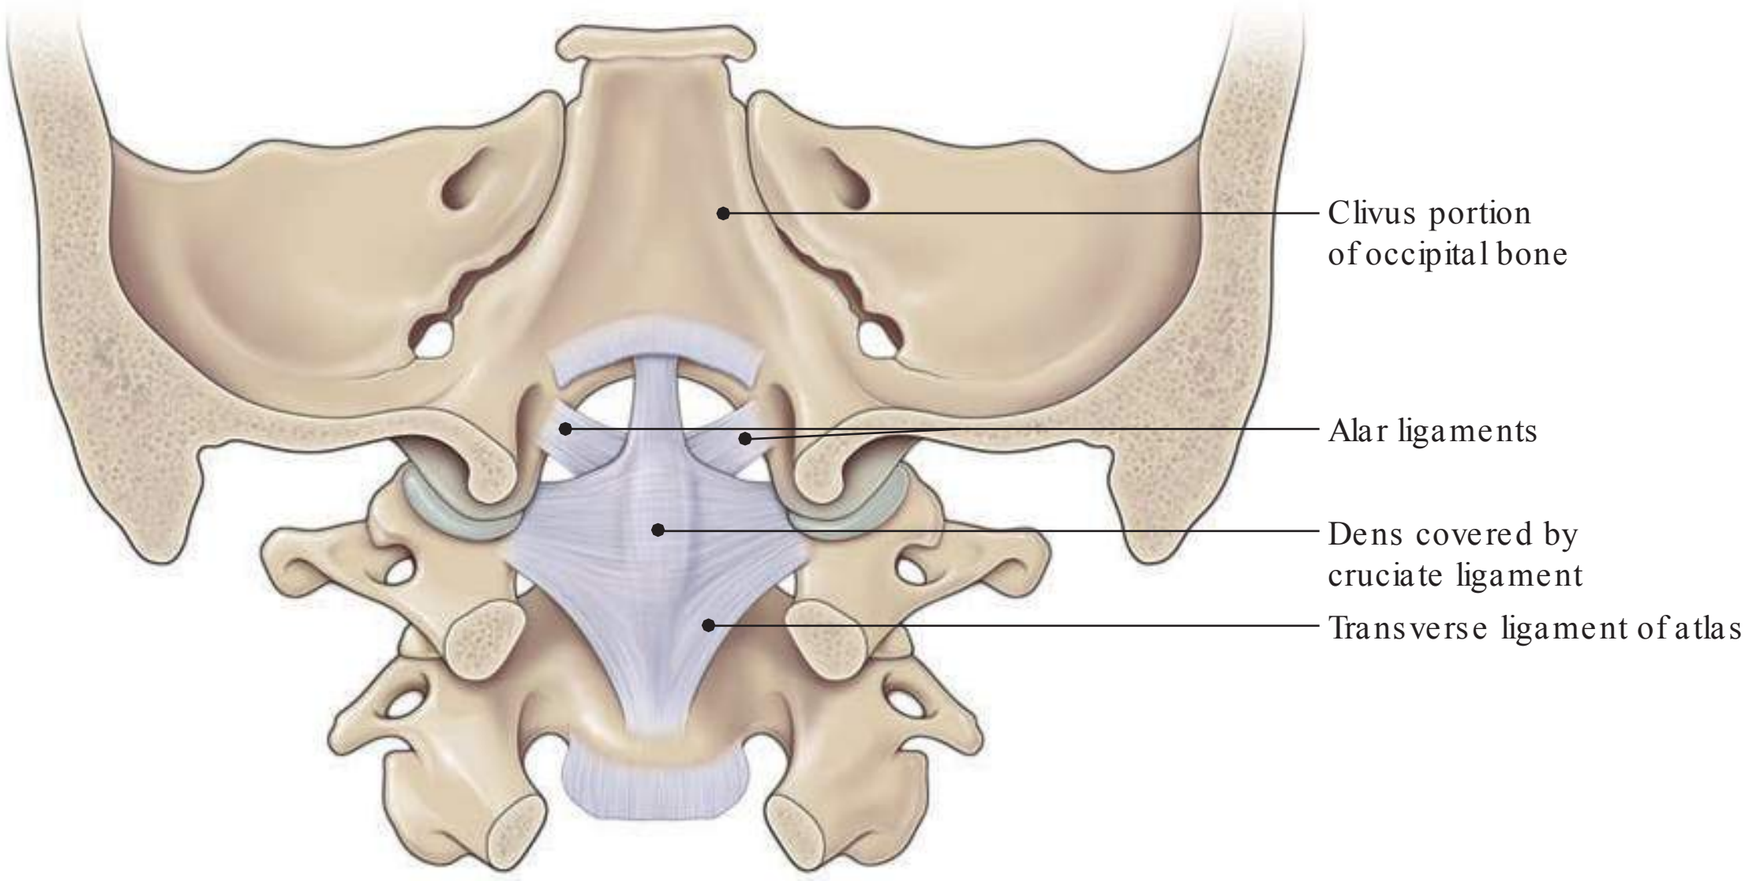

FIGURE 23-2 The dens and its relationship with the ligamentous structures of the craniovertebral region.

A-A Joint

T is is a relatively complex articulation, which consists of

- two lateral zygapophyseal joints between the articular surfaces of the inferior articular processes of the atlas and the superior processes of the axis;
- two medial joints: one between the anterior surface of the dens of the axis and the anterior surface of the atlas, and the other between the posterior surface of the dens and the anterior hyalinated surface of the transverse ligament[6] (Fig. 23-2).

T e relatively large superior articular facets of the axis (Fig. 23-1B) lie lateral and anterior to the dens. T ese facets slope considerably downward from medial to lateral in line with the zygapophyseal facets of the mid-low cervical spine.[10] As the lateral A-A joints function to convey the entire weight of the atlas and the head to lower structures, the lamina and pedicles of the axis are quite robust. T e stout, moderately long spinous process serves as the uppermost attachment for muscles that are essentially lower cervical in nature and for muscles that act specifically on the craniovertebral joints.

One of the functions of the intervertebral disk (IVD) in the spine is to facilitate motion and provide stability. T us, in the absence of an IVD in this region, the supporting soft tissues of the joints of the upper cervical spine must be lax to permit motion, while simultaneously being able to withstand great mechanical stresses.

Craniovertebral Ligaments

T e craniovertebral region is noted for a variety of ligaments, some of which have been the focus of a number of clinical tests to determine their ef ciency in preventing unwanted and potentially dangerous movements. T e controlling structures for these segments, which must be considered together, are as follows:

- Capsule and accessory capsular ligaments. T e lateral capsular ligaments (anterolateral O-A ligament) of the O-A joints are typical of synovial joint capsules. T ese ligaments run obliquely from the basiocciput to the transverse process of the atlas. By necessity, they are quite lax, to permit maximal motion, so they provide only moderate support to the joints during contralateral head rotation.
- Apical ligament. T e apical ligament of the dens extends from the apex of the dens to the anterior rim of the foramen magnum. T e ligament is short and thick. It runs from the top of the dens to the basiocciput and is thought to be a remnant of the notochord. T e apical ligament appears to be only a moderate stabilizer against posterior translation of the dens relative to both the atlas and the occipital bone.
- Vertical and transverse bands of the cruciform ligament. See Fig. 23-2 and later discussion.
- Alar and accessory alar ligaments. See Fig. 23-2 and later discussion.
- Anterior O-A membrane. T e anterior O-A membrane is thought to be the superior continuation of the anterior longitudinal ligament. It connects the anterior arch of vertebra C1 to the anterior aspect of the foramen magnum.
- Posterior O-A membrane. T e posterior O-A membrane is a continuation of the ligamentum flavum. T is ligament interconnects the posterior arch of the atlas and the posterior aspect of the foramen magnum and forms part of the posterior boundary of the vertebral canal.
- Tectorial membrane. T e tectorial membrane is the most superficial of the three membranes and interconnects the occipital bone and the axis. T is ligament is the superior continuation of the posterior longitudinal ligament and connects the body of vertebra C2 to the anterior rim of the foramen magnum. T is bridging ligament is an important limiter of upper cervical flexion and holds the occiput off the atlas.[11]

A-A Ligaments

T e anterior A-A ligament is continuous with the anterior O-A membrane above.[12] T e posterior A-A ligament interconnects the posterior arch of the atlas and the laminae of the axis.

Occipitoaxial Ligaments

T e O-A ligaments are very important to the stability of the upper cervical spine.

Alar Ligament

T e alar ligaments (see Fig. 23-2) connect the superior part of the dens to fossae on the medial aspect of the occipital condyles, although they can also attach to the lateral masses of the atlas.[13,14] A study of 44 cadavers[15] found the orientation of the ligament to be superior, posterior, and lateral. In another study, [13] 19 upper cervical spine specimens were dissected to examine the macroscopic and functional anatomy of alar ligaments. T e study found that the most common orientation (10/19) was cauda-cranial, followed by transverse (5/19). In two of the specimens, a previously undescribed ligamentous connection was found between the dens and the anterior arch of the atlas, the anterior atlantodental ligament. In 12 specimens, the ligament also attached via caudal fibers to the lateral mass of the atlas. T e posteroanterior orientation of the ligaments in 17 of the 19 subjects was directly lateral from the dens to the occipital attachment or slightly posterior.

T e function of the ligament is to resist flexion, contralateral side bending, and contralateral O-A rotation.[16] In addition, the alar ligaments restrict anteroposterior translation of the occiput on C1 to some degree.[17] Because of the connections of the ligament, side bending of the head produces a contralateral or ipsilateral rotation of C2, depending on the source.[18]

CLINICAL PEARL

Insufficiency of the alar ligaments increases the potential for occipitoaxial instability. The degree of instability can be determined in conjunction with other clinical findings, such as neurologic or vascular compromise, pain, and deformity.

The Cruciform Ligament

The cruciform (cross-shaped) ligament has superior, inferior, and transverse portions (Fig. 23-2). The superior and inferior portions of this ligament attach to the posterior aspect of the body of the dens and the anterior rim of the foramen magnum. The transverse portion, which stretches between tubercles on the medial aspects of the lateral masses of the atlas, connects the atlas with the dens of the axis. The transverse portion of the ligament is so distinct and important that it is often considered a separate ligament (Fig. 23-2). The major responsibility of the transverse ligament is to counteract anterior translation of the atlas relative to the axis, thereby maintaining the position of the dens relative to the anterior arch of the atlas.[11]

The transverse ligament also limits the amount of flexion between the atlas and axis.[19] These limiting functions are of extreme importance because the excessive movement of either type could result in the dens compressing the spinal cord, epipharynx, vertebral artery, or superior cervical ganglion. The integrity of the transverse ligament is also essential to the stability of atlas fractures; degenerative, inflammatory, and congenital disorders; and other abnormalities that affect the craniovertebral region.

The importance of the ligament is reflected in its physical properties. Spontaneous or isolated traumatic tears of this ligament are extremely rare events. The ligament is comprised almost entirely of collagen, with a parallel orientation close to the atlas and the dens, but with an approximately 30-degree obliquity at other points in the ligament. Dvorak et al.[20] found the transverse ligament to be almost twice as strong as the alar ligaments and to have a tensile strength of 330 Newtons (N) (33 kg/73 lb).

Craniovertebral Muscles

Anterior Suboccipital Muscles

Rectus Capitis Anterior. The rectus capitis anterior (RCA) runs vertically. It travels deep to the longus capitis from the anterior aspect of the lateral mass of the atlas to the inferior surface of the base of the occiput, anterior to the occipital condyle. The RCA flexes and minimally rotates the head. Thus, an adaptively shortened RCA on the right could feasibly produce a decreased left translation in extension during mobility testing of the O-A joint. The muscle is supplied by the anterior (ventral) rami of C1 and C2.

Rectus Capitis Lateralis. This muscle arises from the superior surface of the C1 transverse process and inserts into the inferior surface of the jugular process of the occiput. It is homologous to the posterior intertransverse muscle of the spine. The rectus capitis lateralis side bends the head ipsilaterally. It is supplied by the anterior (ventral) rami of C1 and C2.

Posterior Suboccipital Muscles. The posterior suboccipitals lie beneath the splenius capitis and trapezius muscles. These muscles function in the control of segmental sliding between C1 and C2[21] and may have an important role in proprioception, having more muscle spindles than any other muscle for their size.[21] All of the posterior suboccipital muscles are innervated by the posterior ramus of C1 and are also strongly linked with the trigeminal nerve.[22,23] The suboccipitals receive their blood supply from the vertebral artery.

Rectus Capitis Posterior Major. The rectus capitis posterior major is the largest of the posterior suboccipitals. It runs from the C2 spinous process, widening as it runs cranially to attach to the lateral part of the inferior nuchal line (Fig. 23-3). Located inferior and lateral to the occipital protuberances, the

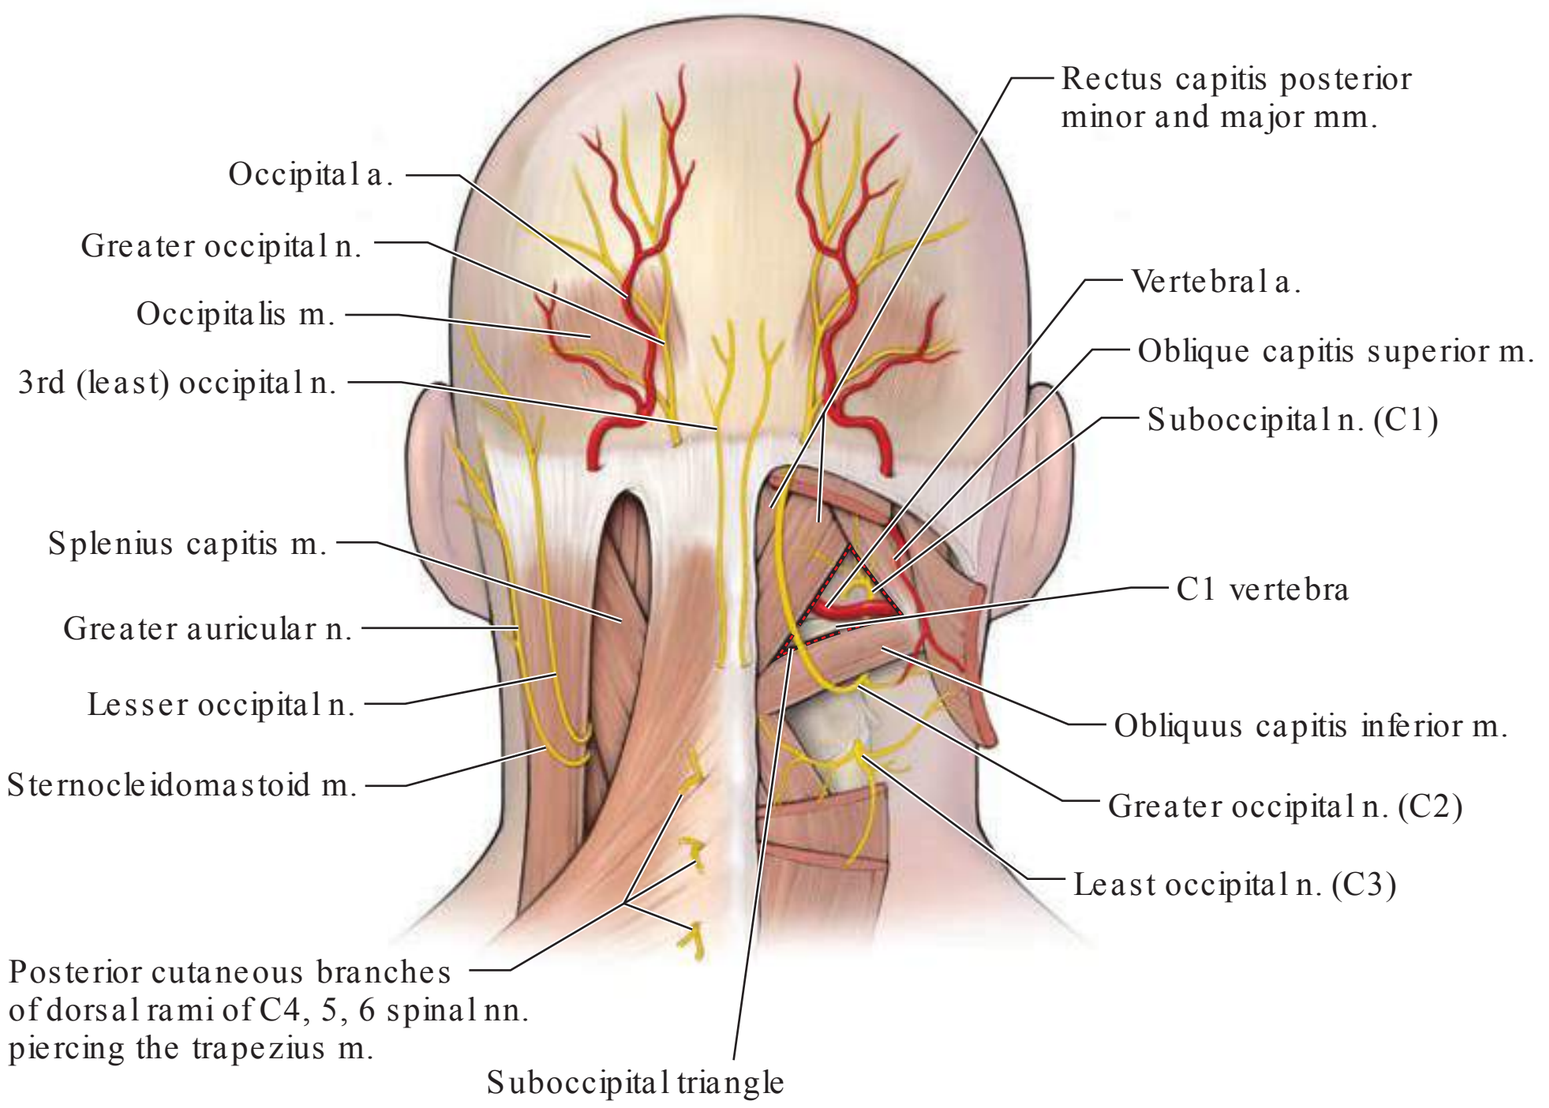

FIGURE 23-3 Muscles of the craniovertebral joints.

rectus capitis posterior major muscles, when working together, extend the head. When working individually, the muscles produce ipsilateral side bending and rotation of the head.

Rectus Capitis Posterior Minor. The rectus capitis posterior minor is a small unisegmental muscle that runs from the posterior arch tubercle of the atlas to the medial part of the inferior nuchal line (see Fig. 23-3). Because of the shortness of the atlantean tubercle, the muscle is very horizontal, running almost parallel with the occiput. The muscle functions to extend the head and provides minimal support during ipsilateral side bending of the head.

CLINICAL PEARL

Connective tissue attachments between the rectus capitis posterior minor and dura mater recently have been identified.[24] This finding has led to the use of cervical flexion with neurodynamic mobility tests (see Chapter 12). The differentiation between adverse neural tension and adaptive shortening of the muscle can be made by performing short neck flexion, with the neural system pretensioned and then relaxed.

Obliquus Capitis Inferior. This is the larger of the two oblique muscles and runs from the spinous process and lamina of the axis superolaterally to the transverse process of the atlas (see Fig. 23-3).

The inferior oblique muscle works to produce ipsilateral rotation of the atlas and skull and to control anterior translation and rotation of C1 (atlas). An adaptively shortened right inferior oblique may exert an inferior and posterior pull on the right transverse process of the atlas, producing a right rotated A-A joint.[25,26] This results in a gross limitation of left rotation of the head while in cervical flexion, but a minimal limitation of left rotation of the head in extension.

Obliquus Capitis Superior. The superior oblique arises from the transverse process of the atlas and runs superoposterior and medially to the bone between the superior and inferior nuchal lines, lateral to the attachment of rectus capitis posterior major (see Fig. 23-3). Because of its posteromedial orientation, the superior oblique functions to provide contralateral rotation and ipsilateral side bending of the O-A joint, when acting unilaterally. When working together, the two superior obliques can produce an extension of the head. Dysfunction of this muscle has been implicated as a common cause of chronic headaches.[27–31]

The posterior suboccipital muscles can work concentrically with the larger extensors and rotators of the cervical spine, or eccentrically, controlling the action of the flexors. Because two of these muscles parallel the occiput, their controlling influence may be more linear than angular, producing or guiding the arthrokinematic, rather than the osteokinematic, motion.[21]

Nerve Supply

The posterior (dorsal) ramus of spinal nerve C1, when present (see Chapter 3), is larger than the anterior (ventral) ramus. It exits from the spinal canal by passing posteriorly between the posterior arch of the atlas and the rim of the foramen magnum, along with the vertebral artery. It then enters the suboccipital triangle and supplies most of the muscles that form that triangle. It usually has no cutaneous distribution.

The posterior (dorsal) ramus of spinal nerve C2 (see Fig. 23-3), also known as the greater occipital nerve, is larger than the anterior (ventral) ramus of C2. It exits from the vertebral canal by passing through a slit between the posterior arch of the atlas and the lamina of the axis. This nerve is the largest of the cervical posterior (dorsal) rami and is primarily a cutaneous nerve. It supplies most of the posterior aspect of the scalp, extending anteriorly to a line across the scalp that runs from one external auditory meatus to the other. Because this nerve has an extensive cutaneous distribution, it has a very large posterior (dorsal) root ganglion. This ganglion is commonly located in a vulnerable location, almost directly between the posterior arch of C1 and the lamina of C2 (see Fig. 23-3). The interval between these two bony structures is small, and it is reduced with the extension of the upper cervical spine. Given the sensitivity of the posterior (dorsal) root ganglion to compression, the possible relationship between the forward head position and occipital headaches is apparent.[27–31] The O-A joints,[32] A-A joints,[33] and the C2 spinal nerve[34] have all been implicated as primary nociceptors in cervicogenic headaches (CHs). Among individuals with chronic neck pain, 58–88% describe associated headaches.[35,36] The prevalence of C2–3 zygapophyseal joint pain has been estimated at 50–53% of those patients with a chief complaint of headaches after whiplash injury.[35,36]

Blood Supply

The intradural vertebral artery supplies the most superior segments of the cervical spinal cord (see Chapter 24). The cervical cord is supplied by two arterial systems, central and peripheral, which overlap but are discrete. The first is dependent entirely on the single anterior spinal artery (ASA). The second, without clear-cut boundaries, receives supplies from the ASA and both posterior spinal arteries.[37] Because the ASA is medial and dominant, unilateral spinal cord infarctions are very rare. However, they may occur in the perfusion territory supplied by the ASA.[38,39] This is a result of obstruction of either a duplicated ASA[39] or one of the sulcal arteries, which arise from the ASA and turn alternatively left or right to supply one side of the central cord.[40] Peripheral hemicord infarction may result from ischemia, in the territory of the ASA[38] or posterior spinal artery.[41]

BIOMECHANICS

The upper cervical spine is responsible for approximately 50% of the motion that occurs throughout the entire cervical spine. Motions at the O-A and A-A joints occur relatively independently, while, below C2, the normal motion is a combination of motion at other levels.

Articular facet asymmetry of the human upper cervical spine has been recognized for more than 30 years.[42,43] The implications of this anatomic observation in the human spine

has been considered in relation to joint disease, specifically facet tropism (the phenomenon observed in living tissue, of moving toward or away from a stimulus), which is associated with subsequent degenerative joint disease.[44,45]

CLINICAL PEARL

Due to the proximity of vital structures, a joint disease in this region can have severe consequences. These consequences can include the following:

- Vertebral artery compromise;
- Compression of the spinal cord;
- Brain stem lesions.

O-A Joint

The deep atlantal sockets of the atlas facilitate flexion–extension but impede other movements. In living individuals, the average mean motion of flexion and extension at this joint is a combined range of 15–20 degrees.[46] However, the variability in range of motion in the normal subject is large. Lind et al.[47] reported a mean of 14 degrees with a standard deviation of 15 degrees in normal subjects. Side-bending motion occurs at an average of a little over 9 degrees to both sides,[48–50] with an axial rotation range of 0 degrees (8 degrees when the movement was forced).[49,50]

Although it is generally agreed that rotation and side bending at this joint occur to opposite sides when they are combined, particular rules for patterns of defined coupled motion are not supported by the current literature.[51]

CLINICAL PEARL

Clinical studies suggest that hypermobility of this joint should only be considered as a diagnosis if the range of rotation exceeds 8 degrees, making rotational mobility and stability testing necessary at this articulation.

A-A Joint

The design of the ligamentous and bony structures at the A-A joint allow for a large arc of rotation.

CLINICAL PEARL

Within the spine, only two articulations permit pure axial rotation:

- The A-A joint
- The thoracolumbar junction

The major motion that occurs at all three of the A-A articulations is an axial rotation. Werne[48] reported 47 degrees to each side in cadavers. A more recent study using CT scanning observed 32 degrees (SD = 10) of axial rotation to either side.[50] This amount of rotation has the potential to cause compression of the vertebral artery (see Chapter 24).[52,53] To help prevent this compression, as the atlas rotates, the ipsilateral facet moves posteriorly while the contralateral facet moves anteriorly so that each facet of the atlas slides inferiorly along the convex surface of the axial facet, telescoping the head downward.

The first 25 degrees of head rotation (approximately 60%) occur primarily at the A-A articulations.[54] However, the axial rotation of the atlas is not a pure motion, because it is coupled with a significant degree of extension (14 degrees) and, in some cases, flexion.[55]

In living individuals, the reported range of flexion–extension motion at this joint is highly variable, averaging 10 degrees.[56] Flexion at the A-A joint is limited by the tectorial membrane. The extension is limited by the anterior arch of C1, as it makes contact with the odontoid process. The flexion and extension motions are associated with small anteroposterior translational movements, which can create a small space between the back of the anterior arch of the atlas and the odontoid. This space is called the atlantoodontoid interval (ADI). Because of the arthrokinematics of the joint, flexion increases the ADI, whereas extension decreases it. Excessive gapping of the ADI can have serious consequences as it can lead to a compression of the spinal cord by the atlas.[57] An ADI of more than 3 mm in adults, and 4.5 mm in children younger than 12 years of age, detected on radiographs is indicative of gross instability and is strongly suggestive of a compromise of the transverse ligament.[57] An increased ADI can be associated with a history of trauma but may also be associated with severe ligamentous laxity in patients with rheumatoid arthritis (RA), neoplastic disease, Down's syndrome, and aplasia or dysplasia of the dens.[18]

Side bending at this joint is approximately 5 degrees. Although coupling at this joint is commonly cited as contralateral side bending during rotation, it is highly variable because of the passive nature of the kinematics of the atlas.[58] Whether the atlas flexes or extends during axial rotation depends on the geometry of the A-A joint and the precise direction of any forces acting through the atlas from the head.[58] The direction of the conjunct rotation appears to be dependent on the initiating movement.[59,60] If the initiating movement is side bending (latexion), the conjunct rotation of the joint is to the opposite side. If the initiating movement is a rotation (rotexion), the conjunct motion (side bending) is to the same side.[59,60] If correct, this principle can be exploited in the assessment of the craniovertebral joints:

1. Rotexion. During rotation of the head to the right (rotexion):
   a. Left side bending and right rotation occur at the O-A joint, accompanied by a translation to the right.
   b. Right side bending and right rotation occur at the A-A joint and at C2–3.

   In other words, if the head motion is initiated with rotation, ipsilateral side bending of the A-A joint and C2–3 occurs, whereas at the O-A joint, contralateral side bending occurs.
2. Latexion. Side bending of the head to the right produces
   a. left rotation of the O-A joint, accompanied by a translation of the occiput to the left;

b. left rotation of the A-A joint;

c. right rotation of C2–3.

In other words, if head motion is initiated with side bending, contralateral rotation of both the O-A and A-A joints occurs, but ipsilateral rotation occurs at C2–3.

EXAMINATION

The primary objective of the examination of this region is to rule out any serious injury, especially if the patient reports any recent trauma to the head or neck. The pain distribution from cervical structures is outlined in Table 23-1, and the differential diagnoses are described in Chapter 5. The initial examination should focus on the general appearance of the patient (including skin lesions such as rashes), vital signs (pulse, blood pressure, and temperature), and the presence of any upper motor neuron signs or symptoms.[62] Once serious injury has been ruled out, a biomechanical assessment of the craniovertebral joints can be performed. In addition, because of their close relationship with the craniovertebral joints, the cervical spine (see Chapter 25) and temporomandibular joint (see Chapter 26) should be assessed as part of a comprehensive examination of this region.

TABLE 23-1 Pain Distribution from Cervical Structures

Structure	Pain Area
Occipital condyles	Frontal
Occipitocervical tissues	Frontal
C1 posterior (dorsal) ramus	Orbit, frontal, and vertex
C1–2	Temporal and suboccipital
C3 posterior (dorsal) ramus	Occiput, mastoid, and frontal

Data from Meadows J. A Rationale and Complete Approach to the Sub-Acute Post-MVA Cervical Patient. Calgary, AB: Swodeam Consulting; 1995.

The biomechanical examination of the craniovertebral joints is best performed in a sequential manner (Fig. 23-4). In

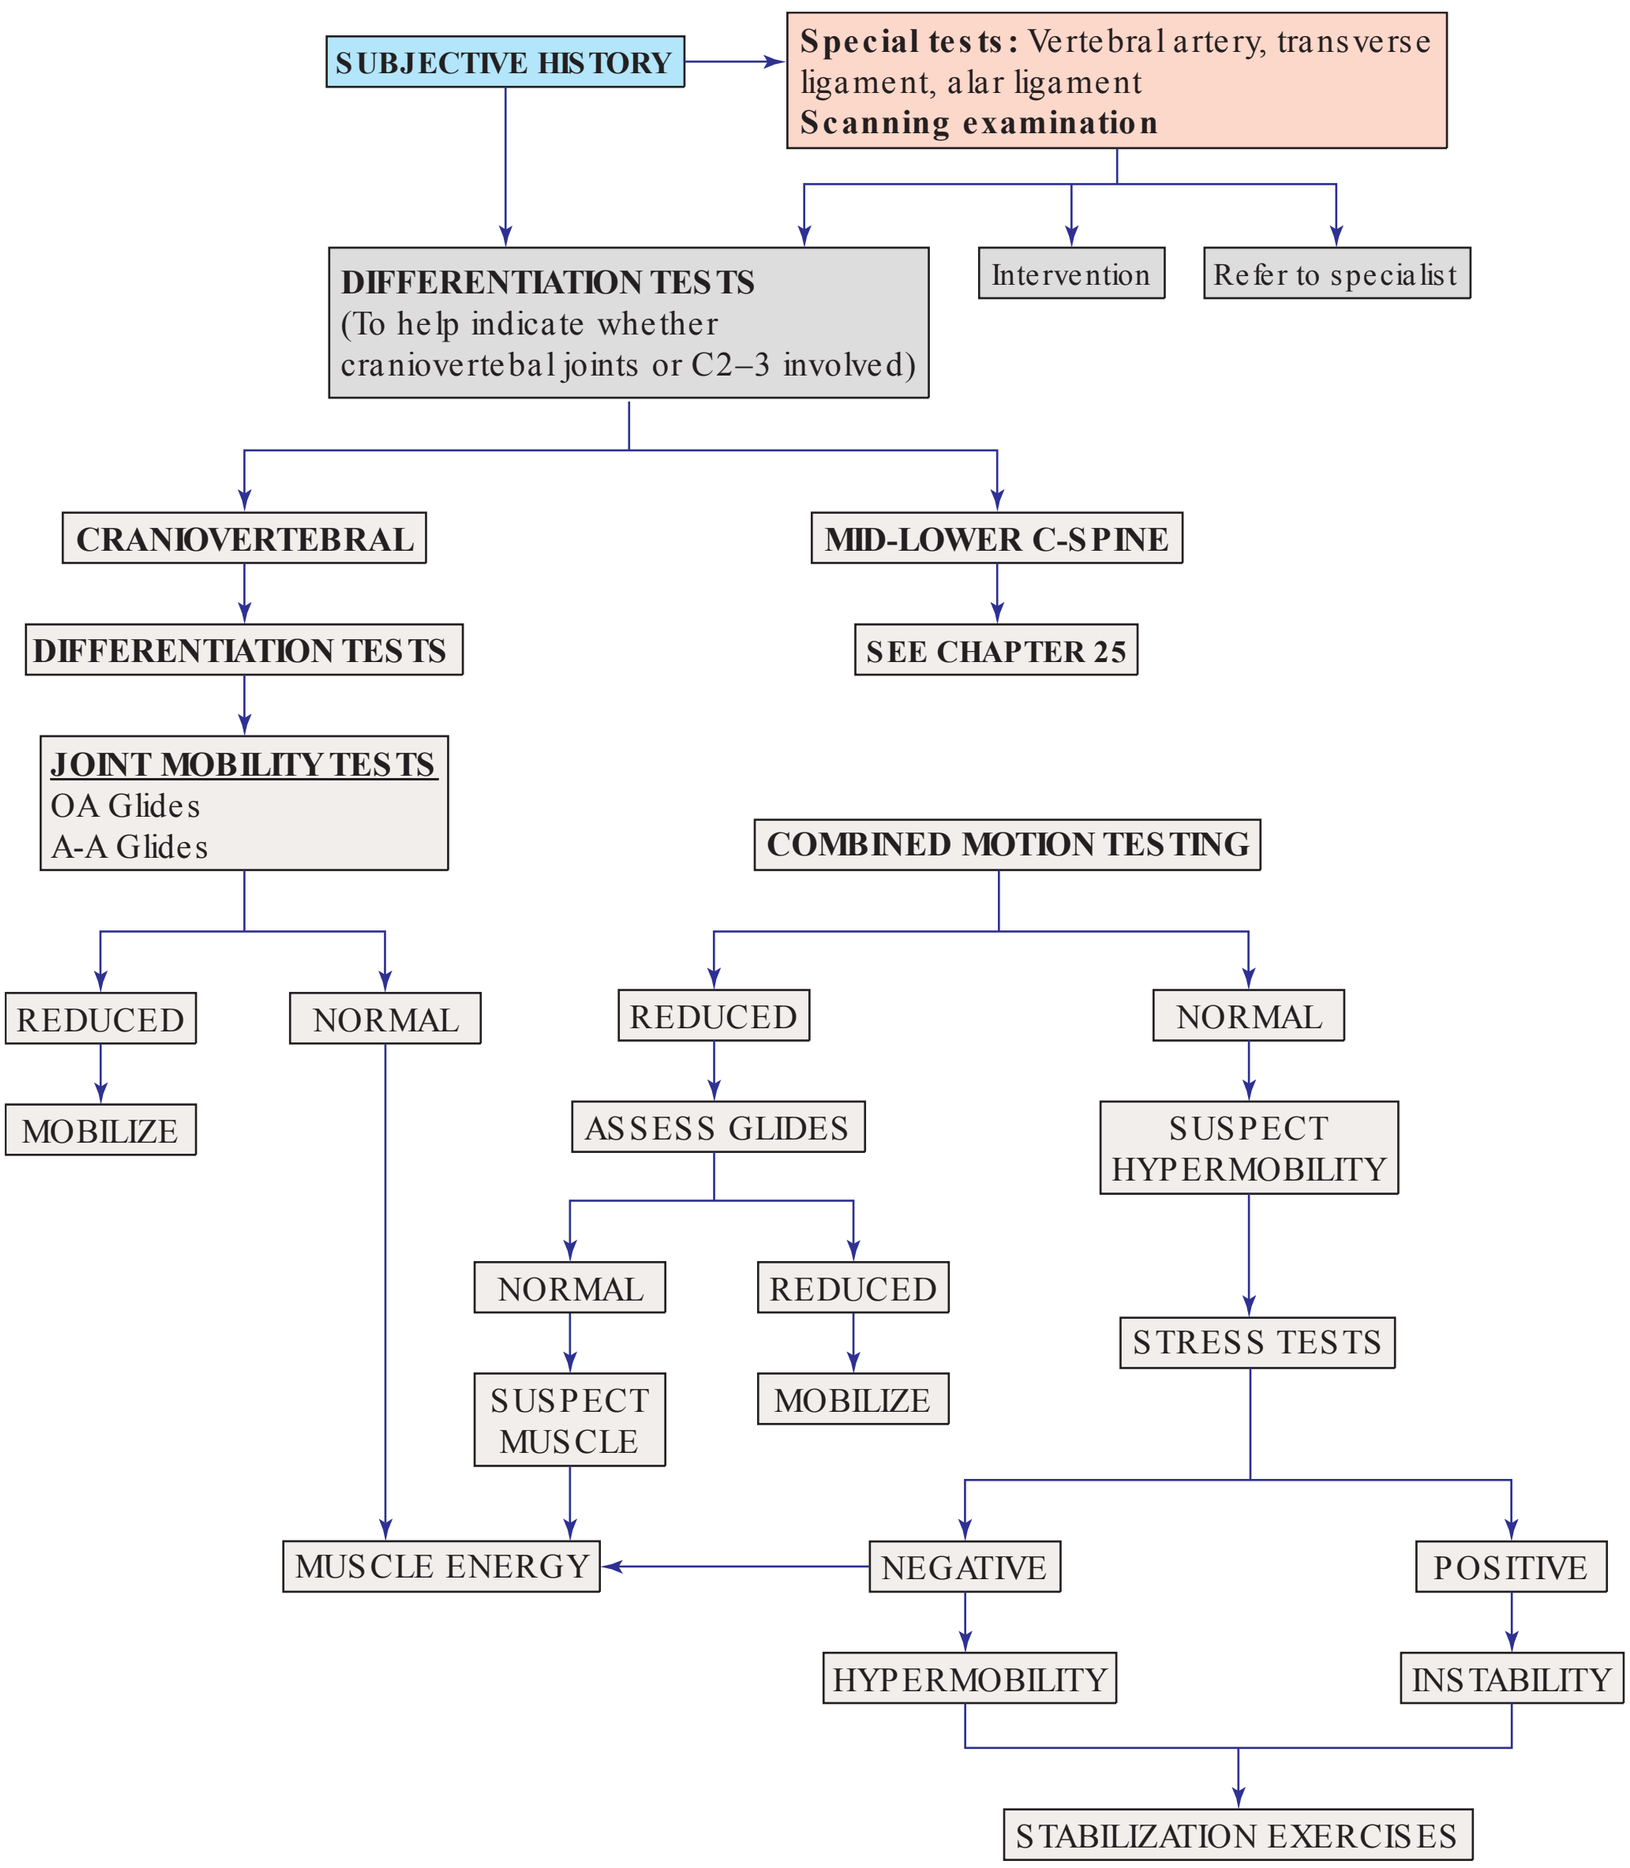

FIGURE 23-4 Craniovertebral examination algorithm.

general, the O-A joint is examined and treated before the A-A joint to avoid confusion between findings from the combined testing of both joints. T e examination and any intervention are terminated if any serious signs and/or symptoms are produced. In these instances, an appropriate referral is made.

History

T e craniovertebral region, as with the rest of the neck, is a common area for myofascial pain syndromes. T ese syndromes are frequently associated with complaints of local muscle soreness, and muscle spasm.[61] Pain may also be referred to this region from trigger points in the upper trapezius muscle, splenius capitis, sternocleidomastoid (SCM) muscle, digastric muscle, cervicis muscles, posterior cervical muscles (semispinalis capitis, semispinalis cervicis, multifidus, and rotators), and suboccipital muscles (rectus capitis posterior major and minor and inferior and superior obliques) (refer to "Intervention" section).[61]

Complaints of headaches are also common in patients with craniovertebral joint dysfunction.[32–34] Some of the more common types of headaches are described in Chapter 5. Cervicogenic headaches are described later in the chapter. In all patients presenting with an unexplained or an unusual headache, a full neurologic and general physical examination is required.[62] T is examination should focus on the patient's mental status and speech, gait, balance and coordination, a cranial nerve and long tract examination (see Chapter 3).[62]

Patients who complain of a headache should be asked to describe the headache. T e clinician must always be alert to the potential coincidental occurrence of secondary headache syndromes. T ese include a headache associated with trauma, vascular disease, nonvascular intracranial disorders, substance abuse or withdrawal, noncephalic infections, metabolic disorders, disorders of facial or cranial structures, and cranial neuralgia.[63] Several conditions may mimic episodic or chronic tension-type headache (see Chapter 5), including muscle tension. Chronic tension-type headaches are often erroneously attributed to chronic sinusitis, but clinical and radiologic evidence must be obtained before making this diagnosis. A causal relationship between a tension-type headache and oromandibular dysfunction is controversial, but the two conditions often coexist.[64] T e most important structures that register pain within the skull are the blood vessels, particularly the proximal part of the cerebral arteries, as well as the large veins and venous sinuses.[65] T e chronic headache of intracranial hypotension is most often distinguished by an increase of pain on standing. Descriptions such as throbbing and pounding are suggestive of a vascular origin but can also inculpate a migraine, fever, neuralgia, or hypertension. Chronic, recurrent headaches can be associated with eyestrain, excessive eating or drinking, or smoking.

Intrinsic to the understanding of the relationship of a headache to the craniovertebral region are the intracranial pain pathways and their interconnections, especially the trigeminocervical pathway (see Chapter 3).

T e location of the headache can provide the clinician with useful information as to the source.

- Forehead pain may be caused by sinusitis or a muscle spasm of the occipital or suboccipital region.
- Occipital pain can be caused by eyestrain, herniated cervical disk, hypertension, neuralgia, or an ear or eye disorder.
- Parietal pain may be indicative of meningitis or a tumor.
- Facial pain can be caused by sinusitis, trigeminal neuralgia, dental problems, or a tumor.

Dizziness (vertigo) and nystagmus are nonspecific neurologic signs that require a careful diagnostic workup (see Chapter 3). A report of vertigo, although potentially problematic, is not a contraindication to the continuation of the examination.

CLINICAL PEARL

Dizziness associated with disorders of motor function, such as clumsiness, weakness, or paralysis, could suggest a compromise of the vertebrobasilar system.

Systems Review

T e craniovertebral region houses many vital structures. T ese include the spinal cord, the vertebral artery, and the brain stem. It is extremely important for the clinician to approach this area with caution and to rule out the presence of serious pathology. Craniovertebral and cranial dysfunction can be responsible for a number of signs and symptoms that may be benign or may indicate the presence of serious pathology (Table 23-2).

Due to the proximity of the cranial structures, the clinician should develop the habit of quickly screening patients with neck and head pain for their ability to orient to time, place, and name; concentrate; reason and process information; make judgments; communicate effectively; and recall information. Obtaining this information needs to be done in a sensitive manner. Asking questions as to whether the patients know their own name and what day it is may be considered inappropriate in some patients. Most of the concerns about the patient's mental status can be addressed through general conversation, or as part of the history. Perhaps surprisingly, the incidence of neurologic involvement in upper cervical spine injury is relatively low (18–26%).[66] T is may be because significant cord damage in the upper cervical spine is usually fatal secondary to respiratory arrest.[7]

When compression of the spinal cord is suspected, a thorough neurologic examination should be performed. If confirmed, the appropriate medical services should be contacted. T e cranial nerves should be assessed, particularly if there are complaints about vision, or the patient appears to have problems with speech or swallowing. Patients with referred pain in the region of the trigeminal nerve commonly have an underlying disorder of the upper cervical spine, such as A-A instability caused by RA.[61,67] As described in Chapter 3, the various cranial nerve tests can be performed in approximately 5 minutes with practice.

Tests and Measures

T e examination is terminated if any serious signs and symptoms are produced.

Observation

T e patient is observed in the sagittal, coronal, and transverse planes.

TABLE 23-2 Examination Findings and their Possible Conditions

Findings	Possible Condition
Dizziness	Upper cervical impairment, vertebrobasilar ischemia, and craniovertebral ligament tear; also may be relatively benign
Quadrilateral paresthesia	Cord compression and vertebrobasilar ischemia
Bilateral upper limb paresthesia	Cord compression and vertebrobasilar ischemia
Hyperreflexia	Cord compression and vertebrobasilar ischemia
Babinski or clonus sign	Cord compression and vertebrobasilar ischemia
Consistent swallow on transverse ligament stress tests	Instability, retropharyngeal hematoma, and rheumatoid arthritis
Nontraumatic capsular pattern	Rheumatoid arthritis, ankylosing spondylitis, and neoplasm
Arm pain lasting >6–9 mo	Neoplasm
Persistent root pain <30 y	Neoplasm
Radicular pain with coughing	Neoplasm
Pain worsening after 1 mo	Neoplasm
>1 level involved	Neoplasm
Paralysis	Neoplasm or neurologic disease
Trunk and limb paresthesia	Neoplasm
Bilateral root signs and symptoms	Neoplasm
Nontraumatic strong spasm	Neoplasm
Nontraumatic strong pain in elderly patient	Neoplasm
Signs worse than symptoms	Neoplasm
Radial deviator weakness	Neoplasm
Thumb flexor weakness	Neoplasm
Hand intrinsic weakness or atrophy	Neoplasm, thoracic outlet syndrome, and carpal tunnel syndrome
Horner's syndrome	Superior sulcus tumor, breast cancer, cervical ganglion damage, and brain stem damage
Empty end-feel	Neoplasm
Severe post-traumatic capsular pattern	Fracture
Severe post-traumatic spasm	Fracture
Loss of ROM posttrauma	Fracture
Posttraumatic painful weakness	Fracture

ROM, range of motion.
Data from Meadows J. Orthopaedic Differential Diagnosis in Physical Therapy. New York, NY: McGraw-Hill; 1999.

Sagittal Plane. Observing the status of the cervical curve and the relative position of the patient's chin to the chest helps the clinician to assess postural alignment in the sagittal plane. A popular view among clinicians is that habitual adoption of extreme cervical posture may account for symptoms of pain and dysfunction arising from the head and neck area.[68] The argument is that alterations in spinal alignment may lead to changes in muscle activity and loading on the surrounding soft-tissue and articular structures, which then predisposes patients to such complaints.[69,70] This argument has been supported by several studies, which have found a statistically significant correlation between the tendency to hold the head forward, relative to the true vertical in the so-called *f*orward head posture, and symptoms of pain.[70,71] However, in other investigations, no such correlation has been confirmed.[72,73]

Tucking or elevation of the chin in the presence of a normal cervical curve may indicate craniovertebral dysfunction.[74]

The ears are observed for the presence of asymmetry in size, shape, or color. The top of the ear is normally in line with the eyebrow.

Coronal Plane. Alignment in the coronal plane is assessed by observing the orientation of the head relative to the trunk and shoulders, the leveling of the mastoid processes, and the symmetry of the cervical soft tissues. The face is observed for any asymmetry or indications of bruising, puffiness, prominence, swelling, perspiration, or abnormal skin color. Any asymmetry in the relative size of the pupils of the eyes and the distance between the upper and lower lids is noted. Pupillary size differences can occur in normal individuals but initially should arouse concern, because an abnormal unilateral change in size may be caused by an autonomic dysfunction or a central nervous system lesion.[75] The superior lid should cover a portion of the iris but not the pupil itself unless ptosis or drooping of the eyelid is present[75] (see Chapter 3).

Missing teeth should be accounted for as a loss of teeth may be a result of trauma, avulsion, or loosening.

Transverse Plane. Alignment in the transverse plane is assessed by observing the patient from behind and noting the orientation of the head. The orientation of the head is best observed by noting any asymmetry in the position of the mastoids, which can indicate whether the head is more rotated or tilted to one side, both of which may indicate a positional fault of the craniovertebral joints. Bruising around the mastoids or around the crown of the head (Battle's sign), with a history of trauma, may indicate the presence of a cranial vault injury, such as a basilar fracture. A low hairline may indicate a condition such as Klippel–Feil syndrome,[76] defined as a short neck with decreased cervical movement and low posterior hairline. Radiologically, patients with Klippel–Feil syndrome show a failure of cervical segmentation. The etiology is unclear, but the syndrome is believed to be caused by faulty segmentation of the mesodermal somites.[77] The syndrome appears to be heterogeneous, with environmental factors possibly contributing.[78] Autosomal dominant and recessive patterns of inheritance also have been reported.[79]

Active Range of Motion, Passive Overpressure, and Resistance

Short Neck Flexion. The clinician instructs the patient to place his or her chin on the surface of the throat. This motion simulates flexion at the craniovertebral joints. If this maneuver produces tingling in the feet or electric shock sensations down the neck (Lhermitte's sign), it is highly indicative of serious pathology. Although Lhermitte's sign is not a specific symptom, it is commonly encountered in patients with meningitis (see Chapter 5) and cervical spinal cord demyelination caused by multiple sclerosis.[80] The sign also has been found in many other conditions that cause a traumatic or compressive cervical myelopathies, such as cervical spondylosis, cervical instability, and epidural or subdural tumors.[81,82]

If the patient reports a pulling sensation during short neck flexion, the cervicothoracic junction may be at fault. Active short neck flexion tests cranial nerve XI and the C1 and C2 myotomes, as well as the patient's willingness to move. Placing the neck in short neck flexion places the short neck extensors (C1), which are innervated by the spinal accessory nerve, on a stretch. The clinician applies overpressure and tests the short neck extensors by asking the patient to resist (Fig. 23-5). Positive findings with this test are severe pain, nausea, muscle spasm, or cord signs, the latter of which may indicate a dens fracture or a tumor and cause the examination to be terminated.[81] Thus, if a patient is able to perform short neck flexion, a cervical fracture or a transverse ligament compromise can be provisionally ruled out.

FIGURE 23-5 Short neck flexion with overpressure and resistance.

Short Neck Extension. The clinician instructs the patient to look upward by only lifting the chin. The patient extends the head on the neck, and the clinician attempts to lift the occiput in the direction of the ceiling (Fig. 23-6). An inability to perform, or pain during, this motion (in the presence of normal motion in the other planes) may indicate significant tearing of the anterior cervical structures. If this test produces tingling in the feet, it is highly suggestive of compression to the spinal cord. This compression may occur because of "buckling" or ossification of the ligamentum flavum, with resultant loss of its elasticity.[83] A loss of balance or a drop attack with this maneuver would strongly suggest a compromise of the vertebrobasilar system. A drop attack is defined as a loss of balance without a loss of consciousness (see Chapter 24). The short neck flexors (C1), which are innervated by the spinal accessory nerve, can be tested in this position by applying overpressure as though lifting the patient's chin toward the ceiling while the patient resists (see Fig. 23-6).

CLINICAL PEARL

If the neck is unstable secondary to a dens fracture or a transverse ligament tear, the patient will be unable or unwilling to flex or extend the neck in the traditional manner, often because of severe muscle spasm.

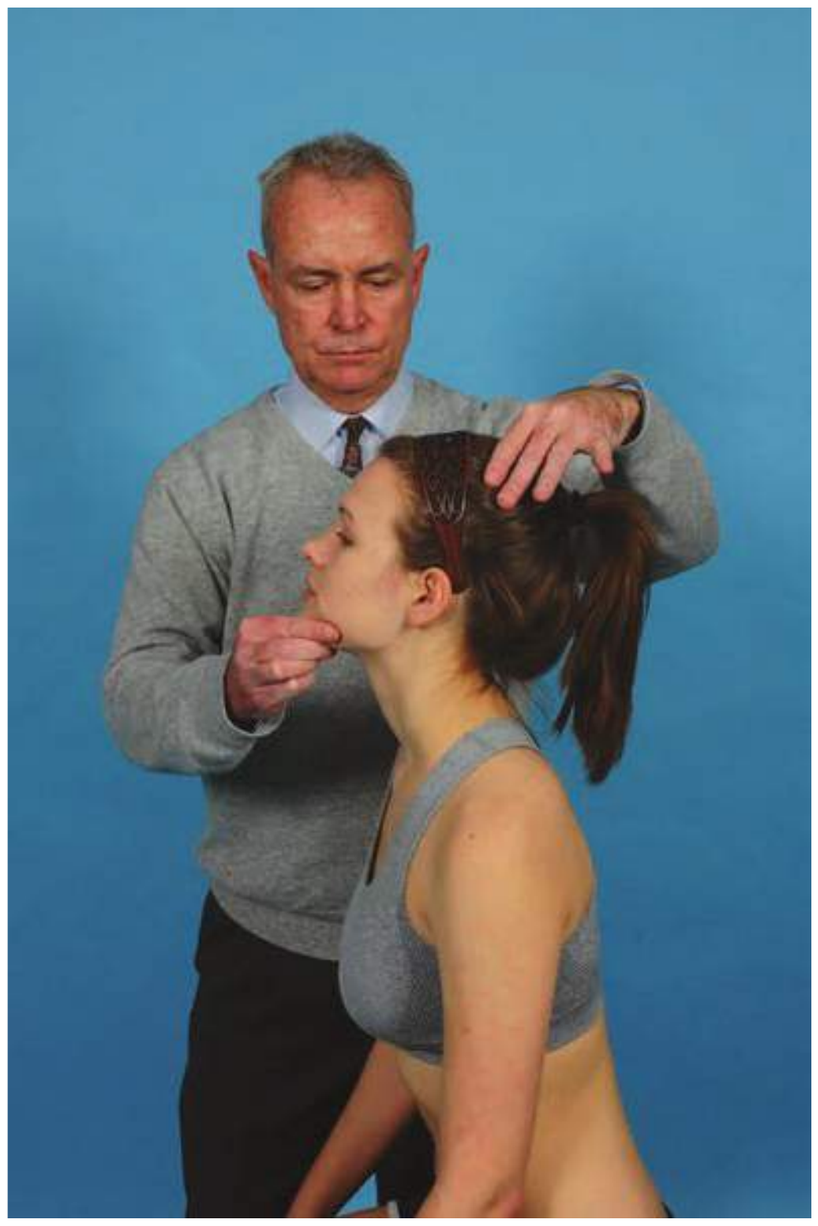

FIGURE 23-6 Short neck extension with overpressure and resistance.

Side Bending. The patient is asked to sidebend their head around the appropriate axis (through the patient's nose). Side bending is included here for completeness. Much more a function of the lower cervical spine, side bending of the neck is nonetheless significantly decreased in cases of craniovertebral instability or articular fixation. It could be argued that, in the presence of serious ligamentous disruption due to a subluxation of the atlas under the occiput, this motion may provoke symptoms, but it is likely that such a significant incidence of instability would be detected earlier in the examination.[84] The side-bending motions that do occur in the craniovertebral joints are essentially conjunct motions, so the results from this test are unlikely to provide much in the way of additional information.

Rotation. Neck and head rotation could be considered as the functional motion of the craniovertebral joints. Thus, if the patient's symptoms and loss of motion are not reproduced with active rotation, it is doubtful that damage to tissues making up the craniovertebral joints is significant or even present. The patient is asked to perform active neck rotation. An inability to move any amount in either direction is potentially a very serious sign, as it could indicate the presence of a dens fracture or a C1–2 dislocation–fracture. Every measure must be taken to determine the cause of this inability to move. In cases of a suspected fracture or severe instability, the patient should be placed in a cervical collar and the physician immediately notified. In addition to the presence of a fracture, some of the other serious conditions that can be provoked by cervical rotation include vertebral artery compromise—cervical rotation is the most likely (single) motion to reproduce signs or symptoms of vertebral artery compromise (see Chapter 24).[81,85–87]

The findings from the cervical rotation tests may also afford the clinician some information with regard to a biomechanical lesion of the craniovertebral joints:

- A loss of rotation associated with pain and a history of recent trauma. This could indicate the presence of an acute/subacute, posttraumatic arthritis of the craniovertebral joints. Since it may also indicate a soft-tissue injury, further testing would be required.
- A loss of rotation associated with pain and a history of chronic trauma. This finding could indicate a chronic painless hypomobility with an adaptive but painful ipsilateral hypermobility involving the craniovertebral joints (e.g., pain with right rotation could occur if the right O-A joint cannot flex, and there is a hypermobility of the right A-A joint). It may also occur if the left O-A joint cannot extend. Again, further testing is needed to confirm this hypothesis.
- A loss of rotation range of motion associated with no pain, but with a history of chronic trauma. This finding, which could indicate a chronic, posttraumatic arthritis, is likely to be an incidental finding since most patients seek help because of pain. However, depending on the extent of the loss of rotation, the patient may have become aware of a loss of function.
- Full rotation range of motion associated with pain and a history of chronic trauma. This could indicate a chronic fibrotic (painless) hypomobility with an adaptive but painful contralateral hypermobility (e.g., pain with right rotation could occur if the left O-A joint cannot flex and the right O-A joint develops a compensatory hypermobility).

Palpation

Objective palpation of this area is guided by a sound anatomic knowledge. Palpation usually proceeds layer by layer. It should be noted that asymmetric joint geometry is common in this region.[88] For spine palpation to be a valid indicator for manual techniques, the clinician applying it must first be able to differentiate between asymmetric motion caused by vertebral dysfunction and that caused by asymmetric joint anatomy.[88] However, examination of the skin overlying the spine has been found to be very helpful, because certain skin changes in a particular location may point in the direction of a dysfunctional spinal area.[89] The skin is assessed for its thickness, moisture, and ease of displacement in all directions. Abnormal autonomic skin reactions, such as erythematous changes, increased sweat production, and pain that can be induced with minimal palpatory pressure, may indicate a segmental dysfunction.[90]

Palpation may be started in the area indicated by the patient as painful. These painful sites must be correctly localized. The bony landmarks of this region that should be routinely palpated include the occiput, mastoid, atlas, and axis.

Occiput. The clinician locates the external occipital protuberance, which is the most prominent bony structure at the occiput in the midline. By following the external occipital protuberance laterally, the clinician can locate the superior nuchal line. The semispinalis capitis muscle is located about 1½ fingerbreadths below the superior nuchal line.[90]

Mastoid. The mastoid processes are located behind each ear. Once this structure is located, the clinician moves the fingers inferiorly toward the tip of the mastoid process. Starting from the medial tip of the mastoid process, the palpating finger is moved superiorly to the upper pole of the mastoid sulcus, an important area in the examination of the irritation zones of the occiput and C1.[90]

Atlas. By placing the palpating fingers between the mastoid process and the descending ramus of the mandible, the clinician can locate the transverse process of the atlas. The inferior oblique and the superior oblique both have attachments to this site.

Axis. The spinous process of C2 is the first prominent bony landmark that is accessible to palpation below the external occipital protuberance of the occiput. The spinous process of C2 serves as the origin of the inferior oblique muscle and the rectus capitis posterior major muscle.

Passive Physiologic Mobility Testing of the Occiput, Atlas, and Axis

O-A Joint. When mobility testing this joint, the first point to remember is that the joint is capable of both flexion and extension, and that side bending and rotation can also occur, albeit slight. The second point to keep in mind is that the arthrokinematics of this joint are the reverse of those occurring in the other zygapophyseal joints and that they occur in a different plane (horizontal). The joint mobility of the O-A joint can be assessed in sitting VIDEO or in supine.

With the patient supine, the head is extended around the axis for the O-A joint VIDEO. The head is then side bent left and right. As the side bending is performed, a gradual translational force is applied in the direction opposite to the side bending. The range of movement of the side bending is assessed from side to side as is the end-feel of the translation. This procedure is then repeated for flexion.

During extension of the O-A joint (Fig. 23-7), the occipital condyles glide anteriorly to the limit of their symmetric extension range. During left side bending and right translation in extension, the coupled right rotation is produced. This rotation causes the right occipital condyle to return toward a neutral position while the left condyle advances toward the extension barrier. If left side bending in extension is limited, then the limiting factor is on the left joint of the segment (ipsilateral to the side bending), which is preventing the advance of the condyle into its normal position. Thus, extension and right translation test the anterior glide of the left O-A joint, whereas extension and left translation stress the anterior glide of the right O-A joint (Table 23-3).

During flexion of the O-A joint, the occipital condyles glide posteriorly (Fig. 23-8). The right rotation associated with left

TABLE 23-3 Movement Restrictions of the Craniovertebral Joints and their Probable Causes

Movement Restriction	Probable Causes
Flexion and right side bending	Left flexion hypomobility Extensor muscle tightness Posterior capsular adhesions Left subluxation (into extension)
Extension and right side bending	Right extension hypomobility Left flexor muscle tightness Anterior capsular adhesions Right subluxation (into flexion)
Flexion and right side-bending motion greater than extension and left side bending	Left capsular pattern (arthritis and arthrosis)
Flexion and right side bending equal to extension and left side bending	Left arthrofibrosis (very hard capsular end-feel)
Right-side flexion in flexion and extension	Probably an anomaly

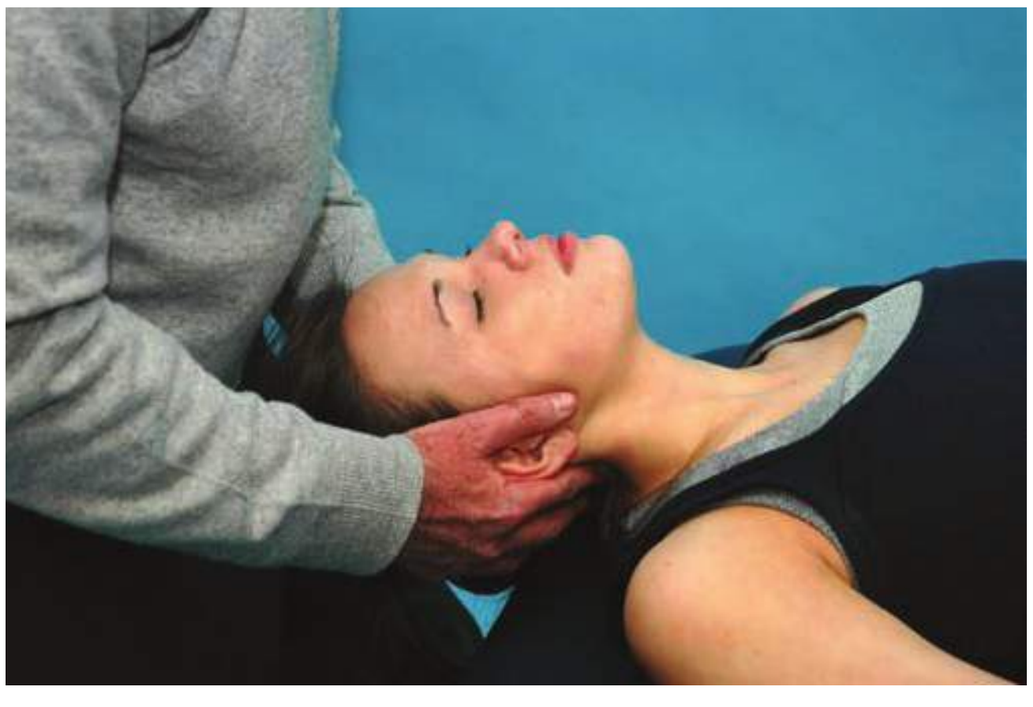

FIGURE 23-7 Passive mobility testing of O-A in extension.

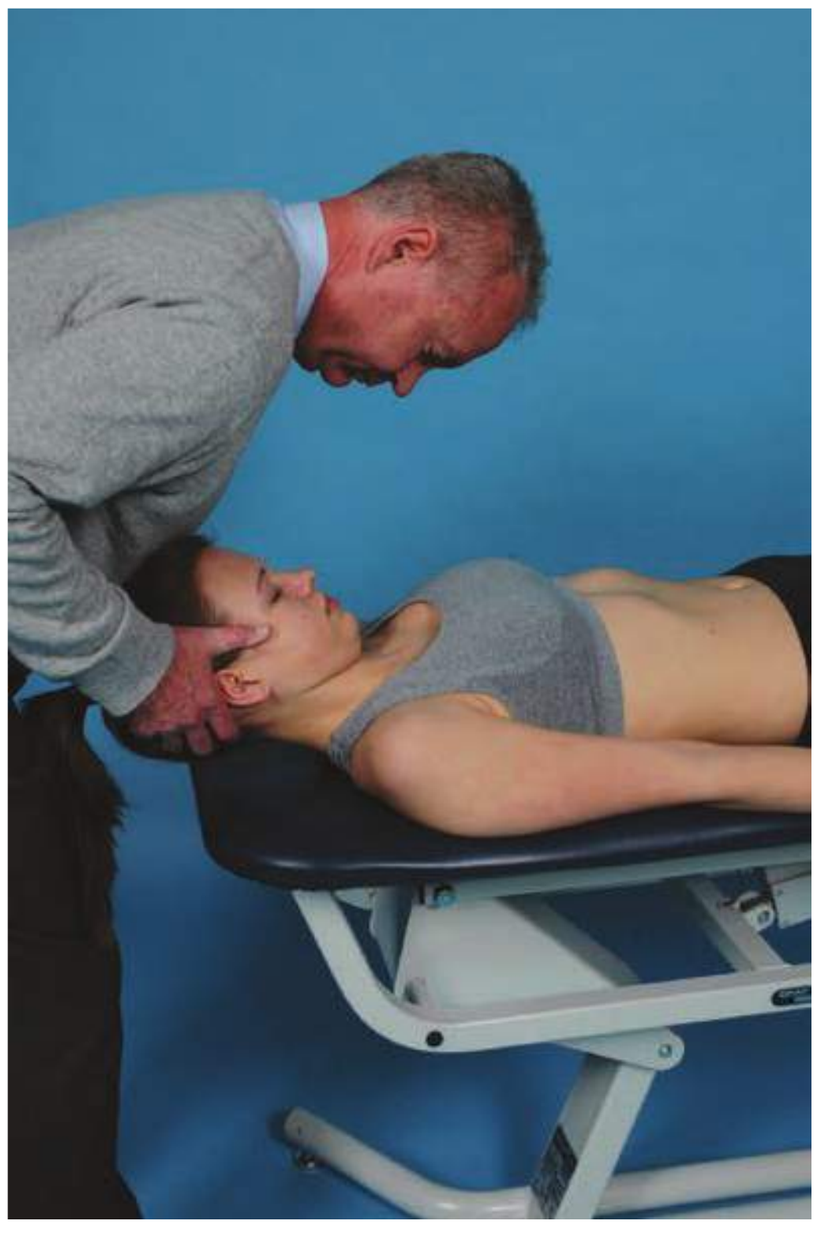

FIGURE 23-8 Passive mobility testing of O-A in flexion.

side bending causes the left condyle to move away from the flexion barrier toward the neutral position, while the right condyle is moved posteriorly further into the flexion barrier. T us, flexion and translation to the right tests the posterior glide of the right O-A joint, whereas flexion and left rotation tests the posterior glide of the left O-A joint (see Table 23-3).

It is apparent that during these tests, the arthrokinematic and osteokinematic movements are tested simultaneously; thus, the end-feel must be used to determine the cause of the restriction. T e following patterns of impairment are more or less commonly seen, and the causes of the impairments can be deduced. However, it must be remembered that deductions are only of value if the resultant intervention is successful.[59]

- A patient who has a subluxation into flexion (loss of anterior glide) on the right O-A joint should demonstrate decreased extension, decreased right side bending and left rotation, and a jammed end-feel with translation to the left.
- A patient with a periarticular restriction of the left O-A joint into flexion (loss of posterior glide) should demonstrate decreased flexion, decreased right side bending and left rotation, and a capsular end-feel with translation to the left.
- A patient with a fibrous adhesion of the right O-A joint (loss of anterior and posterior guide) should demonstrate decreased extension and right side bending and decreased flexion and left side bending, with a hard capsular end-feel at both extremes.
- With motion testing, a decreased flexion and right side bending with a pathomechanic end-feel indicates a left O-A joint being subluxed into extension.
- With motion testing, a decreased extension, and right side-bending limitation indicates a capsular pattern of the right O-A joint. A decreased extension and left side-bending limitation, with a spasmodic end-feel (flexion with greater range), indicates traumatic arthritis of the left O-A joint.
- A decreased right translation of the O-A in flexion may indicate a right posterior O-A joint dysfunction or an impaired or adaptively shortened right superior oblique muscle.

A-A Joint. T ere are a number of methods to assess the passive physiologic mobility of the A-A joint VIDEO. T e most common method described in many texts involves the patient lying supine and the clinician passively applying full cervical flexion and then introducing cervical rotation. T e problem with this technique is that it relies on the fact that the mid-to-lower cervical spine will be locked with the flexion. Because the neck is often prevented from further flexion when the chin meets the sternum, the clinician has no way of knowing whether full cervical flexion has occurred. T us, some of the subsequent rotation may be attributed to a combination of cervical spine and A-A motion. T is assumption may not be important with asymmetric lesions but can result in false-negative findings with symmetric lesions.

A better method of assessment involves the use of cervical side bending. With the patient positioned in supine, the clinician side bends the head and neck around the craniovertebral axis and then rotates the head in the direction opposite to the side bending (Fig. 23-9). T e clinician assesses the amount of range available and then assesses the other side.

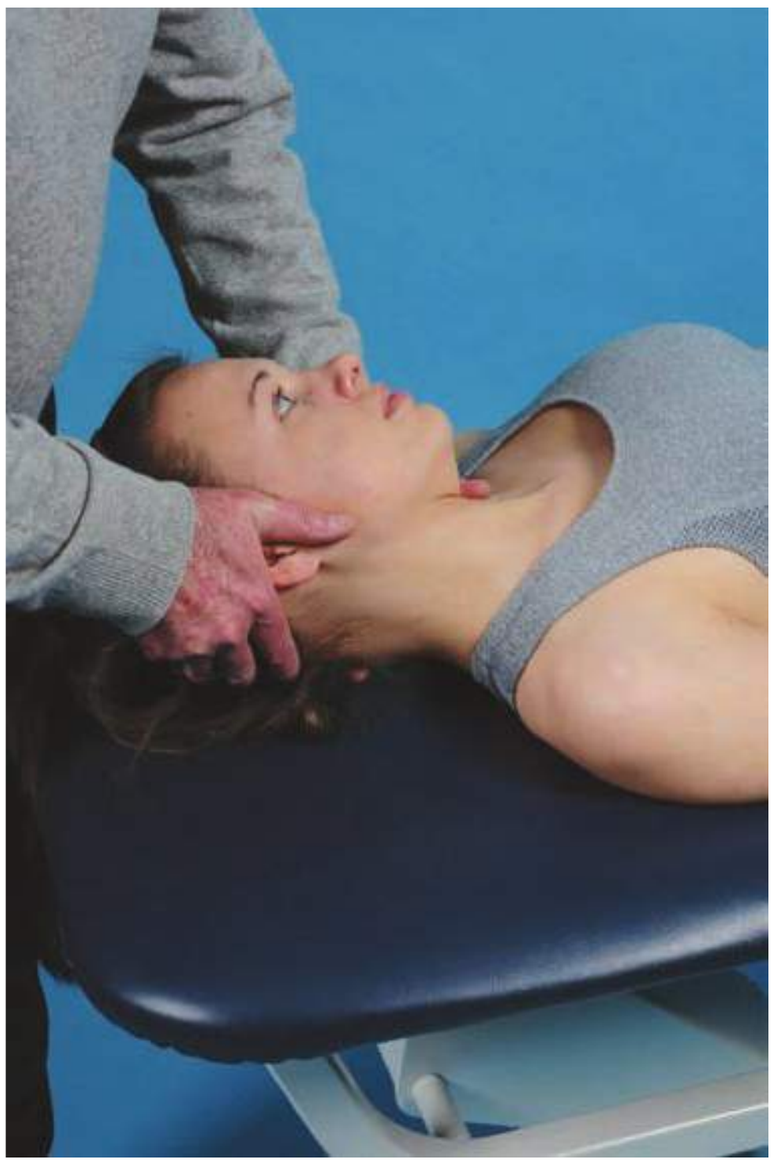

FIGURE 23-9 Passive mobility testing of A-A rotation in supine.

CLINICAL PEARL

In a study by Smedmark et al.,[91] passive intervertebral motion of the cervical spine was assessed independently by two physical therapists. The therapists had equal backgrounds concerning education and clinical experience. Sixty-one patients seeking care for cervical problems at a private clinic were included in the study where three segments of the cervical spine and the mobility of the first rib were graded as stiff or not stiff. Data were analyzed by percentage agreement and kappa coefficient. Results demonstrated interexaminer reliability of between 70% and 87% and kappa coefficients ranging between 0.28 and 0.43 considered to be only "fair to moderate."

In a similar study by Pool et al.,[92] which assessed the interexaminer reproducibility of physical examination of the cervical spine, two physiotherapists independently judged the general mobility and intersegmental mobility (segments C0–T2) of the neck and the pain that was provoked. Agreement for general mobility showed kappa between 0.05 and 0.61, and for the intersegmental mobility, it showed kappa values between −0.09 and 0.63. Agreement for provoked neck pain within one point of an 11-point numerical rating scale varied between 46.9% and 65.7% for general mobility and between 40.7% and 75.0% for intersegmental mobility. The ICCs varied between 0.36 and 0.71 for general mobility and between 0.22 and 0.80 for intersegmental mobility. The study concluded that despite the use of a standardized protocol to assess general mobility and intersegmental mobility of the cervical spine, it is difficult to achieve reasonable agreement and reliability between two examiners. Likewise, the patients were not able to score the same level of provoked pain in two assessments with an interval of 15 minutes.

Combined Motion Testing

Flexion and extension at the O-A joints involve a posterior and anterior gliding of the occipital condyles, respectively. T e same gliding (although reciprocal in opposing facets) is utilized in the rotation. At the A-A joint, flexion and extension primarily involve a "rolling" action of the condyles, with an insignificant amount of gliding. T erefore, craniovertebral flexion and extension will have a minimal effect on A-A rotation.[93] T us, if a symptom or range of motion is drastically altered by craniovertebral flexion or extension, an assumption could be made that the dysfunction is at the O-A joint.[93] For example, if the right occipital condyle cannot glide posteriorly, the right joint will be unable to flex or to permit rotation to the right, as both these motions involve a posterior glide at the right O-A joint. In the combined motion tests, the right rotation restriction will be more evident when combined with craniovertebral flexion but will be less evident when combined with craniovertebral extension.

T e findings from the combined motion tests can be used to determine which joint glide is to be assessed. For example, if it was determined in the combined motion testing that the right O-A joint is restricted or painful with flexion (implicating the posterior glide), the O-A joint is positioned and assessed in its extreme of flexion and right rotation (the two motions associated with a posterior glide of the right O-A joint).

Linear Segmental Stress Testing

T e craniovertebral region demonstrates a high degree of mobility, but little stability, with the ligaments affording little protection during a high-velocity injury. Instability of this region can result from a number of causes:

- Trauma (especially a hyperflexion injury to the neck).
- RA, psoriatic arthritis, or ankylosing spondylitis. Nontraumatic hypermobility or frank instability of the O-A joint has been reported in association with RA.[94]
- Corticosteroid use. Prolonged exposure to this class of drug can produce a softening of the dens and transverse ligament by deteriorating the Sharpey fibers, which attach the ligament to the bone. Steroid use also promotes osteoporosis, predisposing bones to fracture.
- Recurrent upper respiratory tract infections or chronic sore throats in children. Grisel's syndrome[95] is a spontaneous A-A dislocation, affecting children between the ages of 6 and 12 years. T e outstanding symptom is a spontaneously arising torticollis. T e most likely etiology seems to be an inflammation of the retropharyngeal space caused by upper respiratory tract infections or by adenotonsillectomy and producing pharyngeal hyperemia and bone absorption.
- Congenital malformation. Nontraumatic hypermobility or frank instability of the O-A joint has been reported in association with congenital bony malformations.[96]
- Down's syndrome. Nontraumatic hypermobility or frank instability of the O-A joint has been reported in children and adolescents with Down's syndrome.[97,98]
- Immature development. Patients younger than 12 years of age often have an immature or absent dens (see later).
- Osteoporosis.

It must be remembered that the A-A joint complex consists of three joints. T e median joint, although it has no weight-bearing function, is extremely important in maintaining stability, while at the same time facilitating motion within this joint complex. Fielding et al.[99] found that the stability of the A-A joint depends greatly on the ligamentous structures and on a normal and intact dens. Occasionally, the integrity of the dens can be compromised because of the following reasons:

1. Anomalies of the dens, including
   a. Os odontoideum. T is is a condition in which the IVD between the developing bodies of axis and atlas does not ossify.
   b. Congenital absence of the dens.
   c. An underdeveloped dens whose lack of height renders it unchecked by the transverse ligament. T e body of the dens is not of suf cient size to be retained in the osseoligamentous ring of the atlas until a child is approximately 12 years old. Great care and justification are needed with any craniovertebral mobilization or manipulative technique with this age group.
2. Pathologies affecting the dens, including
   a. Demineralization or resorption of the dens, such as occurs with Grisel's syndrome or RA.[95]
   b. An old, undisplaced fracture (especially of the dens), which originally escaped diagnosis and subsequently formed a pseudoarthrosis.

Indications for Stability Testing. Clinical cervical spine instability may demonstrate only subtle symptoms and clinical examination features, and frequently normal radiographic findings.[100] T e following findings are considered to be indications to perform stability or stress tests of the craniovertebral region[81]:

- History of neck trauma or any of the causes of instability listed previously.
- Patient report of neck instability usually described as the head feeling heavy.
- Presence of the following signs and symptoms:
  - A lump in the throat
  - Lip paresthesia
  - Nausea or vomiting
  - A severe headache and muscle spasm
  - Dizziness

T e patient is positioned in supine to remove any muscular influences. If the patient is unable to lie down, the clinician may need to reconsider the appropriateness of performing these tests.

Longitudinal Stability. General traction is applied to the entire cervical region. If this maneuver does not reproduce the signs or symptoms, C2 is stabilized so that the traction force may be directed at the craniovertebral region (atlantoaxial membrane) (Fig. 23-10). T e diagnostic value of longitudinal stability testing to the entire cervical region is as yet unknown. When localized to the atlantoaxial membrane, the test has been found to have a sensitivity of 95% and a specificity of 95%.[101]

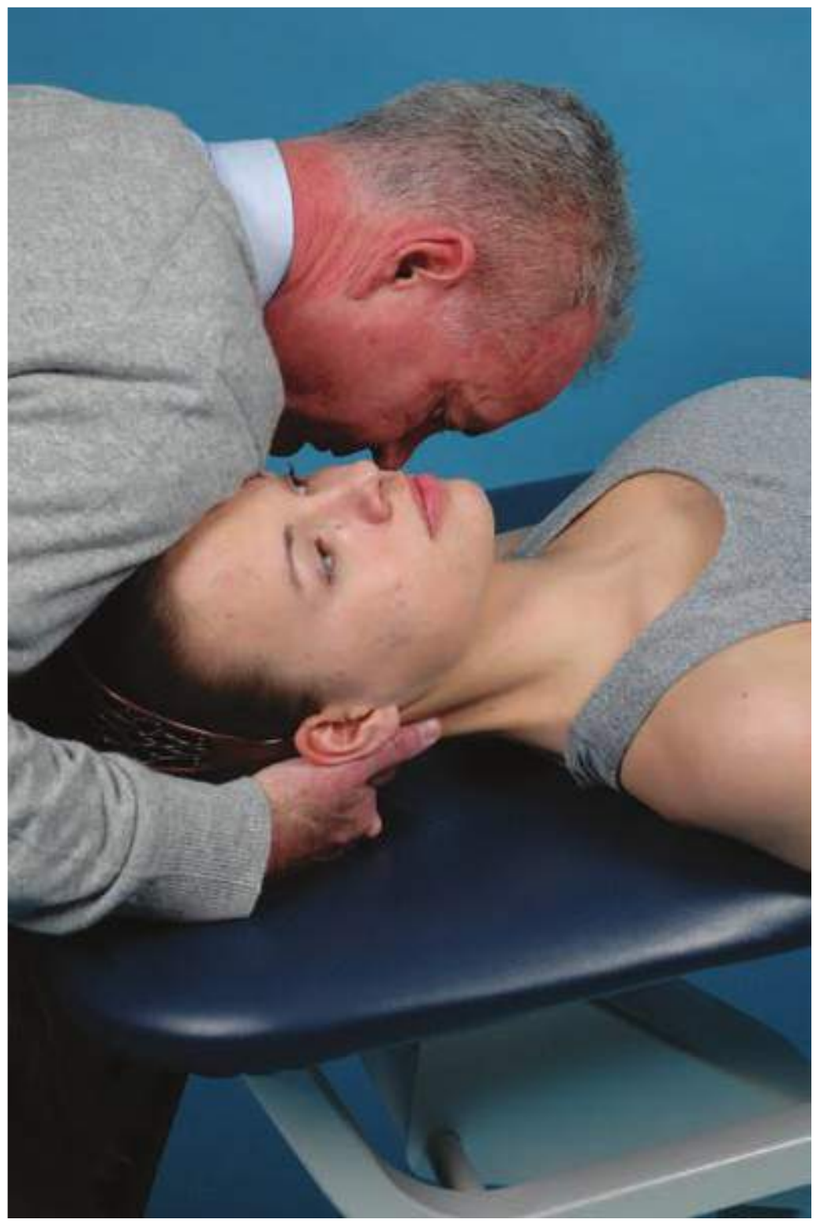

FIGURE 23-10 Longitudinal stability testing.

Anterior Shear: Transverse Ligament. The patient is positioned in supine, with his or her head cradled in the clinician's hands. The clinician locates the anterior arches of C2 by moving around the vertebra from the back to the front using the thumbs. Once the arches are located, the clinician pushes down on the anterior arches of C2 with the thumbs toward the table, while the patient's occiput and C1, cupped in the clinician's hands, is lifted, keeping the head parallel to the ceiling but in slight flexion[81] (Fig. 23-11) VIDEO. The patient is instructed to count backward aloud. The position is held for approximately 15 seconds or until an end-feel is perceived. This test has been found to have a specificity of 95% and a sensitivity of 95%.[101]

Sharp–Purser Test. This test was designed originally to test the sagittal stability of the A-A segment in patients with RA, because a number of pathologic conditions can affect the stability of the osseoligamentous ring of the median joints of this segment in this patient population. These changes result in degeneration and thinning of the articular cartilage between the odontoid process and the anterior arch of the atlas, or, occasionally, in a softening of the dens.

The aim of the test was to determine whether the instability was significant enough to provoke central nervous system's signs or symptoms. Uitvlugt and Indenbaum[102] assessed the validity of the Sharp–Purser test in 123 outpatients with RA. The study findings indicated a predictive value of 85% and a high specificity of 96%. The sensitivity was 88% when subluxation was greater than 4 mm.[102] The authors concluded that the Sharp–Purser test is a useful clinical examination to diagnose A-A instability in the RA population.[102]

However, the original test was poorly defined and only involved upper cervical flexion. Hence, a modified version was introduced which is described.

The patient is positioned in sitting. The patient is asked to segmentally flex the head around a craniovertebral axis (short neck flexion) and relate any signs or symptoms that this might evoke to the clinician. In addition, a positive test may be indicated by the patient hearing or feeling a clunk. Local symptoms, such as soreness, are ignored for the purposes of evaluating the test. If no serious signs or symptoms are provoked, the clinician stabilizes C2 posteriorly with one hand and applies a posteriorly oriented force to the forehead of the patient (Fig. 23-12) VIDEO.

In the presence of a positive test, a provisional assumption is made that the symptoms are caused by excessive translation of the atlas, compromising one or more of the sensitive structures listed previously, and the physical examination is terminated. No intervention should be attempted other than the issuing of a cervical collar to prevent craniovertebral flexion and an immediate referral to the patient's physician.

Coronal Stability: Alar Ligament. The alar ligaments have been described primarily as limiting occipito-atlanto-axial rotation and side bending (e.g., rotation or side bending to the right tightens the left alar), whereas flexion typically tightens both alar ligaments. Both the side bending and rotation stress test for the alar ligaments are based on preventing the inherent coupling of rotation and side bending in the occipito-atlanto-axial complex, that is, side bending of the

FIGURE 23-11 Transverse ligament test.

FIGURE 23-12 Modified Sharp–Purser test.

FIGURE 23-13 Alar ligament test in sitting.

occiput on the atlas is accompanied by immediate ipsilateral rotation of the axis beneath the atlas.[103]

The patient can be positioned in sitting or supine. The posterior aspect of the spinous process and lamina of the axis (C2) is palpated/stabilized with one hand while the patient's head is side bent or rotated (Fig. 23-13). VIDEOS). This is a test of immediacy—if the C2 transverse process does not move as soon as the head begins to side bend or rotate, laxity of the alar ligament should be suspected. To confirm the findings in this test, the point of rotation is maintained, as the patient's head is cradled by the clinician (Fig. 23-14), and while monitoring the motion at the C2 segment, the clinician introduces slight compression to the crown of the head, to facilitate atlanto-occipital side bending through the craniovertebral joints, to slacken the alar ligament. Further rotation should now be possible. Testing is recommended to be performed in three planes (neutral, flexion, and extension) to account for variation in alar ligament orientation.[104] Osmotherly et al.[103] examined the direct effect of the side bending and rotation stress tests on the alar ligaments using magnetic resonance imaging (MRI) and concluded that both side bending and rotation stress testing result in a measurable increase in length of the contralateral alar ligament, which is consistent with the mechanisms that have been described to support their clinical use.

FIGURE 23-15 Transverse shear of O-A joint.

Transverse Shear. Transverse shearing of the craniovertebral joints is performed with the patient supine.[81] The clinician stabilizes the mastoid, and C1 is moved in a transverse direction, using the soft part of the metacarpophalangeal joint of the index finger (Fig. 23-15). The test is repeated by stabilizing C1 and translating the mastoid.

C1 and C2 can be tested similarly. The soft aspect of each second metacarpal head is placed on the opposite transverse processes and laminae of C1 and C2, with the palms facing each other. The clinician stabilizes C1 and then attempts to move C2 transversely using the soft part of metacarpals (Fig. 23-16). No movement should be felt. The diagnostic value of this test is as yet unknown.

Neurologic Examination

The neurologic examination is performed to assess the normal conduction of the central and peripheral nervous systems. The presence of neurologic symptoms deserves special attention. Many of the symptoms that occur in the upper limb have their origins in the neck. The patient with neck trauma can report seemingly bizarre symptoms, but these need to be heeded until the clinician can rule out serious pathology. Cervical myelopathy, involving an injury to the spinal cord itself, is associated with multisegmental paresthesias, upper motor

FIGURE 23-14 Confirmatory test for alar ligament in sitting.

FIGURE 23-16 Transverse shear of A-A joint.

neuron (UMN) signs and symptoms such as spasticity, hyperreflexia, visual and balance disturbances, ataxia, and sudden changes in bowel and bladder function. T e presence of any UMN sign or symptom requires immediate medical referral.

In addition to the muscle stretch (deep tendon) reflexes and sensory tests outlined in Chapter 25, the clinician should perform the spinal cord reflexes of Babinski and Hoffman (see Chapter 3). Studies by Boden et al.[105] and Sung and Wang have demonstrated that the Hoffman test is the most sensitive reflex test in the detection of cervical myelopathy.[106]

Imaging Studies

T e standard, initial cervical spine radiographic series in trauma patients includes a cross-table lateral view, an anteroposterior view, and an open-mouth view, the latter of which is used to help rule out a fracture of the dens (see Chapter 7).[7] T e usefulness of the anteroposterior view has been questioned because it provides little additional information.[107] Although this three-view screening series can detect 65–95% of axis injuries,[108,109] the C2 vertebra is often obscured by overlying bony maxillary, mandibular, and dental structures; therefore, C2 fractures may be missed.[7] T e clinician needs to be aware of the limitations of plain radiographs, as problems exist with both specificity and sensitivity. However, radiographs can provide a gross assessment of the severity of the degenerative changes of the spine.

T in-section CT is the best study for evaluating C2 bony fractures.[110] Sagittal reconstruction of CT images is important because axial images may not detect a transverse odontoid fracture.[7] Although CT is excellent in evaluating bony injuries, it can miss soft-tissue and significant ligamentous injuries.[7] Recently, therefore, dynamic flexion/extension lateral fluoroscopic evaluation has been advocated in polytrauma patients to identify occult ligamentous instabilities and confirm that the cervical spine is uninjured.[111] As with any diagnostic study, the findings must be correlated with the history and physical examination.

INTERVENTION STRATEGIES

T e gamut of musculoskeletal injury to the craniovertebral region of the spine ranges from a simple strain (muscle) or sprain (ligament) to injuries of the bone and neurovascular injuries. T e most common injuries seen clinically are muscle strains and postural dysfunctions.

Muscle strains are common in the cervical spine because most of the cervical muscles attach via myofascial tissue inserting into the periosteum rather than by the more resilient tendon.[112] T e severity of the strain is dependent on the magnitude of forces involved. If the force is suf cient, both the muscle and the associated joint become involved. In an abnormal spine, the forces needed to cause injury are reduced. Repetitive microtrauma is a common cause of craniovertebral dysfunction.

Postural dysfunctions of this region, particularly the forward head posture (see Chapter 25), usually manifest themselves at the O-A joint, resulting in fixed capital extension and a loss of O-A flexion. Patients with postural dysfunctions may develop secondary myofascial trigger points (MTrPs) and myofascial pain syndromes. In postural dysfunctions and trauma-related injuries, other joints and regions may be involved and require further investigation.

Pain, tenderness, active range of motion restrictions, muscle imbalances, and segmental motion restrictions are common findings with craniovertebral dysfunction.

T e structure at fault should determine the intervention[113]:

- If ligamentous tissue damage or an intra-articular lesion is suspected, the safest initial approach would be to help in unloading the joint and controlling the extremes of motion with a soft collar for a 7–10-day period.
- Within the patient's pain tolerance, contractile lesions should be treated aggressively once the acute phase has subsided, with the emphasis on regaining maximal muscle length.[113]

T e techniques to increase joint mobility and soft-tissue extensibility are described later, under "T erapeutic Techniques" section.

A correct diagnosis can usually be accomplished through a detailed history and a comprehensive examination. Confirmation of the correct diagnosis can be made with an assessment of the response of the patient to the initial rehabilitation program. T e intervention for the craniovertebral region may commence when the possibility of serious injury, including fracture, dislocation, or injury to the spinal cord and vertebral artery, has been ruled out.

Acute Phase

T e goals of this phase include

- reducing pain, inflammation, and muscle spasm;
- reestablishing a nonpainful range of motion;
- improving neuromuscular postural control;
- retarding muscle atrophy;
- promotion of healing.

Various electrotherapeutic modalities and physical agents may be used during the acute phase to modulate pain and to decrease inflammation and muscle spasm (see Chapter 8). T erapeutic cold and electrical stimulation may be used for 48–72 hours. T e cryotherapy is continued at home. A transcutaneous electrical nerve stimulation (TENS) unit may be prescribed to help control pain and encourage range of motion exercises. Joint protection may be appropriate. In such cases, a soft or semirigid cervical collar may be prescribed for 7–10 days to reduce muscle guarding (see Chapter 25). Nonsteroidal anti-inflammatory drugs (NSAIDs) often are prescribed for 2–3 weeks to help decrease inflammation and to control pain, thereby increasing the potential for an early return to function. Bed rest, along with analgesics and muscle relaxants for no more than 2–3 days, is prescribed for patients with a severe injury. However, in less severe cases, bed rest has not been shown to improve recovery and, compared with mobilization or patient education, the rest tends to prolong symptoms.[114,115]

T e patient is also taught how to find the neutral position for the upper cervical spine. T e neutral position is defined as the least painful position that minimizes mechanical stresses.

T e range of motion exercises are initiated as early as possible, based on patient tolerance, to prevent hypomobility. Neck flexion and rotation exercises are usually performed first. Extension and side-bending exercises are introduced based on the response of the patient to the flexion and rotation exercises. T e rotation and side-bending exercises are performed in the supine position and then progressed to weight bearing. All the exercises should be performed in the pain-free range.

Upper extremity range of motion and strengthening exercises should also be introduced to promote the early integration of the entire upper kinetic chain. Important muscles to include are the rhomboids, middle and lower trapezius, latissimus dorsi, serratus anterior, and deltoid. In addition, the muscles of the rotator cuff should be strengthened.

Gentle manual techniques (see "T erapeutic Techniques" section), such as sustained or rhythmic specific traction (grade I or II) mobilizations and massage, may also be used. As the patient progresses, muscle stretching may be introduced. Manual techniques can have a mechanical effect on joint mobility and soft-tissue extensibility. In addition, these techniques can have beneficial neurophysiologic effects, which can help alleviate pain and muscle spasm. Self-stretching and self-mobilization techniques are taught to the patient at the earliest and appropriate opportunity (see "T erapeutic Techniques" section).

Active joint protection techniques may be part of the acute phase. Joint protection exercises work by supporting the joint and reducing the applied stresses. Joint protection exercises include cervical stabilization exercises. T ese exercises are initially performed in single planes and in the neutral position, using submaximal isometric contractions. As with the range of motion exercises, it is recommended that these exercises be performed initially in the supine position, and later in sitting, as tolerance increases. As the pain-free ranges increase, the exercises are performed throughout the newly attained pain-free ranges.

Aerobic conditioning must also be included as part of the comprehensive rehabilitation program. A stationary bike, tread-mill, or a stair-stepping machine can be used.

T e patient is advanced to the functional phase when

- the pain has significantly decreased so that there is minimal pain with activities of daily living;
- there is a significant improvement in the pain-free ranges of motion.

Functional Phase

T e duration of this phase can vary tremendously and depends on several factors:

- T e severity of the injury.
- Healing capacity of the patient.
- How the condition was managed during the acute phase.
- T e level of patient involvement in the rehabilitation program.

T e goals of this phase are to

- significantly reduce or completely resolve the patient's pain;
- restore full and pain-free range of motion;
- fully integrate the entire upper kinetic chain;
- restore full cervical and upper quadrant strength and neuromuscular control.

During this phase, the range of motion exercises are continued until maximum range of motion is attained. T e strengthening program is progressed from submaximal isometrics in single planes to maximal isometrics in single planes. T en the patient is progressed to isometrics in combined motions (flexion and side bending and extension and side bending). T e strength training is then progressed to concentric and eccentric exercises in single planes, using elastic tubing, pulleys, or isolation exercises. Proprioceptive neuromuscular facilitation patterns are introduced when appropriate. Elastic tubing is issued to the patient to allow training at home.

For progression to return to play, the athlete should demonstrate the following:

- Normal and pain-free single-plane and multiplane range of motion;
- Normal cervical, cervicothoracic, glenohumeral, and scapulothoracic strength;
- T e normal flexibility of cervical, cervicoscapular, and cervicothoracic musculature.

Return to sports activities should be designed to mimic the sport as closely as possible. T e goal should be to improve the balance, power, and endurance of the cervical, cervicothoracic, glenohumeral, and scapulothoracic muscle groups and force couples.

Pattern 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Connective Tissue Dysfunction

Transverse Ligament Injuries

Injuries to the transverse ligament are classified as follows[48,57]:

- Type I injuries. Disruptions of the substance of the transverse ligament, without an osseous component.
- Type II injuries. Fractures or avulsions involving the tubercle for insertion of the transverse ligament on the C1 lateral mass, without disruption of the ligament substance.

T e medical literature supports the conclusion that a type I injury is incapable of healing without surgery for internal fixation but that most type II injuries heal when treated with an orthosis.[116]

Integration of Patterns 4B and 4D: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Secondary to Impaired Posture and Connective Tissue Dysfunction

Myofascial Pain Patterns

Myofascial pain syndromes are closely associated with tender areas that have come to be known as MTrPs (see Chapter 10). T e term myo*f*ascial trigger point is a bit of a misnomer because trigger points may also be cutaneous, ligamentous, periosteal, and fascial.[117] Dysfunctional joints are also associated with trigger points and tender attachment points.[118]

For a more detailed description of myofascial pain patterns in the upper quadrants, including their causes, signs and

symptoms, and interventions, the reader is referred to the excellent book by Travell and Simons, Myofascial Pain and Dysfunction—The Trigger Point Manual (Volume 1, The Upper Extremities).[61]

The interventions for MTrPs are outlined in Chapter 10. These include stretch and spray, muscle stripping, massage therapy, myofascial release, ischemic compression, stretching, postural correction and education to eliminate any causative or perpetuating factors, electrotherapeutic and thermal modalities, cryotherapy, injections, and joint mobilizations.

Integration of Patterns 4D and 4E: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Secondary to Connective Tissue Dysfunction and Localized Inflammation

Osteoarthritis. Osteoarthrosis of the A-A joints, unrelated to trauma, is a rare cause of pain in the craniovertebral region and an even more uncommon cause of A-A instability. It could be argued that if osteoarthrosis of the lateral mass articulations progresses, the synovitis may gradually involve the ligamentous structures, thereby weakening them and rendering them prone to rupture.[119]

Inflammatory Arthritis. The greatest risk for complications with the spondyloarthropathies in the craniovertebral region occurs at the A-A joint, where there are two different synovial articulations: the two lateral facet joints and the articulation between the odontoid process of C2 and the anterior part of C1.[85] The transverse ligament is typically the weakest part of the complex in the presence of spondyloarthropathy.

Rheumatoid Arthritis. The most common inflammatory lesion found in the retro-odontoid space is RA, which induces abnormal proliferation of the synovial soft tissue (pannus) and frequently causes the destruction of the bony structure[120] (see Chapter 5).

Ankylosing Spondylitis. See Chapter 5.

Gout. See Chapter 5.

Craniovertebral Instability

There has been much controversy about defining and diagnosing spinal instability. Segmental spinal instability is generally defined as a greater displacement between vertebrae than that which occurs under physiologic load. Therefore, maximum flexion and extension radiographs are usually used to determine hypermobility between vertebrae. Craniovertebral instability is frequently encountered in inflammatory, neoplastic, degenerative, and traumatic disorders, in addition to congenital and developmental abnormalities. Clinically, instability appears as a subluxation or spinal deformity accompanied by severe pain or neurologic deficits. Several types of craniovertebral instability are recognized; among them are the following:

- Translational or rotary instability of C1. Translational anterior A-A instability is detected on lateral cervical radiographs as a widened, mobile atlantodental interval (ADI) of greater than 3 mm, caused by laxity or rupture of the transverse ligament or from an odontoid fracture.[121] Patients with congenital abnormalities of the odontoid process may develop chronic A-A subluxation. This leads to the formation of fibrous granulation tissue or a hypertrophic scar in the peri- or retro-odontoid epidural space, which is known as a "pseudotumor."[122] Chronic mechanical irritation associated with neck movement is speculated to be one of the causes of fibrous scar formation.[123] Posterior translation of C1 is also possible, but for this to occur, the dens or anterior arch of the atlas must be fractured or incompetent. Rotational A-A instability appears as asymmetric rotation of the C1 lateral masses on plain radiographs. Rotational subluxations that are irreducible, recurrent, or associated with transverse ligament disruption require surgery.[121] Patients with A-A subluxations exceeding 6 mm are at high risk for neurologic injury and sudden death and are, therefore, immediately considered for fusion.[124]
- O-A instability. O-A instability is demonstrated radiographically by movement between the dens and basion (the middle point on the anterior margin of the foramen magnum), by distraction or translation of the occipital condyles, or by vertical migration.[125]

Surgical stabilization is required to correct instability when conservative intervention has failed or when spontaneous healing with an orthosis, such as a halo brace, is unlikely.

Pattern 4F: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion, or Reflex Integrity, Secondary to Spinal Disorders

Peripheral Vertigo

Dizziness is the third most common complaint among outpatients, after chest pain and fatigue.[126] There are several types of dizziness, some benign and some serious, and it is important that the clinician be able to make the distinction. Among the causes of dizziness that must be carefully considered by the clinician examining the cervical spine are the central and peripheral (Table 23-4) causes of vertigo or dizziness (see Chapter 3).[127] The following are some of the potential causes of peripheral vestibular dysfunction.

Vestibular Neuritis. Vestibular neuritis is thought to represent a reactivated dormant herpes infection in Scarpa's ganglion, within the superior division of the vestibular nerve, which innervates the anterior and horizontal semicircular canals (SCC) (see Chapter 3).[128,129]

Ramsay hunt Syndrome. Ramsay Hunt syndrome is caused by varicella zoster and is a variant of vestibular neuritis, with multiple cranial nerves involved. This involvement results in facial paresis, tinnitus, hearing loss, and a vestibular defect.[130,131] It may also involve cranial nerves V, IX, and X.

Labyrinthitis. Infection of the labyrinth can be viral or bacterial. Acute labyrinthitis usually presents with severe vertigo, sudden or progressive hearing loss, nausea, vomiting, and fever. The condition lasts for 1–5 days, with subsequent resolution of complaints over a 2–3-week period.

Benign Paroxysmal Positional Vertigo. Benign paroxysmal positional vertigo (BPPV), a mechanical disorder of the inner ear, is the most common peripheral vestibular disorder

TABLE 23-4 Peripheral Vestibular Disorders

Autoimmune disease of the inner ear

Data from Huijbregts P, Vidal P. Dizziness in orthopaedic physical therapy practice: classification and pathophysiology. J Man Manip Ther. 2004;12:199–214.

and the most common cause of dizziness in the elderly, with the incidence increasing with age.[130] BPPV presents as brief periods of vertigo experienced with a change in the position of the person's head relative to gravity.[132] BPPV is typically caused by the otoconia being dislodged from the utricle and settling within one or more of the three SCCs creating abnormal stimulation of the fluid-filled canal dynamics. The more serious causes of BPPV (see also Chapter 3) include head trauma, vestibular neuritis, an insult to the labyrinth, surgical stapedectomy, degeneration of the inner ear, and vestibular artery compromise. Two pathophysiological theories have been proposed to explain the etiology of BPPV: cupulolithiasis and canalithiasis[133]:

- Cupulolithiasis. The sedimentous material, possibly macular otoconia, is released into the endolymphatic fluid in the SCC within the short arm of the canal. This release of the sedimentous material is hypothesized to result from trauma or degenerative changes. The canal most commonly involved is the posterior SCC. When the head is upright, this material will settle on the SCC cupula. Fixed deposits on the cupula increase the density of the structure, making the cupula, which previously had the same density as the surrounding endolymphatic fluid, more sensitive to gravity and, therefore, to the head position.
- Canalithiasis. An accumulation of utricle debris (otoconia) within the long arm of the canal, which can move within the posterior SCC and stimulate the vestibular sense organ (cupula), causing vertigo and nystagmus.[130]

The name BPPV implies that this type of vertigo is positional in nature. However, it may be more correct to call BPPV a positioning-type vertigo.[133] Symptom duration is brief (30–60 seconds); hence, it is a positioning-type vertigo rather than a positional-type vertigo, as occurs in vertebrobasilar insufficiency.[133]

The diagnosis is usually made solely on the basis of the history and findings on positional testing, although it is possible to confuse BPPV with orthostatic hypotension, another common cause of dizziness in the elderly. While orthostatic hypotension causes dizziness when the patient sits up or stands, BPPV can occur in all positions, especially with changes in head position. For example, patients who complain of vertigo with rolling on a bed of getting out of bed are 4.3 times more likely to have BPPV.[134]

The two tests commonly used to diagnose BPPV are the Dix–Hallpike test[135] and the side-lying test.[136] The diagnostic criteria for posterior canal BPPV are vertigo associated with the characteristic nystagmus—torsional (superior pole of the eye directly toward the lowermost ear, i.e., the involved ear)[132] and upbeating,[137] with a latency of 1–45 seconds before onset,[138] and the duration of less than 60 seconds[139]—and fatigue with repeated positioning.[139] The side of the lesion is diagnosed with a maneuver similar to the Dix–Hallpike test (see Fig. 3-26). Once diagnosed, one of the two procedures can be used to treat BPPV.

Epley's Canalith-Repositioning Procedure.[140] The Epley canalith repositioning maneuver is designed to return the otoconia from the SCC back to the macule of the utricle, from whence it can be reabsorbed. The maneuver uses a series of head positions. With each head position, the debris settles to the lowest portion of the canal, moving the debris away from the ampulla into the common crus and then into the utricle.[132] In addition to the head position changes, there are a number of body position changes. With each change in position, the movement of debris through the canal and away from the ampulla may create changes in pressure across the cupula, resulting in the generation of the typical torsional and upbeating nystagmus, which is predictive of a successful outcome of the maneuver.[132] The procedure for treatment of the right posterior SCC is performed as follows. The patient is seated on the bed with the legs extended, with the clinician standing to the side of the patient (Fig. 23-17). The patient's

FIGURE 23-17 Patient seated on the bed with the legs extended and with the clinician standing to the side of the patient.

FIGURE 23-18 The patient's head is rotated 45 degrees toward the right, and then lowered into the supine position.

head is rotated 45 degrees toward the right, and the patient is then lowered into the supine position, toward the side of the involved ear with the neck extended 30 degrees over the edge of the treatment table (Fig. 23-18). This is the head-hanging position. While maintaining the cervical extension, the head is slowly rotated through 90 degrees of motion ending in 45 degrees of neck rotation toward the uninvolved side (Fig. 23-19). The patient is then asked to roll onto the uninvolved side while maintaining the position of the head in relation to the trunk (Fig. 23-20). The patient then sits up (Fig. 23-21). Each position is maintained for a minimum of 45 seconds or as long as the nystagmus lasts plus an additional 20 seconds, and the procedure is repeated three times.

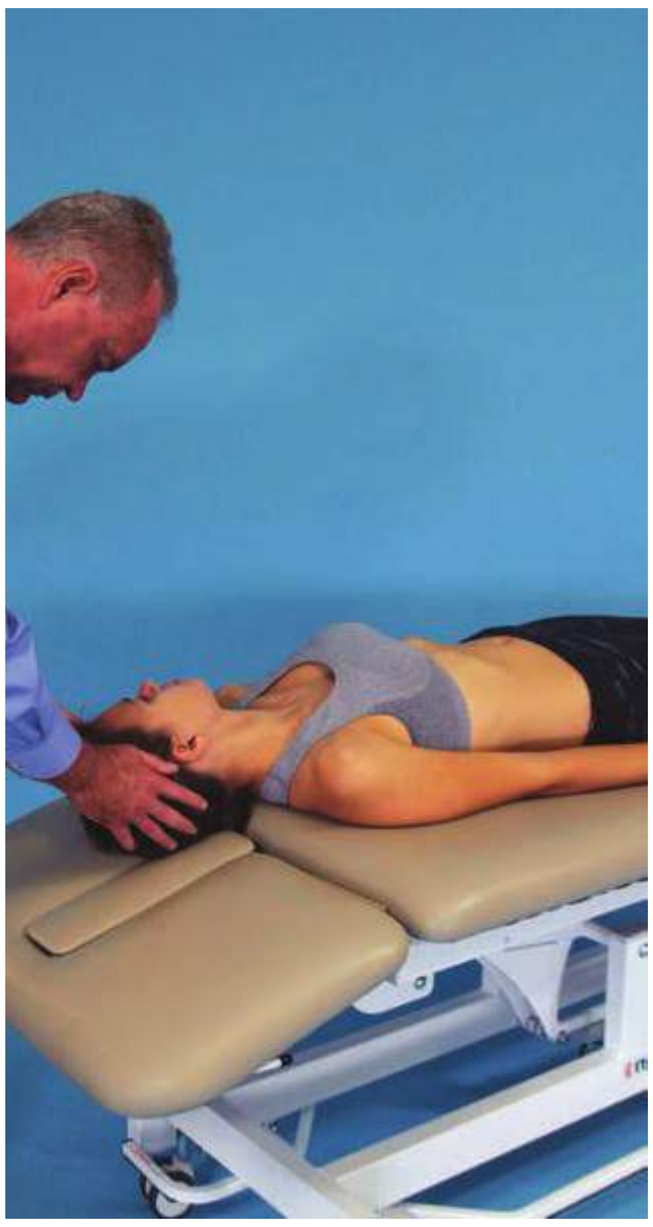

FIGURE 23-19 While maintaining the cervical extension, the head is slowly rotated through 90 degrees of motion.

FIGURE 23-20 The patient rolls onto the uninvolved side while maintaining the position of the head (right side shown versus left).

Liberatory (Semont) Canalith-Repositioning Maneuver.[141] The patient is positioned upright on a bed (Fig. 23-17). The procedure for treatment of the right posterior SCC is performed as follows. The clinician turns the patient's head 45 degrees toward the left ear (Fig. 23-22). The patient is then asked to drop quickly onto his or her right side so that the

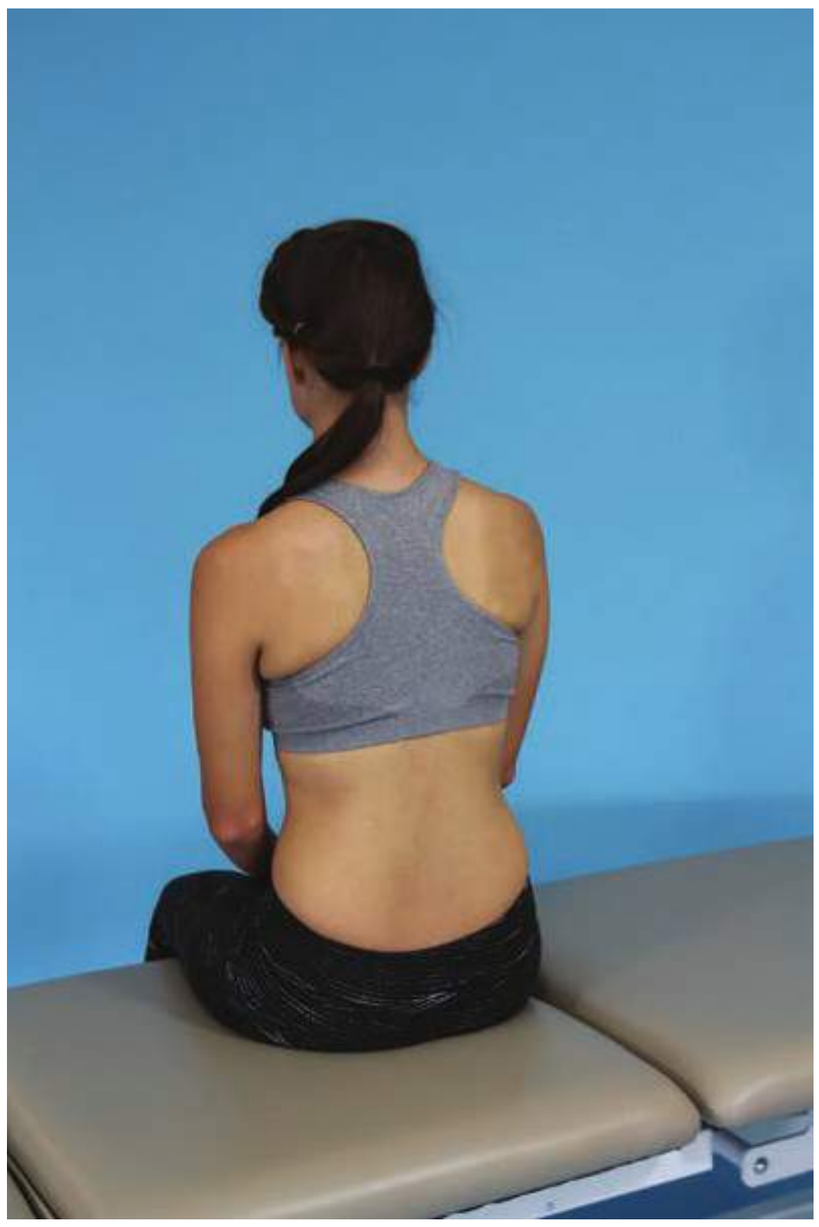

FIGURE 23-21 The patient sits up.

FIGURE 23-22 The clinician rotates the patient's head to the left.

head touches the bed behind the right ear (Fig. 23-23). The position is maintained for 90 seconds and then the patient is asked to move the head and trunk in a swift movement toward the other side without stopping in the upright position, so that the head comes to rest on the left side of his or her forehead (Fig. 23-24). The head is then gently tapped on the treatment table, and the position is maintained for 1.5 minutes. The patient is then asked to sit up (Fig. 23-21). This maneuver should be repeated three times.

To maintain the otoconia in the utricle following either of these maneuvers, the patient is fitted with a soft collar and is instructed not to bend over, lie back, move the head up or down, or tilt the head to either side for the remainder of the day.

Ménière's Disease. This condition is characterized by paroxysmal vertigo, lasting minutes to days, accompanied by tinnitus, fluctuating low-frequency hearing loss, and a sensation

FIGURE 23-23 The patient drops quickly onto her right side.

FIGURE 23-24 The patient moves the head and trunk in a swift movement toward the other side.

of fullness in the ear.[133,142] Attacks are often associated with nausea and vomiting. Age at onset is usually between the 20 and 50 years, and men are more often affected than women.[142] The underlying cause is thought to be an increase in the volume of the endolymphatic fluid in the membranous labyrinth, which displaces the inner ear structures with resultant signs and symptoms of horizontal or rotary nystagmus.[142]

Acute Peripheral Vestibulopathy

This condition is characterized by a sudden onset of vertigo, nausea, and vomiting, which last for up to 2 weeks and is not associated with hearing loss. Differential diagnosis of central disorders characterized by acute vertigo is imperative.[142]

Otosclerosis

The pathophysiologic mechanism behind otosclerosis is immobility of the stapes and resultant conductive hearing loss. Associated signs and symptoms include vertigo and nystagmus.

Vestibular Rehabilitation. The use of a custom-designed physical therapy program in the rehabilitation of patients with unilateral peripheral vestibular hypofunction is aimed at promoting vestibular compensation, promoting central habituation and adaptation, and readjusting the vestibulo-ocular and vestibulospinal reflexes (see Chapter 3).[143,144]

Repetition of head movements and positions that provoke dizziness and vertigo form the basic premise of habituation training, even though many of the exercises may initially increase the patient's symptoms. Adaptation exercises consist of repeated head movements while focusing on a target and are designed to improve gaze stability through adaptation of the vestibulo-ocular reflexes (VOR) and development of compensatory saccadic eye movements (see Chapter 3). Several progressions have been devised (Table 23-5 and Box 23-1). Brown et al., in a retrospective case series of 48 patients with central vestibular dysfunction, noted improvement in both subjective and objective measures of balance after physical therapy intervention.[145] The treatment consisted of one or more of the following: balance and gait training, general strengthening and flexibility exercises, vestibular adaptation exercises, education in the use of assistive devices

TABLE 23-5 Cawthorne–Cooksey Exercises for Patients with Vestibular hypofunction

A. In bed
   1. Eye movements—at first slow, then quick
      a. Up and down
      b. From side to side
      c. Focusing on a finger moving from 3 to 1 ft away from face
   2. Head movements—at first slow, then quick; later with eyes closed
      a. Bending forward and backward
      b. Turning from side to side

B. Sitting
   1. Same as A1 and A2, above
   2. Shoulder shrugging and circling
   3. Bending forward and picking up objects from ground

C. Standing
   1. Same as A1 and A2 and B3, above
   2. Changing from sitting to standing position with eyes open and shut
   3. Throwing a small ball from hand to hand (above eye level)
   4. Throwing ball from hand to hand under knee
   5. Changing from sitting to standing and turning round in between

D. Moving about (in class)
   1. Circle around center person who will throw a large ball and to whom it will be returned
   2. Walk across room with eyes open and then closed
   3. Walk up and down slope with eyes open and then closed
   4. Walk up and down steps with eyes open and then closed
   5. Any game involving stooping and stretching and aiming, such as skittles, bowls, or basketball

Diligence and perseverance are required, but the earlier and more regularly the exercise regimen is carried out, the faster and more complete will be the return to normal activity.

Data from Dix MR. The rationale and technique of head exercises in the treatment of vertigo. Acta Oto-Rhino-Laryngol Belg. 1979;33:370.

and safety awareness techniques to avoid falls, and utilization of varied senses, particularly somatosensation and vision, to aid in maintaining balance.[145]

Cervical Vertigo. Cervical vertigo is a diagnosis and disorder that seems to be poorly understood, and yet dizziness is a common clinical symptom in patients with cervical and upper quadrant syndromes.[127] Cervical or reflex vertigo is thought to originate from a disturbance of the tonic neck reflex input from the neck to the vestibular nucleus. T is disturbance can be caused by a dysfunction in the cervical joints[146] or the SCM.[147] As early as 1926, Barré[148] described a syndrome involving suboccipital pain and vertigo, which was usually precipitated by turning the head. Ryan and Cope[149] coined the term "cervical vertigo" in 1955 for this syndrome.

Cervical vertigo symptoms appear to result from an alteration to proprioceptive spinal afferents from the mechanoreceptors of the neck, usually, but not always, resulting from trauma.[150] Macnab[151] thought that the 575 patients he studied exhibited little evidence of overt neck damage, or of neurologic damage. He thought areas other than the neck itself, such as the brain, brain stem, cranial nerves, cervical nerve roots, or inner ear, might be responsible for the symptoms. Biesinger,[152] on the other hand, proposed two possible neurologic origins:

1. A contributor from the sympathetic plexus surrounding the vertebral arteries
2. Functional disorders of proprioception in segments C1–2

It would seem likely that direct damage to the vestibular apparatus, or severe damage to the vertebral artery, will produce immediate dizziness, whereas dizziness arising from the cervical joints or a less severely injured vertebral artery may not occur until the joints themselves became abnormal, or until the ischemia has had time to make itself felt (Table 23-6).[113] Because cervical pain also frequently is delayed, it is at least arguable that delayed dizziness commonly originates from injured cervical joints and less commonly from ischemia.[113]

T e intervention for cervical vertigo generally begins with conservative physical therapy and anti-inflammatory medications, once testing rules out other causes. With time and therapy, most patients with abnormal electroneurograms end up having normal results at follow-up testing.[113]

Cervicogenic Headache

T e World Cervicogenic Headache Society has defined a CH as "referred pain perceived in any part of the head and caused by a primary nociceptive source in musculoskeletal tissues that are innervated by cervical nerves." According to

Box 23-1 Exercises to Improve Postural Stability

These exercises are devised to incorporate head movement (vestibular stimulation) or to foster use of different sensory cues for balance.

1. The patient stands with his or her feet as close together as possible, with both or one hand helping maintain balance by touching a wall if needed. The patient then turns his or her head to the right and to the left horizontally, while looking straight ahead at the wall for 1 minute without stopping. The patient takes his or her hand or hands off the wall for longer and longer periods of the time while maintaining balance. The patient then tries moving his or her feet even closer together.
2. The patient walks, with someone for assistance if needed, as often as possible (acute disorders).
3. The patient begins to practice turning his or her head while walking. This will make the patient less stable, so the patient should stay near a wall as he or she walks.
4. The patient stands with his or her feet shoulder-width apart with eyes open, looking straight ahead at a target on the wall. He or she progressively narrows the base of support from feet apart to feet together to a semi-heel-to-toe position. The exercise is performed first with arms outstretched, then with arms close to the body, and then with arms folded across the chest. Each position is held for 15 seconds, before the patient does the next-most-difficult exercise. The patient practices for a total of 5–15 minutes.
5. The patent stands with his or her feet shoulder-width apart with eyes open, looking straight ahead at a target on the wall. The patient progressively narrows his or her base of support from feet apart to feet together to a semi-heel-to-toe position. The exercise is performed with eyes closed, at first intermittently and then for longer and longer periods of time. The exercise is performed first with arms outstretched, then with arms close to the body, and then with arms folded across the chest. Each position is held for 15 seconds, and then the patient tries the next position. The patient practices for a total of 5–15 minutes.
6. A headlamp can be attached to the patient's waist or shoulders, and the patient can practice shifting weight to place the light into targets marked on the wall. This home "biofeedback" exercise can be used, with the feet in different positions and the patient standing on surfaces of different densities.
7. The patient practices standing on a cushioned surface. Progressively more difficult tasks might be standing on hard floor (linoleum, wood), thin carpet, shag carpet, thin pillow, and sofa cushion. Graded-density foam can also be purchased.
8. The patient practices walking with a more narrow base of support. The patient can do this first, touching the wall for support or for tactile cues and then gradually touching only intermittently and then not at all.
9. The patient practices turning around while walking, at first making a large circle but gradually making smaller and smaller turns. The patient must be sure to practice turning in both directions.
10. The patient can practice standing and then walking on ramps, either with a firm surface or with more cushioned surface.
11. The patient can practice maintaining balance while sitting and bouncing on a Swiss ball or while bouncing on a trampoline. This exercise can be incorporated with attempting to maintain visual fixation of a stationary target, thus facilitating adaptation of the otolith-ocular reflexes.
12. Out in the community, the patient can practice walking in a mall before it is open and, therefore, while it is quiet; can practice walking in the mall while walking in the same direction as the flow of traffic; and can then walk against the flow of traffic.

Data from Macnab I. Acceleration extension injuries of the cervical spine. In: Rothman RH, Simeoni FA, eds. The Spine. Philadelphia, PA: WB Saunders; 1982:515–527.

the International Headache Society (IHS),[153] a CH is defined as one that meets the following criteria: (1) pain localized to the neck and occipital region that may project to the forehead, orbital region, temples, vertex, or ears; (2) pain precipitated or aggravated by specific neck movements or sustained neck posture; and (3) resistance to or limitation of active or passive physiologic and accessory neck movements or abnormal tenderness of neck muscles, or both. In addition, the IHS guidelines require radiographic examination to diagnose CHs. According to the IHS, radiologic examination must reveal at least one of the following: (1) movement abnormalities during flexion–extension, (2) abnormal posture, or (3) fractures, bone tumors, RA, congenital abnormalities, or other distinct pathology other than spondylosis or osteochondrosis.[153] CHs[29] are difficult to define and classify because of their variable distribution and character of symptoms. The patient with a CH usually reports a dull aching pain of moderate intensity, which begins in the neck or occipital region and then spreads to include a greater part of the cranium.[154] Neck pain can arise from injuries of the cervical muscles, ligaments, disks, and joints. From lower cervical segments, the pain may be referred to the shoulder and upper limb (see Table 22-1). From upper segments, neck pain may be referred to the head and manifested as a headache.[155] Jull et al.[156] provided a cluster

TABLE 23-6 Differential Diagnostic Characteristics of Cervicogenic Dizziness, BPPV, and VBI

	Vertigo Type	Nystagmus Characteristics	Associated Signs and Symptoms
Cervicogenic dizziness	Positioning type	No latency period Brief duration Fatigable with repeated motion	Nystagmus Neck pain Suboccipital headaches Cervical motion abnormality
BPPV	Positioning type	Short latency: 1–5 s Brief duration: <30 s Fatigable with repeated motion	Nystagmus
VBI	Positional type	Long latency: 55 ± 18 s Increasing symptomatology with maintained head position Not fatigable with repeated motion	Dizziness Drop attacks Diplopia Dysarthria Dysphagia Ataxia of gait Nausea Numbness Nystagmus

BPPV, benign paroxysmal positional vertigo; VBI, vertebrobasilar insufficiency.
Data from Huijbregts P, Vidal P. Dizziness in orthopaedic physical therapy practice: classification and pathophysiology. J Man Manip Ther. 2004;12:199–214.; Terrett AGJ. Current Concepts in Vertebrobasilar Complications Following Spinal Manipulation, 2nd ed. Norwalk, IA: Foundation for Chiropractic Education and Research, 2001.

of examination findings to discern CHs from primary headaches. The combination of reduced cervical range of motion, painful upper cervical segmental manual palpation, and reduced strength in the cervical cranioflexor muscles delineated people with CHs from those with primary headaches with 100% sensitivity and 90% specificity.[156] To help in the determination when examining a patient complaining of a headache, the clinician is advised to follow the simple diagnostic clinical algorithm set out below[62]:

- Exclude possible intracranial causes on history and physical examination. If intracranial pathology is suspected, then an urgent workup is required, which may include neuroimaging studies and laboratory investigations.
- Exclude headaches associated with viral or other infective illness.
- Exclude a drug-induced headache or a headache related to alcohol or substance abuse.
- Consider an exercise-related (or sex-related) headache syndrome (see Chapter 5).
- Differentiate between vascular, tension, cervicogenic, or other causes of a headache.

CHs can emerge from a number of sources, including[157]

- irritation of the posterior (dorsal) root ganglia and nerve root components caused by compression of the C2 posterior (dorsal) root ganglia between the C1 posterior arch and the superior C2 articular process[158];
- compression of the C2 anterior (ventral) ramus at the articular process of C1–2[87];
- entrapment of the C2 posterior (dorsal) root ganglia by the C1–2 epistrophic ligament.[159]

Neck pain and headache are also the cardinal features of a whiplash mechanism.[36,160,161] According to the international classification, headache after whiplash is best classified as cervicogenic (group 11.2.1) and thus related to injured structures around the cervical spine.[162] The incidence of a headache after whiplash injury is said to decrease during the first 6 months after trauma.[163] A headache after whiplash can be from cervical spine trauma as listed or from a possible coup–contracoup injury from the rapid acceleration–deceleration of the brain in a closed calverium. Particularly relevant is the relation between a history of a headache and the development of a trauma-related headache after whiplash injury. In addition, psychological variables, which may be important in an idiopathic headache,[164,165] should be evaluated in relation to the development and recovery from a headache after whiplash.

Several interventions have been recommended for CHs, including posture training, manual therapy, exercise, rest, and minor analgesics.[63] Manual therapy studies have demonstrated positive effects on both the impairment (pain and muscle function) and the disability level, with most studies focusing on short-term outcomes.[166,167]

In a single case study, McDonnell et al.[166] described an intervention approach for CH, consisting of a specific active exercise program and modification of postural alignment, with good results after seven visits over a 3-month period. The intervention focused on the following:

- Increasing the strength and control of the abdominals;
- Increasing the length of the anterior thorax muscles;
- Increasing the length of the posterior cervical extensor muscles;

- Improving the strength and decreasing the length of the posterior scapulothoracic muscles;
- Increasing shoulder joint and cervical motion.

Schoensee et al.[168] found that a treatment regimen of joint mobilization to the upper cervical spine in 10 CH patients decreased headache frequency, duration, and intensity.[169] CH frequency remained lower 1 month after the study.[168]

McKenzie[170] recommends a home program of cervical retraction exercises to decrease CH symptoms and maintain correct cervical alignment VIDEO. These exercises, which are performed throughout the day, are progressed based on changes in symptom location and intensity. If an exercise fails to reduce CH pain, a new component is added, and the prior exercise is discontinued.[169]

For the prevention of chronic tension-type headaches, behavioral approaches commonly involve regular sleep and meals, stress coping, meditation, or relaxation strategies, and avoidance of initiating or trigger factors, including work-related or family stress and emotional problems.[63]

Hammill et al.[171] conducted a study, in which 20 subjects with tension-type headaches were treated with posture training, massage, and stretches. The results showed a significant decrease in headache frequency and in sickness impact profile scores at the end of the 6-week treatment period and again 12 months after the treatment concluded.[169]

Bronfort et al.[172] performed a systematic review of randomized controlled trials to include nine trials of 683 subjects with chronic headaches. They found that spinal mobilization treatment had a better effect than massage for CH and that it had a comparable effect to commonly used prophylactic prescription medications for tension-type and migraine headaches.[169,172]

Chiari Malformations

Chiari malformations are a group of disorders that manifest varying degrees of inferior displacement of the cerebellum and brain stem through the foramen magnum. Four types are recognized[173]:

- Chiari type I malformation. This type consists of the inferior displacement of the cerebellar hemispheres (cerebellar tonsils) through the foramen magnum. This is tongue-like projection of the medial inferior cerebellum envelops the medulla. The fourth ventricle is in a normal position. As the degree of descent increases, the outflow of cerebrospinal fluid decreases, and a tubular cavitation of the upper spinal cord called syringomyelia, then occurs. Syringomyelia is distinct from hydromyelia, which is an enlargement of the central canal of the spinal cord.
- Chiari type II malformation. Chiari type II malformation is associated with an inferior displacement of the brain stem and fourth ventricle through the foramen magnum into the vertebral canal, often with hydrocephalus and meningomyelocele.
- Chiari type III malformation. This type is associated with a herniation of the cerebellum into a high cervical meningocele.
- Chiari type IV malformation. In Chiari type IV malformation, the cerebellum is generally hypoplastic.

Chiari types II–IV typically present with florid symptoms and are usually diagnosed in infancy or childhood.[173] In contrast, in Chiari type I malformation, the signs of brain stem dysfunction evolve slowly over years and are, thus, more likely than the other types to be encountered in physical therapy.

The clinical manifestations of Chiari I malformation are among the most protean in clinical medicine, which can lead to a delay in diagnosis. The most common presenting symptoms are upper extremity weakness and various pain syndromes that often include neck and arm pain.[174] Occipital headaches, which are exacerbated by coughing, sneezing, stooping, or lifting, are also frequent.[174] Clumsiness, upper extremity sensory changes ataxia, vertigo, hearing loss, tinnitus, dysphagia, hiccups, dysarthria, and hoarseness of voice are some of the other reported symptoms.[174]

The diagnosis of Chiari malformation is most commonly made with MRI. If surgical intervention is necessary, it involves decompression of the Chiari malformation with or without drainage of the syringomyelia.[173]

Pattern 4G: Impaired Joint Mobility, Motor Function, Muscle Performance, and Range of Motion Associated with Fracture

Although the intervention for fractures is beyond the scope of practice for a physical therapist, being able to detect their presence, especially in this region, is critical. Clinical findings that could suggest the possibility of a craniovertebral fracture include the following[175,176]:

- Painful neck muscle splinting;
- Neck and occipital numbness;
- Pain and stiffness in the neck, with a reluctance to move the head;
- Presence or absence of neurological signs and symptoms.

Fractures of the Axis

There are three types of fractures of the C2 (axis) vertebra: odontoid fractures involving the dens, bilateral traumatic spondylolisthesis of the pars interarticularis ("hangman's" fracture), and nonodontoid/nonhangman's (miscellaneous) fractures.[177]

Odontoid Fractures. Odontoid fractures are a relatively common upper cervical spine injury, comprising nearly 60% of all fractures of the axis and 10–18% of all cervical spine fractures.[66,178–181] Although odontoid fractures occur in all age groups, the mean age is approximately 47 years with a bimodal distribution.[7] In younger patients, who comprise the first peak, these fractures are usually secondary to high-energy trauma; motor vehicle accidents are responsible for the majority of the odontoid injuries.[182] The second peak in the incidence of odontoid fractures is in the elderly.[109] In fact, odontoid fractures are the most common cervical spine fracture in patients older than 70 years.[7] These fractures, unlike those in the younger patients, tend to result from low-energy injuries, such as falls from a standing height.[7] The mechanism of injury is often hyperextension resulting in posterior displacement of the odontoid.[7]

Described in 1974, the Anderson and D'Alonzo system divides fractures into three types based on anatomic location[179]:

- **Type I.** Type I is an oblique avulsion fracture from the tip of the odontoid above the transverse ligament, attached to the alar ligament. T is fracture is clinically rare, accounting for 1–5% of odontoid fractures, and may be associated with O-A dislocation.[180]
- **Type II.** Type II fractures occur through the neck of the odontoid. T ey are the most common type of odontoid fracture (38–80%).
- **Type III.** Type III fractures extend into the body of C2. T ey account for 15–40% of all odontoid fractures.

Current management of odontoid fractures is based on three principles: timely diagnosis, reduction of the fracture, and suf cient immobilization to permit healing.[181] Numerous treatment methods have been developed to achieve anatomic alignment and optimal stability, including cervical orthoses, Minerva jackets, halo-thoracic vests, posterior cervical fusion, and direct anterior dens screw fixation.[183]

Jefferson Fracture. Jefferson fracture was defined as the association of a lateral mass fracture of C1 and the disruption of the C1 ring (either on the posterior or on the anterior arch).[184] Jefferson fractures now represent a spectrum of injuries from bilateral ring fractures, to lateral mass fracture, to the pathognomonic four-point fracture (both anterior and posterior arches) of the C1 ring that the fracture was originally named for.[185] Jefferson fracture classically results from axial loading on the atlas and is generally associated with minimal neurologic deficit and good prognosis for neurologic recovery.[186] Presently, three general types of Jefferson fractures are described[187]:

- **Type I.** Type I involves bilateral single-arch (anterior or posterior, but not both) fractures.
- **Type II.** Type II is the concurrent anterior and posterior arch fractures, which include the classic four-point break Jefferson fracture.
- **Type III.** Type III is the lateral mass fracture of C1, which may extend into the anterior or the posterior osseous arch.

No prognostic significance has been attached to the different types of Jefferson fracture.[187] Isolated Jefferson fracture can be treated effectively with external immobilization. T e traditional mode of cervical immobilization is the halo vest.[185]

THERAPEUTIC TECHNIQUES

Techniques to Increase Soft-Tissue Extensibility

Soft-tissue techniques are generally applied before performing the local segmental examination and in preparation for a mobilization or manipulation intervention. Soft-tissue techniques are capable of producing a strong analgesic and relaxing effect. With a reduction in cervical muscle tension or spasm, it becomes much easier for the clinician to palpate and register movement.

General Kneading

General kneading techniques can be applied to the soft tissues of the craniovertebral region. T ese techniques are especially useful before performing a specific mobilization or manipulation VIDEO.

FIGURE 23-25 Suboccipital massage.

Suboccipital Massage

Soft-tissue techniques can be performed at several sites in the cervical region. In principle, every tender site can be treated, even though it usually involves areas of referred pain or tenderness.[188]

T e patient is positioned prone or sitting, and the head is positioned in slight flexion, without rotation. T e clinician stands on the uninvolved side. T e SCM may need to be displaced laterally, in order to palpate the muscles attaching to the transverse process of C1. T e clinician locates the most tender area and places the thumb directly lateral to the tender spot (Fig. 23-25). During the massage, the thumb moves from laterally to medially and slightly cranially, while, at the same time, the pressure is exerted in an anteromedial and superior direction.

A similar technique is used in a combination of upper cervical traction and soft-tissue mobilization of the suboccipital muscles. T is technique is best performed with the patient supine because the neck is unloaded, and the patient can relax more in the supine versus seated position. While one hand grasps the patient's head, the clinician uses the fingers of the other hand to press gently into the muscles between two vertebrae. While maintaining the pressure on the muscles, a slight traction force is applied and sustained for several seconds before being released. T e procedure is repeated in a rhythmic manner.

T e paravertebral muscles can be treated in a similar fashion. With one hand, the clinician stabilizes the patient's head at the forehead. With the index or middle finger of the left hand, or both fingers, the clinician pulls the musculature in a lateral and anterior direction. At the same time, the hand on the patient's forehead rotates the patient's head away from the side being treated. T e end position is held for 2–3 seconds, before returning to the initial position. T e clinician repeats this technique for several seconds or minutes in a rhythmic manner.

Muscle Stretching of the Suboccipital Muscles

Rectus Capitis Posterior Major and Minor. To stretch these muscles, the patient is positioned in supine or sitting. T e

FIGURE 23-26 Stretch for rectus capitis posterior major and minor.

clinician fixes C2 into craniovertebral flexion (see Fig. 23-26). To stretch the left muscle, a right side bending and right rotation motion is added, and the patient is instructed to not let the head drop back. Hold–relax or contract–relax techniques can be used.

Inferior Oblique. To stretch the left muscle, the patient's head and neck are positioned into flexion (see Fig. 23-27), left side bending, and right rotation. A massage to the muscle can be applied by stroking the muscle from the C1 transverse process to the C2 spinous process, applying a force in the direction of less pain.

Superior Oblique. The patient is positioned in sitting. The clinician places the index finger over the posterior aspect of the transverse process of C1, and the other hand wraps around the patient's head. To stretch the right superior oblique, the patient's head and neck must be placed in flexion, left side bending, and right rotation (see Fig. 23-28). Hold–relax or contract–relax techniques can be used.

Self-Stretching

The following exercises should be performed at an intensity level that achieves an improvement without a regression of status.

Chin Retraction. The patient is seated in the correct posture. The patient is instructed to attempt to move the head, as a unit, in a posterior direction, while maintaining eye level VIDEO. The clinician should limit the number of chin tucks the patient performs, to remove any potential for harm to the cervical structures from overuse.

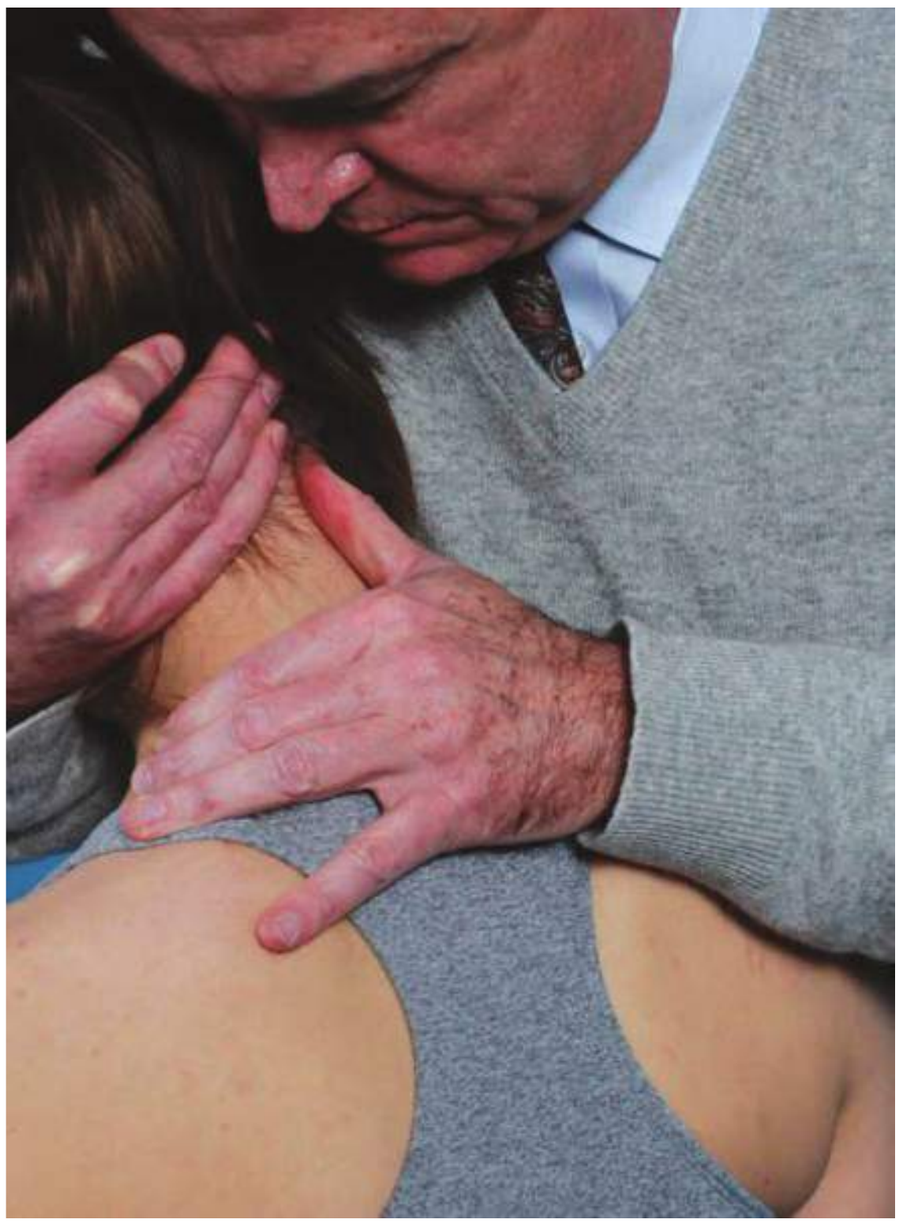

FIGURE 23-28 Stretch for the superior oblique.

C2–3 Side Bending and Rotation. The pattern of limitation for this area is usually one of a closing restriction. The patient is seated in the correct posture. The patient places both hands behind the neck, with the ulnar border of the little finger being just below the C2 spinous process and the rest of the hand covering as much of the midcervical region as possible. The patient then simultaneously side flexes and rotates the neck and head in the direction of the restriction (Fig. 23-29), by attempting to look downward and backward (for a closing restriction).

A-A Rotation. The patient is seated in the correct posture. The patient places both hands behind the neck, with the ulnar

FIGURE 23-27 Stretch for the inferior oblique.

FIGURE 23-29 C2–3 side-bending and rotation exercise.

FIGURE 23-30 Exercise to increase right rotation at the A-A.

border of the little finger being at the level of the C2 spinous process and the rest of the hand covering as much of the midcervical region as possible. The patient then gently turns the head in the direction of the restriction (Fig. 23-30) VIDEO. Coupled motions should be encouraged. For example, if the patient has a restriction with right rotation, right rotation and left side bending are emphasized.

O-A Flexion. The patient is seated in the correct posture. The patient performs a chin tuck. From the chin-tucked position, the patient is instructed to place the tips of the index and middle fingers of both hands over the anterior aspect of the chin (Fig. 23-31). The fingertips provide resistance for an attempted extension movement of the head on the neck. The patient then attempts to look upward, while resisting the motion with the fingertips. This is followed by relaxation and then another chin tuck. An alternative method involves asking the patient to clasp their figures behind the neck so that the little fingers are placed at the base of the skull VIDEO.

O-A Extension. The patient is seated in the correct posture. The patient places both hands behind the neck, with the ulnar border of the little finger being at the level of the C1 spinous process and the rest of the hand covering as much of the midcervical region as possible. The patient then gently lifts the chin around the appropriate axis (Fig. 23-32).

FIGURE 23-31 Home exercise for O-A flexion.

FIGURE 23-32 Home exercise for O-A extension.

Techniques to Increase Joint Mobility

A series of studies that have investigated the efficacy of manual therapy in the treatment of upper cervical dysfunction and headache are outlined in Table 23-7.

Joint Mobilization Techniques

O-A Joint: Specific Traction. Specific traction is used here, as elsewhere in the spine, to apply a gentle degree of distraction and mechanical stimulation. It typically is used with acute conditions.[188]

The patient is positioned in supine. The clinician stabilizes the C1 vertebra using a wide pinch grip, and the patient's forehead is stabilized against the clinician's shoulder (see Fig. 23-33). A traction force is then applied, a graded cranial force (I to II) by the occipital hand and the chest VIDEO.

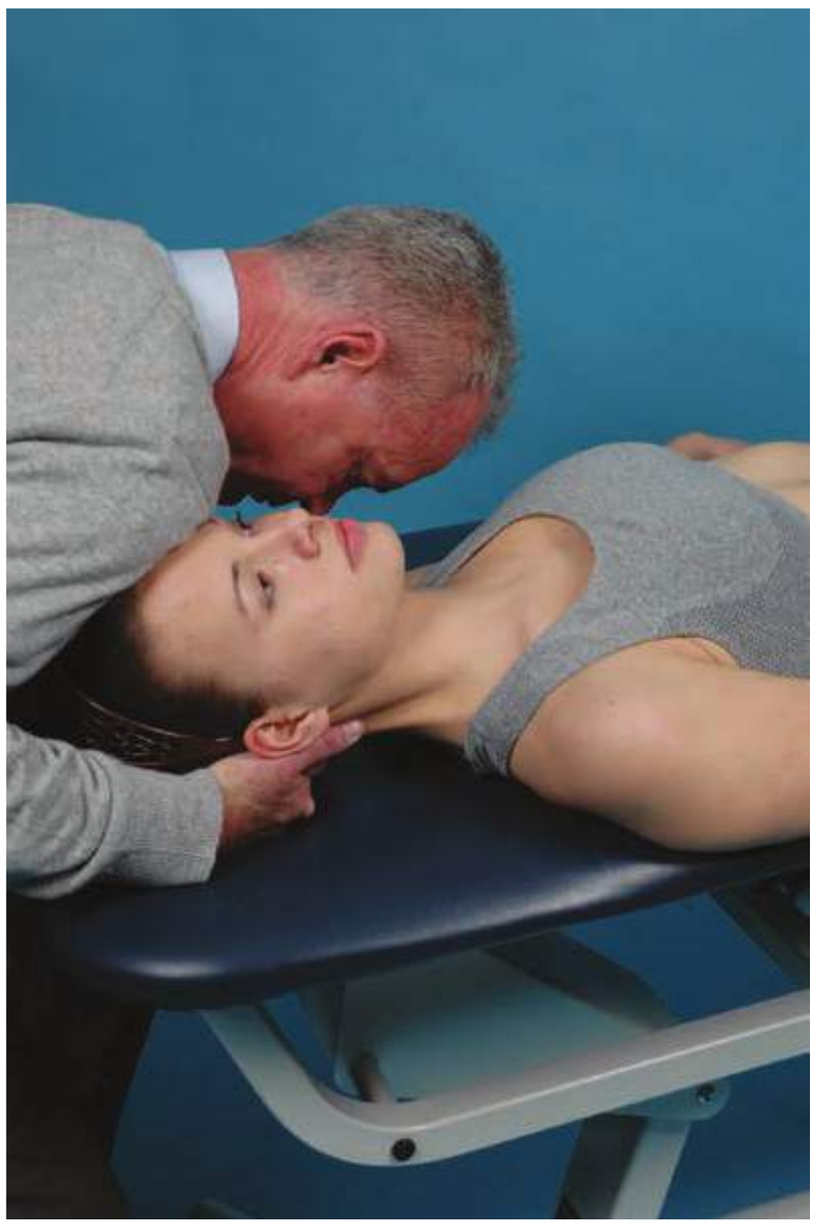

FIGURE 23-33 Specific traction to O-A joint in supine.

TABLE 23-7 Summary of Published Studies Investigating Manual Therapy Treatment for Upper Cervical Dysfunction and headache

Author	Sample Size	Intervention Group	Control Group	Outcome Measured	Number of Visits and Duration of Care
Boline et al.[a]	150	Manipulation	Medication	Headache frequency and intensity. Number of medications. SF-36 score	12 visits 6 wks
Howe et al.[b]	52	Manipulation ± Injection +Medication	Medication only	Cervical range of motion. Neck, scapular, arm, and hand pain. Neck stiffness. Headache intensity	1 visit only
Jensen et al.[c]	19	Mobilization Muscle energy	Cold packs	Frequency of medications. Pain intensity, dizziness, visual, and hearing	6 visits 12 wks
Nilsson[d]	39	Manipulation	Laser Friction massage	Headache duration and intensity. The number of nonsteroidal anti-inflammatory drugs	6 visits 3 wks
Nilsson et al.[e]	39	Manipulation	Laser Friction massage	Cervical passive range of motion	6 visits 3 wks
Osterbauer et al.[f]	20	Manipulation Electrical ± stimulation ± Medication	No treatment (10 nonimpaired)	Pain intensity. Cervical range of motion. Kinesthesia	2–3 visits per wk 6 wks
Parker et al.[g]	85	Manipulation by Chiropractor Manipulation by physical therapist	Mobilization by a physical therapist	Migraine frequency, intensity, and duration. Disability	Up to 16 visits 8 wks
Rogers[h]	20	Manipulation	Stretching	Pain. Kinesthesia	6 visits
Schoensee et al.[156,i]	10	Mobilization	None	Headache frequency, duration, and intensity	3–4 wks 9–12 visits 3–4 wks
Vernon[j]	33	Manipulation	None	Headache frequency, duration, and intensity	9 visits Unspecified
Whittingham et al.[k]	26	Manipulation at C1 and C2	None	Headache frequency, duration, and intensity	4 visits 2 wks
Yeomans[l]	58	Manipulation	None	Cervical intersegmental range of motion	3 visits per wk 2–6 wks

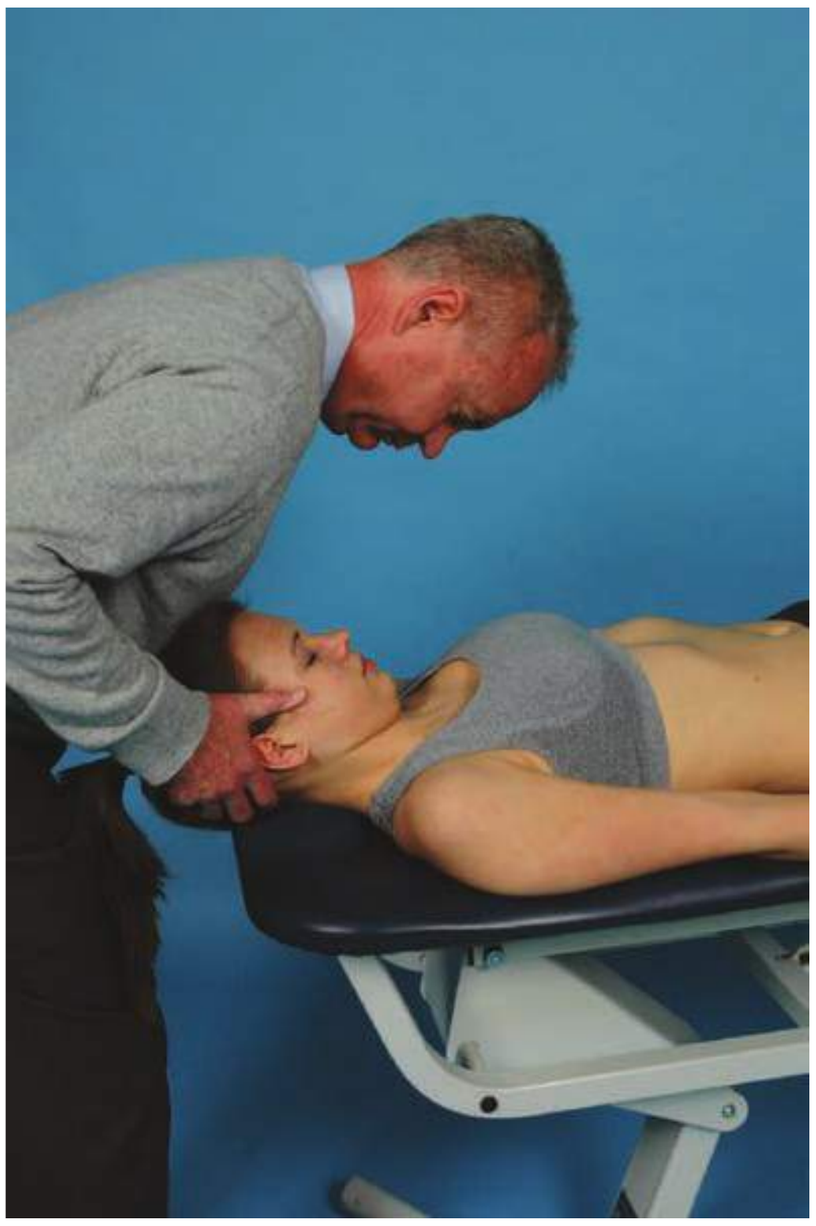

FIGURE 23-34 Supine technique for a symmetrical loss of O-A extension.

Supine Technique for a Symmetrical Loss of O-A Extension. The patient is positioned in supine, head on a pillow, and knees flexed over a pillow. The clinician is positioned at the head of the table. The clinician cradles the patient's head in both hands with the finger pads under the occiput and places each thumb over the zygomatic arches of the patient. Using thumb pressure, the clinician tilts the patient's head into craniovertebral flexion, while the finger pads produce a posterior glide of the occipital condyles (see Fig. 23-34) VIDEO

The joint slack is taken up. The patient is instructed to attempt to place the chin on their throat. After an isometric contraction of 3–5 seconds, the patient is instructed to relax, and the resultant joint slack is taken up by the clinician. When, following repeated muscle-assisted mobilizations, no further increased motion is apparent, it can be assumed that the inert barrier to the motion has been reached. Passive soft-tissue mobilization is then performed. This combination of muscle-assisted and passive mobilizations is continued until no further soft-tissue slack is appreciated.

Seated Technique for a Loss of Extension at the Left O-A Joint. The following mobilization techniques can be used for a restriction of the anterior glide of the left O-A joint.[188] The reader is expected to extrapolate the information to produce the necessary technique for a restriction of the anterior glide of the right joint.

The patient is seated with the clinician standing on the right side. C1 is stabilized anteriorly, using a wide pinch grip by the left hand and wrapping the pads of the index finger and thumbs around the front of the transverse process (Fig. 23-35). The right arm stabilizes the patient's head against the clinician's chest, and the right hand grasps the occiput. The

FIGURE 23-35 Seated technique for a loss of extension at the left O-A joint.

patient's head is then extended and left side flexed around the appropriate axes, with the right translation being produced by means of the side bending until the extension barrier is reached. The mobilization is then performed by applying a graded force against the translation barrier.

Active participation from the patient can be introduced. From the motion barrier, the patient is asked to gently meet the clinician's resistance. The direction of resistance is that which facilitates further extension, left side bending, and right rotation. The isometric contraction is held for up to 5 seconds and followed by a period of complete relaxation. The joint is then passively taken to the new motion barrier. The technique is repeated three times and followed by a reexamination.

Supine Technique for an Asymmetrical Loss of O-A Extension (e.g., Loss of Left O-A Joint Extension). The patient is positioned in supine, head on a pillow, and knees flexed over a pillow.[93] The clinician is positioned at the head of the table. The clinician cradles the patient's head in both hands. The left index and middle finger pads are placed just medial to the patient's left mastoid process, with the palm supporting the occiput. The clinician's right hand is placed on the right side of the patient's head VIDEO

Using both hands, the clinician passively moves the patient's head into craniovertebral extension and right translation, until the extension motion barrier of the left O-A joint is reached. The joint slack is taken up by the clinician using their left fingers to push upward toward the patient's lips and the clinician's right hand, thereby inducing side flexion of the patient's head to the left.

The patient is instructed to resist left side flexion of the O-A joint using the command "Don't let me pull your left ear upwards." The contraction is held for 3–5 seconds and the patient is asked to relax. As the patient relaxes, the new joint slack is taken up by the clinician pushing further toward the patient's lips with the left finger pads and side flexing the patient's head to the left with clinician's right hand. To ensure that the extension is occurring around a craniovertebral axis, the clinician looks at the patient's face. As slack is taken up, flexion of the right O-A joint should simultaneously produce chin movement toward the ceiling while the forehead moves toward the bed. To ensure that the left side flexion is

occurring around the correct axis, the clinician should note the chin movement occurring to the right while the forehead moves to the left. During the conjunct right rotation, the chin and forehead should both be seen to rotate to the right.

As with the technique to increase unilateral flexion, once the inert barrier is reached, the combined passive motion into the barrier is stressed with oscillatory passive stretch, and then muscle-assisted mobilizations are repeated. T is is continued until there is no further "give" to the motion barrier.

Supine Technique for an Asymmetrical Loss of O-A Flexion (e.g., Loss of Left O-A Joint Flexion). T e patient is positioned in supine, head on a pillow, and knees flexed over a pillow.[93] T e clinician is positioned at the head of the table. T e clinician cradles the patient's head in both hands, so that the right hand is placed on the right side of the patient's head and the clinician's left index and middle finger pads are placed just medial to the patient's left mastoid processes, with the palm supporting the patient's occiput VIDEO.

Using both hands, the clinician produces craniovertebral flexion to the barrier. At this point, the patient's head is translated to the left until a firm end-feel is encountered. T is maneuver induces a right side bending and left rotation at the O-A joints. T e barrier to flexion of the left O-A joint is thus achieved.

Joint slack is taken up as the clinician uses a lumbrical action to pull on the patient's left mastoid process, in the direction toward the bed surface, with the left index and middle fingers. Simultaneously, the patient's head is side flexed to the right by the clinician's right hand. Using fingertip pressure of the right hand, the clinician instructs the patient: "Don't let me lift your right ear upwards." T e clinician then attempts to draw the patient's right mastoid process superiorly. T is produces an isometric resistance of right side flexion of the O-A joint (and, therefore, left rotation).

After an isometric contraction of 3–5 seconds, the patient is instructed to relax, and as the relaxation is felt by the clinician, the resultant joint slack is taken up by the clinician by simultaneously pulling the patient's left mastoid process toward the bed (with the left hand) and side bending the head to the right (with the right hand). When, following repeated muscle-assisted mobilizations, no further increased motion is apparent, it can be assumed that the inert barrier to the motion has been reached. Passive soft-tissue mobilization is then achieved by pushing further into the left O-A joint flexion barrier by simultaneously pulling the left mastoid process toward the bed (left hand) and right side bending of the head (right hand). T is combination of muscle-assisted and passive mobilizations is continued until no further soft-tissue slack is appreciated. To ensure that the flexion is occurring around a craniovertebral axis, the clinician looks at the patient's face. As slack is taken up, flexion of the left O-A joint should simultaneously produce the following:

- A downward motion of the patient's chin and an upward motion of the patient's forehead (flexion);
- A left-sided motion of the patient's chin with a left-sided motion of the forehead (right side flexion); and
- A rotation of chin and forehead to the left (left rotation).

If these facial movements are not seen, then the right hand is used to ensure that these motions are occurring, thus maintaining a craniovertebral axis.

A-A Joint: Loss of the Anterior–Inferior Glide of the Left A-A Joint (e.g., Loss of Right Rotation of A-A Joint, Loss of Left Anterior–Inferior Glide). T e patient is positioned in supine, head on a pillow, and knees flexed over a pillow.[93] T e clinician is positioned at the head of the table. T e clinician cradles the patient's head in both hands. T e clinician's right index and middle finger pads are placed around the left side of the patient's C2 neural arch, making firm contact with the left side of the C2 spinous process VIDEO. T e clinician's left hand supports the left side of the patient's head. T e patient's head is side flexed by clinician's left hand. Using the fingers of the right hand, the clinician feels for the C2 spinous process to move to the right. At this point, the C2 spinous process is pulled by the index and middle fingers of the right hand until the motion barrier is detected. T e patient is instructed to push their head into clinician's left hand, that is, resisted left side flexion. T e C2 spinous process should be felt to move to the right, and the clinician's right fingers move to fix it, as the patient is instructed to relax. As patient relaxes, the slack in left side bending of the head is taken up. T is is repeated until no further motion of the C2 spinous process is detected.

A similar technique can be performed with the patient in sitting (Fig. 23-36). Using one hand (left, in the photo), the clinician stabilizes the C2 segment and the inferior vertebral segments using a lumbrical grip. T e fifth digit of the other hand wraps around the neural arch of C1 and supports the head. T e patient's head is side flexed by clinician's shoulder and rotated by the clinician's right hand until the rotation barrier is reached. T e mobilization is then performed by applying a graded force against the barrier. Active participation from the patient can be introduced. From the motion barrier, the patient is asked to gently meet the clinician's resistance. T e direction of resistance is that which facilitates further rotation. T e isometric contraction is held up to 5 seconds and followed by a period of complete relaxation. T e joint is then passively taken to the new motion barrier. T e technique is repeated three times and followed by a reexamination.

Mobilizations with Movement

Upper Cervical Traction. T is is an excellent technique for the intervention of upper cervical headaches.[189] T e patient

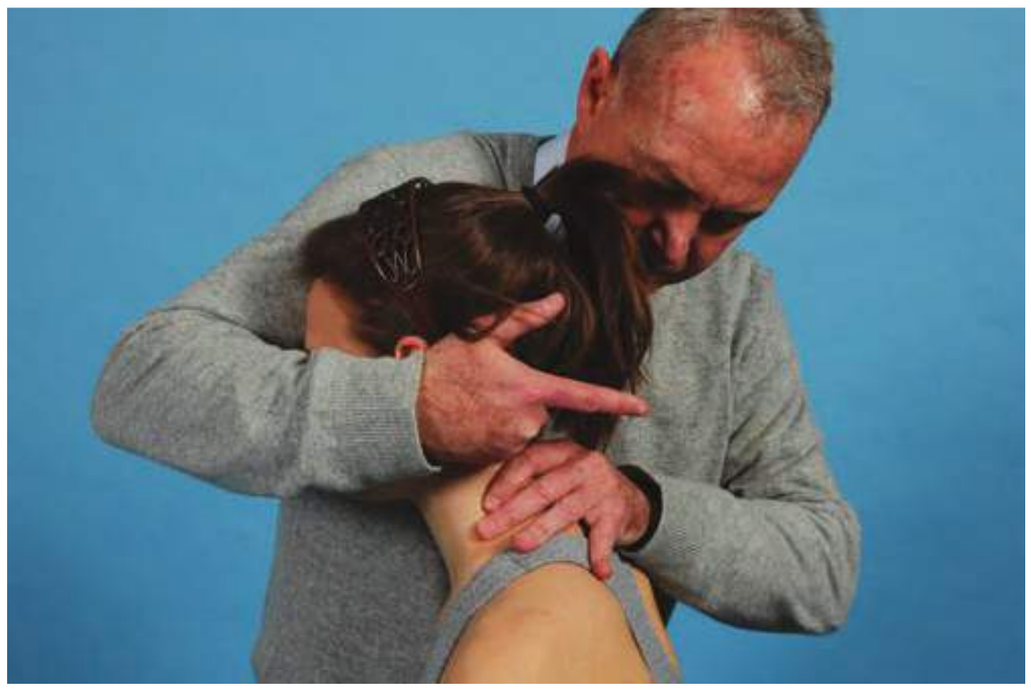

FIGURE 23-36 Seated technique for loss of right rotation in A-A joint—loss of left anterior/inferior glide.

FIGURE 23-37 Upper cervical traction.

FIGURE 23-38 Mobilization to increase right rotation of the A-A.

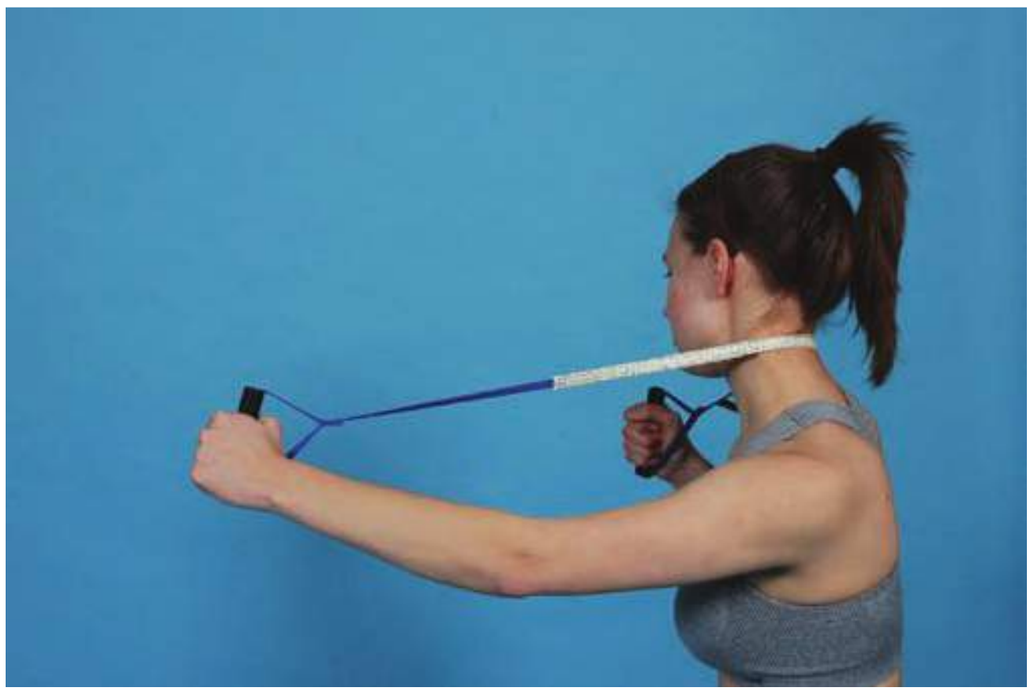

FIGURE 23-39 Home exercise to increase right rotation of the A-A.

is positioned in sitting, with the clinician standing in front, facing the patient. The patient's head against the clinician's chest and the fingers wrap around the patient's head to provide firm support (Fig. 23-37). The clinician's other hand is used to stabilize the inferior segment (see Fig. 23-37).

The clinician applies pressure to the inferior segment while preventing motion of the head and applying a longitudinal force to the head. The end-feel is obtained and is maintained for 10–20 seconds.

To Improve Right Rotation of the A-A Joint. The patient is positioned in sitting, with the clinician sitting behind. The clinician places the thumb of one hand over the left aspect of the transverse process of C2, and the other thumb over the first thumb to help reinforce it. The remaining fingers of the hands are placed on the patient's neck and upper back, or to the side of the head (Fig. 23-38).

The patient is asked to rotate the head and neck slowly to the right, while the clinician simultaneously assists the movement using pressure from both thumbs, rotating C2 to the left.

This technique can be taught as part of the patient's home exercise program, using a towel, belt, or a strap (Fig. 23-39). The same technique can be used to improve cervical rotation to the left by altering the position of the thumbs.

CASE STUDY

Headache and Neck Pain

HISTORY

A self-employed 42-year-old man presented to the clinic complaining of posterior upper neck pain and right suboccipital and occipital headache, which began 2 months earlier after a diving accident. He denied being knocked unconscious and could remember everything about the accident except for the period a few minutes after it. The posterior neck pain was felt immediately but was much worse the next morning upon waking. The occipital headaches started a few days later and became worse with fatigue or exertion. The patient also reported difficulty concentrating and sleeping and had occasional bouts of dizziness, especially when turning his head to the left, during which he would become unsteady, but denied vertigo. When the neck and occipital pain fared up, it

spread from the occipital region over the head to the right eye. Previous interventions included physical therapy in the form of ultrasound, massage, spray and stretch, myofascial release, and cranial sacral therapy, which had provided no relief.

The patient had no history of back or neck pain, apart from the occasional ache, and his medical history was unremarkable.

Questions

1. List the concerns the clinician should have following this history.
2. Using a flow diagram describe how you would proceed with this patient following the history.
3. What special tests should be considered at this point?
4. Are additional questions needed with regard to the history?

CHAPTER 24

Vertebral Artery

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy and distribution of the vertebral artery.
2. Describe the four commonly recognized portions of the vertebral artery.
3. Outline the causes of vertebral artery occlusion or compromise.
4. Recognize the characteristics of vertebral artery occlusion or insufficiency.
5. Describe various special tests used to assess the patency of the vertebrobasilar system and their diagnostic value.

OVERVIEW

The vertebral artery (VA), a component of the vertebrobasilar artery (VBA) system, supplies 20% of the blood to the brain (primarily the posterior cranial fossa), with the remaining 80% being supplied by the carotid system.[1] The first studies of the VA were recorded as far back as 1844.[2] Since that time, recognition of the importance of the VA has continued to grow, and it is now discussed in more detail than any other artery by physical therapists. For this reason, the VA is afforded its own chapter. To fully comprehend its significance, a review of its anatomy and function is in order.

ANATOMY

The VBA system consists of three key vessels: two VAs and one basilar artery. The basilar artery is formed by the two VAs joining each other at the midline (Fig. 24-1).

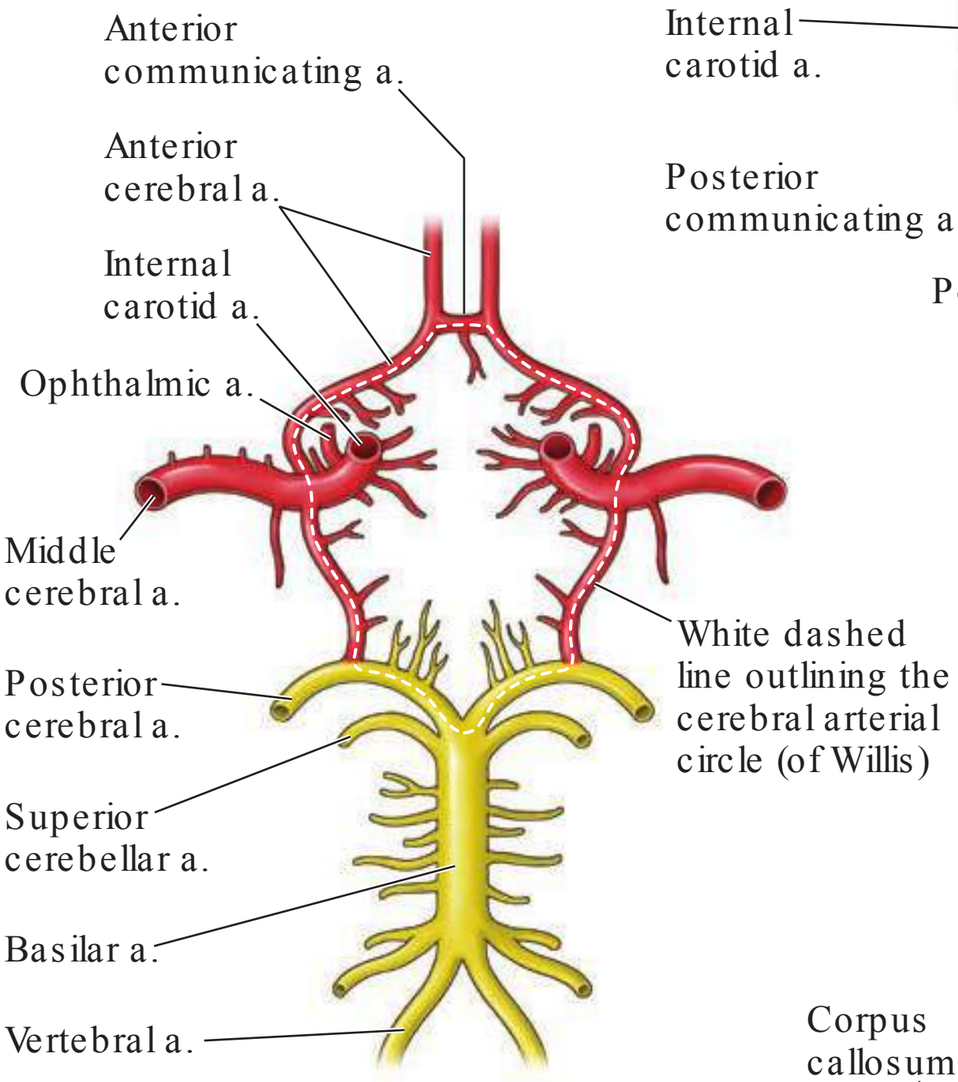
Along its course, the artery can be viewed as having four portions: proximal, transverse, suboccipital, and intracranial.[3,4]

Proximal Portion

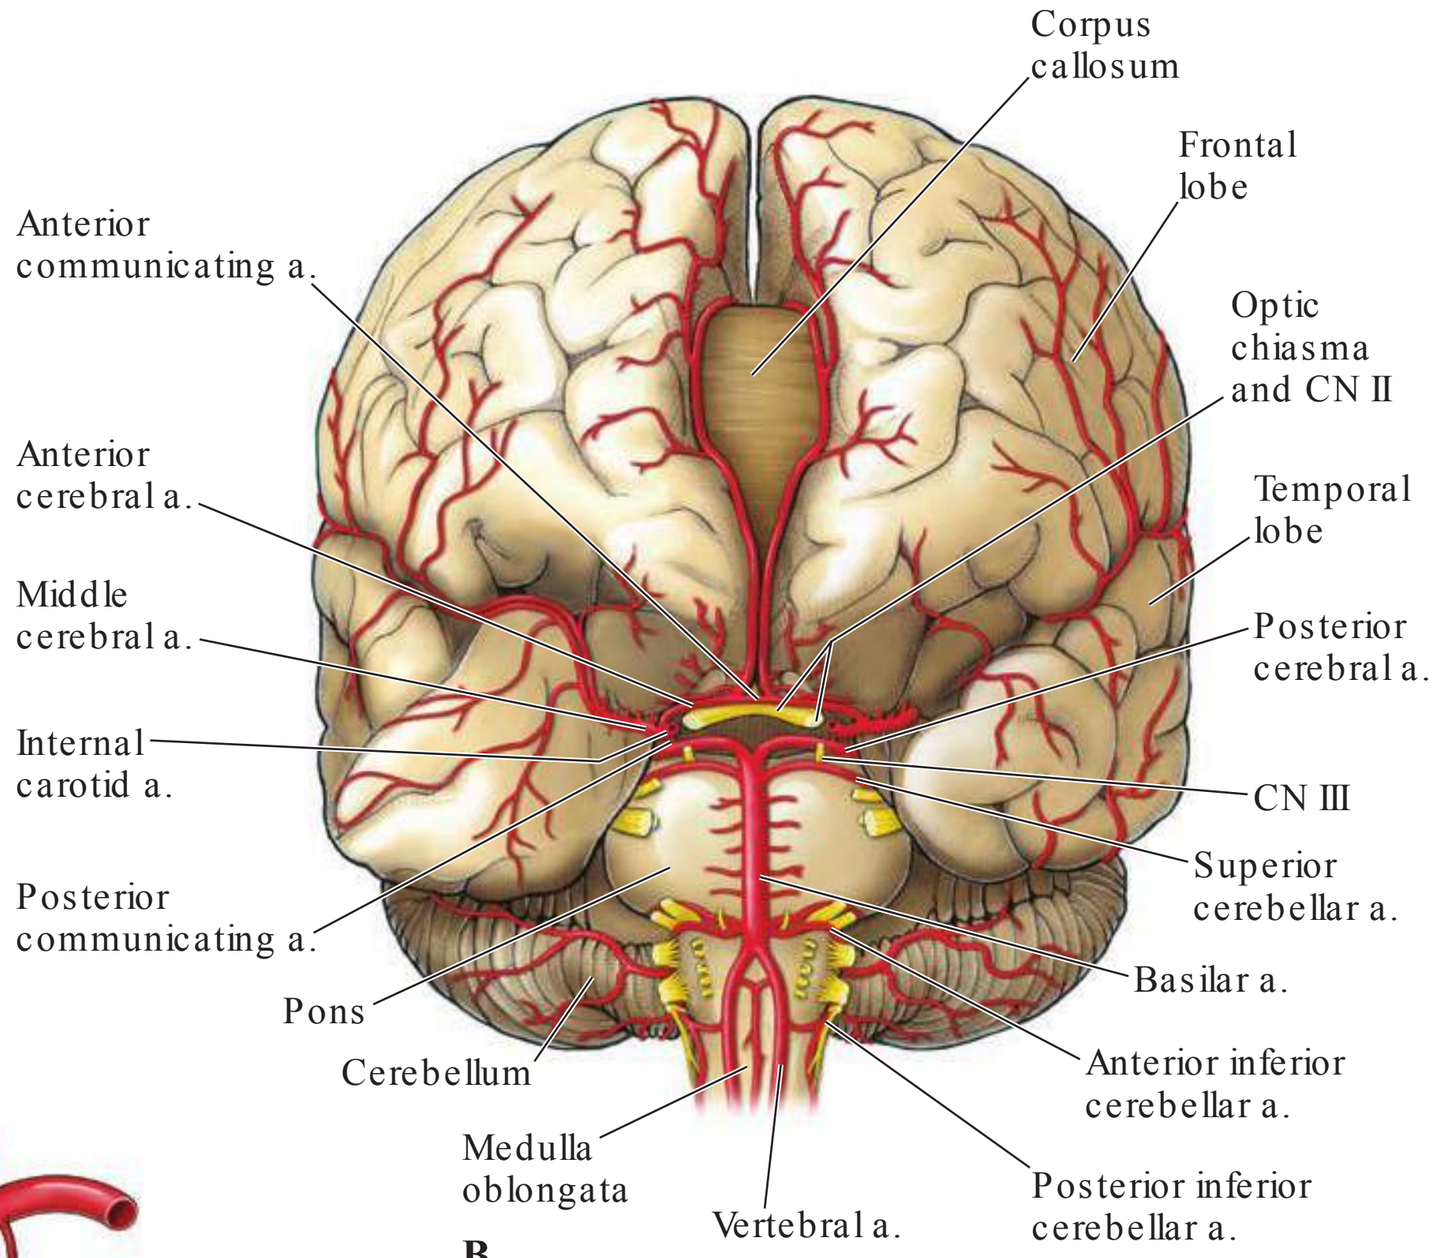
This portion runs from the origin of the artery to its point of entry to the cervical spine. The VA usually originates from the posterior surface of the subclavian artery, but it can also originate from the aortic arch and common carotid artery.[5]

The VA runs vertically, slightly medial, and posteriorly lateral to the longus colli and medial to the anterior scalene muscles to reach the transverse foramen of the lower cervical spine, although its exact direction is dependent on its exact point of origin. The artery's anomalous origin in this region has been suggested as a potential factor increasing the chance of blood flow compromise due to compression by the longus colli or scalene muscles.

In approximately 88% of individuals, the artery enters the transverse foramen of C6, but it has been shown to enter as far superior as the transverse foramen of C4.[6]



CLINICAL PEARL



Tortuosity and compression of this portion of the artery are common. The reasons for this can be congenital, muscular (resulting from compression by the longus colli and medial aspect of the anterior scalene), or a consequence of advancing years.

Transverse Portion

The second portion of the VA runs from the point of entry at the spinal column to the transverse foramen of C2 (Fig. 24-2). As already described, the origin of this part of the artery is typically at the C6 level, but this may vary between individuals and even from side to side in the same individual.

Throughout this section of the spinal column, the artery travels vertically in a true canal called the transverse canal (TC). The TC is formed by the bony transverse foramina at each spinal level and the overlying anterior and posterior intertransverse muscles, the scaleni, and the longus colli muscle. The dimension of the TC is proportionate to the diameter of the artery which itself is variable. Within the TC, the artery is surrounded by a periosteal sheath that is adherent to the boundaries of the canal and affords protection for the artery. However, the artery is in close proximity to the uncinate processes of each vertebral body on its medial

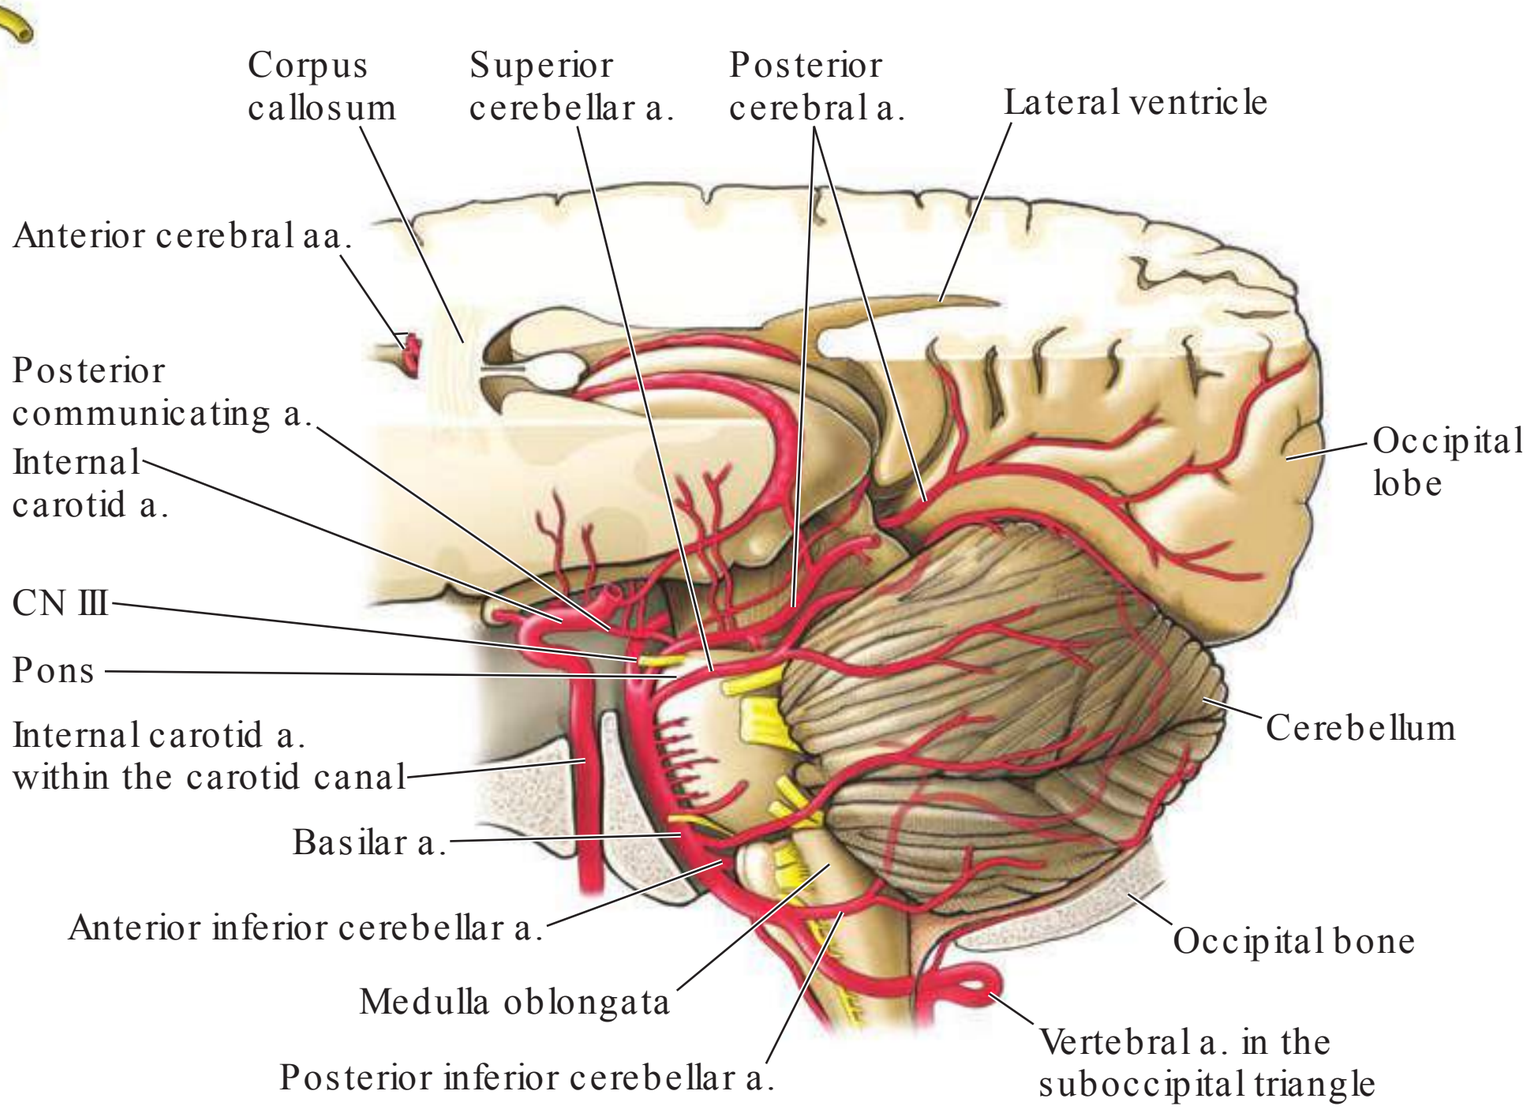


FIGURE 24-1 The vertebral artery and its relationship to the cranial arteries. (Reproduced, with permission, from Chapter 16. Brain. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

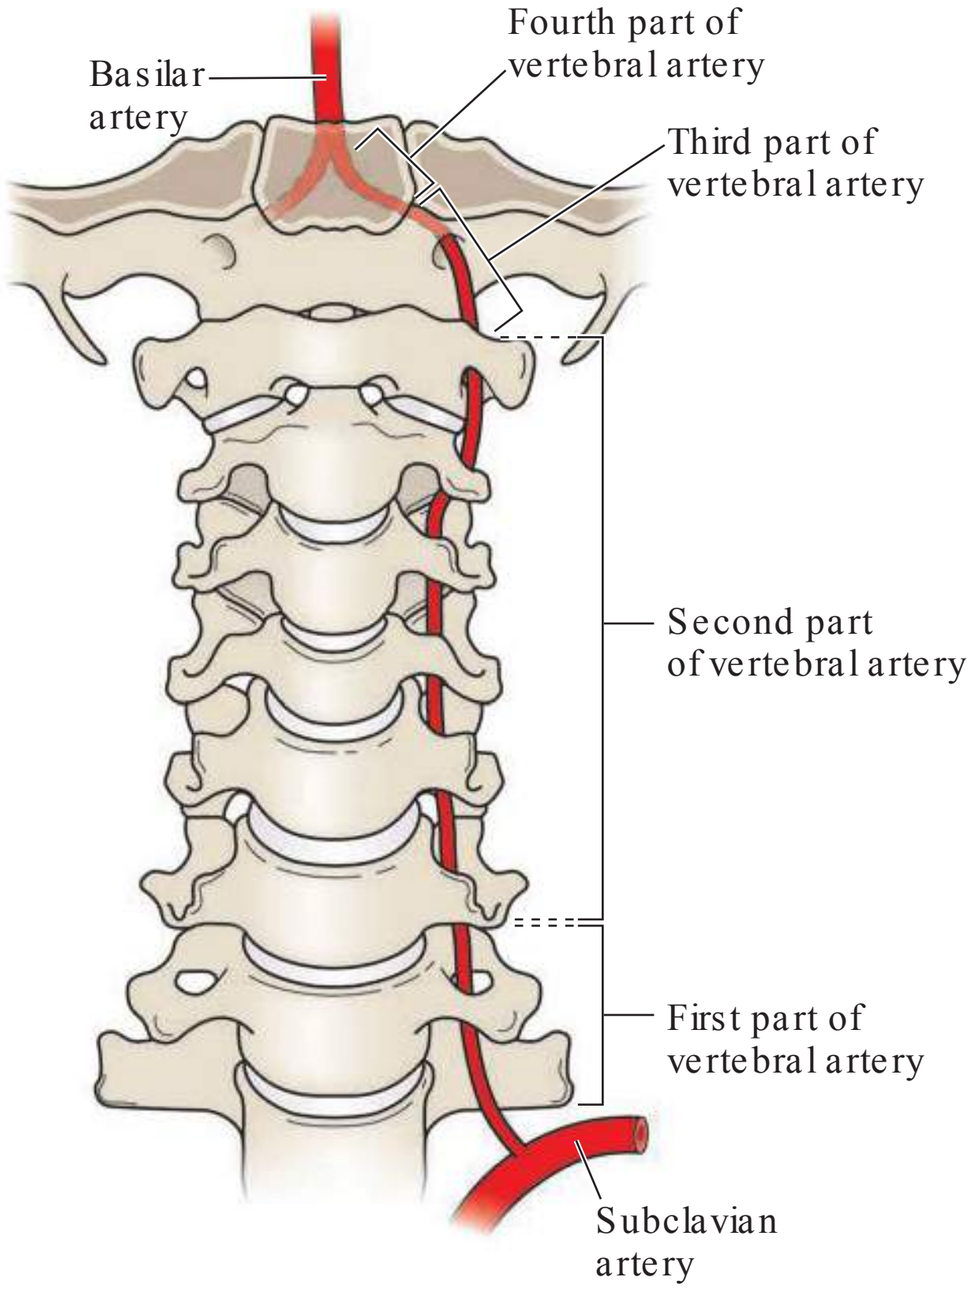

FIGURE 24-2 The left vertebral artery showing the four parts of its route.

aspect and is prone to compression from osteophyte formation or subluxation from the zygapophyseal joint.[4,7] The VA in the transverse foramen is also adjacent to the anterior spinal roots. Arterial enlargement by an intramural hematoma or a dissecting aneurysm may cause radiculopathy by compressing or stretching the spinal root.[8]

Anomalies in this portion of the artery, which can include looping within the intervertebral foramina, can occur because of an abnormal origin of the artery from the aorta.[9]

The proximal and suboccipital portions of the artery are more elastic and less muscular than the transverse part.[10] This variation is believed to be an adaptation to the greater mobility required in the proximal and transverse portions of the artery.

Suboccipital Portion

This portion of the artery extends from its exit at the axis (C2) to its point of penetration into the spinal canal. This portion can be further subdivided into four parts:

1. Within the transverse foramen of C2 (see Fig. 24-2). This portion lies in a complete bony canal formed by the two curves of the transverse foramen of C2. The inferior curve is almost vertical, whereas the superior curve is more horizontal and orientated laterally.
2. Between C2 and C1 (see Fig. 24-2). The second part runs vertically upward to the transverse foramen of C2. Throughout its journey, it is covered by the intertransversarii, the levator scapulae muscle, and the inferior oblique capitis muscle. Compression of the VA may occur in conditions in which these muscles have increased tone or loss of flexibility.[11] It is also at this level that the VA is subjected to the most mechanical stress, as more than 50% of cervical spine rotation occurs here.
3. In the transverse foramen of C1 (see Fig. 24-2). In its third part, the suboccipital portion of the VA bends posteriorly and medially in the transverse foramen of C1 in which it is completely enclosed.
4. Between the posterior arch of the atlas and its entry into the foramen magnum (see Fig. 24-2). On exiting from the transverse foramen of C1, the artery and the nerve of C1 wind behind the mass of the superior articular process of the atlas (C1) to cross the posterior arch of the atlas in a groove in which the artery is held by a restraining ligament. Anomalies in this portion of the artery include ossification of the restraining ligament of the atlantal groove, turning this into a complete bony tunnel. From the medial end of this groove, the artery runs forward, inward, and upward to pierce the posterior atlantooccipital membrane. The artery penetrates the dura mater on the lateral aspect of the foramen magnum about 1.5 cm lateral to the midline of the neck. This upper portion of the extracranial VA is relatively superficial and covered only by the trapezius, semispinalis capitis, and rectus capitis muscles. Having unyielding bone beneath it, and only muscles above, the artery is vulnerable to direct blunt trauma at this part of its course, whereas in the remainder of its course, it is threatened more by penetrating trauma or disease processes such as osteophytosis or atherosclerosis.[12,13]

Although the artery is affected by cervical motion in the lower cervical region, it is affected even more between C2 and the occipital bone.[14]

CLINICAL PEARL

The VA is most vulnerable to compression and stretching at the level of C1–2 because of the amount of cervical rotation that can occur at the atlantoaxial joint.[15]

In addition, because the transverse foramen of C1 is more lateral than that of C2, the artery must incline laterally between the two vertebrae. At this point, the artery is vulnerable to impingement from the following:

- Cervical extension at the craniovertebral joints, such as that which occurs with a forward head posture.[11]
- Excursion of the transverse mass of C1 during rotation. Approximately 50% of the cervical axial rotation occurs between C1 and C2; hence, there is a large excursion of the transverse mass of C1 with rotation. The artery is stretched during this process, and the size of the lumen can be reduced.[14,16] Any reduction in the size of the lumina is more profound in the presence of arterial disease.
- The atlantoaxial membrane. Ossification of this membrane can occur.

Intracranial Portion

This portion of the VA that runs from its penetration of the dura mater into the arachnoid space at the level of the foramen magnum to the formation of the basilar artery by the

midline union of the two arteries at the lower border of the pons (Fig. 24-1).

CLINICAL PEARL

The artery that is most vulnerable to a stretch injury during neck rotation is usually the one that is contralateral to the side of the rotation.[17,18] For example, the left artery is more vulnerable to rotation to the right. During right rotation, the left transverse foramen of C1 moves anteriorly and slightly to the right. This movement imparts a marked stretch on the left artery, and it increases the acuteness of the angle formed between its ascending and posteromedial courses.

After its penetration of the cranium, the VA inclines medially toward the medulla oblongata. It courses up the front of the medulla to reach the lower border of the pons, where the artery from each side unites with its partner to form the basilar artery. A major change in the structure of the VA occurs as it becomes intracranial.[4] The tunica adventitia and tunica media become thinner, and there is a gross reduction in the number of elastic fibers.[10] This decrease in elasticity can result in the distortion of the VA during cervical extension and rotation.[14,16,19]

CLINICAL PEARL

The intracranial portion of the artery is prone to mechanical obstructions including atherosclerotic plaques and stenosis.[11]

Branches

Intracranially, the VA first generates small meningeal branches that supply the bone and dura mater of the cerebellar fossa. It is possible that ischemia of these tissues, which occurs with VA occlusion, could be responsible for the suboccipital pain that often accompanies damage to the artery.[15]

Spinal Branches[8]

Each of the vertebral arteries gives off single branches (Fig. 24-1), which fuse to form the anterior spinal artery (ASA) that descends in the median anterior fissure and is additionally supplied by anterior radicular arteries (typically two to four). While the ASA is bilaterally derived, the anterior radicular arteries may arise exclusively or predominately from one VA. This helps to explain how a unilateral insufficiency of the VA may cause bilateral spinal cord infarction.

The paired posterior spinal arteries (PSAs) originate superiorly from the vertebral arteries or posterior inferior cerebellar arteries (PICAs). The PSAs are also supplied by posterior radicular arteries (usually two or three), which themselves arise exclusively or predominately from one VA, again demonstrating how a unilateral VA dissection can lead to bilateral spinal cord infarction. The PSAs supply the posterior one-fifth to one-quarter of the spinal cord including the posterior columns, the posterior (dorsal) horns, and parts of the corticospinal and spinothalamic tracts. The ASA is the exclusive arterial supply to the gray matter of the cord. The watershed area between the PSA and ASA encompasses the anterior (ventral) horns and part of the corticospinal and spinothalamic tracts.

Muscular Branches

The muscular branches arise from the suboccipital part of the artery as it winds around the superior articular process of the atlas. They supply the deep suboccipital muscles and anastomose with the occipital and cervical arteries.

Posterior Inferior Cerebellar Artery

The PICA (see Fig. 24-1) is the largest branch of the VA, usually being formed opposite to the medulla oblongata about 1 cm below the formation of the basilar artery. It supplies, either directly or indirectly, the medulla and the cerebellum and, via the PSAs, the posterior (dorsal) portion of the spinal cord.

CLINICAL PEARL

The term cervical arterial dysfunction (CAD) has been suggested for use when referring to arterial problems of the cervical spine as the term embraces both the completeness of the arterial anatomy (i.e., the vertebrobasilar system, internal carotid arteries, and the circle of Willis), and the range of pathologies that the clinician may encounter.[20]

Basilar Artery

The formation of the basilar artery at the lower border of the pons marks the termination of the VA. The basilar artery runs in a fissure on the anterior surface of the pons (see Fig. 24-1). Directly and indirectly, the basilar artery supplies the pons, the visual area of the occipital lobe, the membranous labyrinth, the medulla, the temporal lobe, the posterior thalamus, and the cerebellum.

Collateral Circulation

Fortunately, there is an inherent redundancy in the vascular supply to the brain. The posterior and anterior vessels, and the vessels stemming from the internal carotid arteries form an anastomotic network via the circle of Willis. Thus, occlusion of the left VA may be compensated for by perfusion of the right VA, the occipital artery, the ascending and deep cervical arteries, and the internal carotid arteries.[21,22] In fact, there is evidence that suggests that blood flow velocity and blood flow volume can increase in the arteries to compensate for occlusion in another vessel.[23] It is worth considering that palpation of the carotid pulse would give the clinician information regarding the ability of the carotid to perform its normal function, and if the pulse appears excessively strong, this could be an indication that the carotid artery is compensating for loss of VA flow.[24,25]

VERTEBROBASILAR INSUFFICIENCY

Damage and occlusion of the VA are felt to occur because of the close proximity of the VA and the bony and ligamentous structures of the cervical spine.[26] Trauma to this area may lead to thrombosis, dissection, transection, transmural

hematoma, pseudoaneurysm, and spasm of the VA. VA insuf ciency may also occur because of atherosclerotic involvement of the artery, sickle cell disease (see Chapter 5), rheumatoid arthritis, arterial fibroplasia, an arteriovenous fistula, and a number of congenital syndromes.

Whatever the cause of VA compromise, the diagnosis requires a high index of suspicion for prompt recognition and intervention. Vertebrobasilar insuf ciency (VBI) is associated with signs and symptoms of focal neurologic compromise that are of sudden onset and brief duration and relate to the specific areas that are normally supplied by the vessels.

Occlusion

T e VA is subject to occlusion from external and internal causes.

External Causes

Extracranial Compression

Extracranial compression of the VA may cause neurologic symptoms depending on the acuteness of the occlusion or the presence of underlying pathologic conditions such as atherosclerosis, sickle cell disease, fibromuscular dysplasia, rheumatoid arthritis, or osteogenesis imperfecta.

Many blood flow studies have demonstrated a reduction in blood flow in the contralateral VA during cervical rotation.[27–30] Other studies, however, have found no change in blood flow.[31,32]

What is known is that the greatest mechanical stress affecting the contralateral artery occurs at a position of cervical rotation and extension. Furthermore, if this position is sustained, the arterial flow takes longer to return to normal.[32]

In addition to the C1–2 portion, the VA is vulnerable to compression in the portion that courses through the transverse foramen from C6 to C1. Because of its fixation to the spine in this segment, subluxations of one vertebral body on another may exert undue tension and traction on the artery. Positions of the cervical spine can cause compression of the VA.[19,33] Rotation–extension–traction appears to be the most stressful, followed by rotation–extension, rotation alone, side flexion alone, extension alone, and then flexion.[19,33,34]

If the main restraint to atlantoaxial rotation, the alar ligament, is ruptured, then the degree of C1–2 rotation has been shown to increase by 30%.[35] Insuf ciency of the alar ligament has been shown to follow a rear-end collision in motor vehicle accidents, and it may also exist because of a congenital defect of the dens.[36] Other contributing factors to the preponderance of lesions occurring at the second cervical joint level are the fixation of the periosteal sheath of the artery to the dura mater, the superficiality of the artery in this region, and the hard neural arch beneath the artery.

CLINICAL PEARL

Beauty parlor stroke syndrome—an episode of VBA insufficiency with cerebellar infarction caused by neck hyperextension in a hairdressing salon—was first described by Weintraub in 1993.[37] Since then, various authors have reported similar cases.[38,39] The position of neck hyperextension occurs as the patron has a shampoo treatment in the beauty parlor sink. Because this syndrome is not recognized widely, a careful history is necessary for the presence of symptoms such as those described. Such symptoms are often thought to be nonspecific and might be attributed to neurosis, psychogenic headache, or menopause, particularly when imaging studies do not show specific findings. Routine radiography, computed tomography, and magnetic resonance imaging studies usually do not help to identify lesions in this syndrome. Special care is, therefore, necessary to evaluate the clinical findings during the examination of the nervous and auditory systems. The most likely pathophysiologic mechanism of the beauty parlor stroke syndrome is stenosis of the VA caused by compression at the atlantooccipital junction. This compression leads to damage of the intima, thrombus formation, stenosis of the artery by fibrosis, or embolism followed by infarction of the brainstem or cerebellum.

Unilateral occlusion of the VA rarely results in a neurologic deficit because of the collateral supply through the contralateral vertebral and PICAs.[40]

CLINICAL PEARL

The most common mechanism for a nonpenetrating trauma injury to the VA, is a hyperextension of the neck, with or without rotation, or cervical side fexion.[41,42] These motions can result in a stretching and tearing of the intima and media, especially at the points where the artery is tethered to a bone.[43,44]

After the primary tear of the intima, blood flows into the arterial wall between the intima and the media causing intramural hematoma and thickening of the vessel wall. Subintimal hemorrhage can produce various degrees of stenosis; subadventitial hemorrhage can cause a pseudoaneurysm. Tearing of the artery is not always related to remarkable trauma, and so this aspect may not appear in the history unless the symptoms appear immediately following the injury. T e presence of a pseudoaneurysm has been a commonly noted angiographic feature following sudden head and neck movements. In this injury, the two internal coats of the VA are torn from the tunica adventitia, which under the influence of arterial pressure slowly balloons out and sometimes ruptures.

CLINICAL PEARL

Even in the absence of underlying trauma, cervical rotation (approximately 20 degrees) and extension (approximately 20 degrees) have been shown to reduce the lumen of the VA to the point where blood fow is compromised to the point of almost nonexistence.[45] An underlying pathology may, therefore, be quiescent, and the patient may not complain of vascular like symptoms prior to an infarction except with specific movements.[46]

Extracranial Dissection

Extracranial VA dissection (vertebrobasilar infarction) is recognized with increasing frequency as a cause of stroke, and

spontaneous dissections of the carotid and vertebral arteries are well-recognized causes of stroke in young and middle-aged adults.[47–50] Traumatic dissection can also occur in the extracranial part of the internal carotid arteries, often after only moderate blunt trauma.[51]

Postmortem studies have shown that neurologic deficits, or even death, have followed posterior neck injuries by up to 8 days after the accident.[52,53] T e most common clinical findings are brainstem or cerebellar ischemic symptoms preceded by severe neck pain, occipital headache, or both. Occasionally, these patients report radicular symptoms.[48]

Spinal manipulation, in particular manipulation of the upper spine, has been associated with serious adverse occurrences, including dissection of the vertebral[54] and internal carotid artery,[55] resulting in strokes[56] and death.[57] However, the evidence implicating cervical manipulations with these serious consequences is conflicting, especially in light of the fact that even normal neck movements have been associated with spontaneous dissections. T e reciprocal finding of increased blood flow through the carotid artery during VA occlusion was made by Stern,[58] who demonstrated that the flow rate in the contralateral carotid artery increased by one and a half to two times with experimental occlusion of the VA. T ese alterations in the flow rates following an occlusion of the parallel artery serve as an apparent safety mechanism and may explain why more patients are not injured during cervical manipulation.

CLINICAL PEARL

The potential risk of a VBA dissection after manipulation is reported to be somewhere between 1 in 1.3 million treatment sessions[59] to 1 in 400,000 manipulations.[60] The clinicians involved in such instances have stated that the patient's prognosis is greatly enhanced if they can be treated by anticoagulant therapy quickly enough.[24] This requires that the manipulative clinician is totally familiar with the signs and symptoms of VBA damage.

Frisoni and Anzola[61] concluded that VA dissection at the atlantoaxial joint with an intimal tear, intramural bleeding, or pseudoaneurysm leading to thrombosis or embolism was the mechanism for VBI when associated with chiropractic manipulation. T e same study found that possible risk factors for VBI after neck motion are VA size asymmetry, anomalous course of VA, atherosclerosis, osteoarthritis, and vertebral ligament laxity.[61] However, despite the reports of 115 cases of cerebrovascular accidents after manipulation in English language publications during the period of 1966–1998 (198 articles), there is virtually no detailed information on the magnitude of forces that were exerted or the type of procedure used. It has even been suggested that, in many cases, cervical manipulation may have been administered to patients who already had a spontaneous dissection in progress.[62]

CLINICAL PEARL

It is the responsibility of all healthcare providers who use cervical manipulation to be cognizant of the potential adverse consequences.

Internal Causes

Atherosclerosis and Thrombosis

Atherosclerosis of the extracranial part of the VA primarily affects the proximal and transverse portions, leaving the suboccipital part relatively free. Atherosclerosis in the transverse portion of the artery occurs at any level between C2 and C6 and tends to occur at levels of the artery opposite osteophytic spurs. Castaigne et al.[63] investigated 44 patients with VBA occlusions and found that the cause in almost 90% of cases was atherosclerosis, mostly affecting the proximal and intracranial portions of the artery. Approximately 40% of the patients in this study had concomitant carotid stenosis.

Atherosclerosis may, as with any other artery, produce signs and symptoms resulting from ischemia of the tissues supplied by the artery distal to the occlusion. However, if the contralateral artery is not occluded and is of good caliber, the condition may be asymptomatic.

T rombosis can occur at any level of the VA but is more common in the suboccipital and intracranial portions than in the transverse part.[64]

Arterial Fibrodysplasia

T is condition is a nonatheromatous, noninflammatory segmental angiopathy of unknown etiology. It occurs in less than 1% of all patients receiving cerebral angiograms, but it is the third most frequent structural lesion affecting the VA following atherosclerosis and dissection.[65] Arterial fibrodysplasia is believed to be hereditary, affecting mainly young and middle-aged female patients.

Klippel–Trenaunay Syndrome

Klippel–Trenaunay syndrome consists of a constellation of anomalies including capillary malformation, varicose veins or venous malformations, and hypertrophy of both bony and soft tissues primarily involving limbs and to a much lesser degree, intraabdominal, thoracic, or facial structures.[66,67] T e vascular abnormalities commonly occur in the lower extremity but have been observed in other areas as well (head, neck, buttocks, abdomen, chest, and oral cavity).[67] Klippel–Trenaunay syndrome is theorized to result from a mesodermal abnormality.[68] T e syndrome is diagnosed on the basis of the presence of any two of the three aforementioned features, and any intervention is based on the severity of these features.

Arteriovenous Fistulas

An arteriovenous fistula is an abnormal communication between the extracranial VA, or one of its muscular or radicular branches, and an adjacent vein. It has variable causes, including traumatic dissections or dissecting aneurysms, and may occur spontaneously as a result of the existing disease, such as fibromuscular dysplasia, or as a congenital condition. Most spontaneous arteriovenous fistulas occur at the level of C2–3 and come directly from the VA through what is believed to be a tiny rupture in the wall of the artery.[69,70] Although rare, progressive myelopathy from an intracranial arteriovenous fistula can occur.[71] In these cases, endovascular embolization, either alone or followed by surgery, is the intervention of choice.

The Clinical Manifestations of Vertebrobasilar Insufficiency

The clinical manifestations of VBI are difficult to distinguish from other causes of brainstem ischemia (see later) and can include any or all of the following: dizziness, visual disturbance, drop attacks (a sudden loss of postural tone without loss of consciousness), ataxia, dysarthria, dysphagia, hemiplegia, hemianesthesia, nausea, and ringing in the ears. Indeed, no single consistent pattern of neurologic signs and symptoms is pathognomonic for VA insufficiency. The most common presenting symptoms are vertigo, nausea, and headache that can be subtle, intermittent, and even chronic in nature.[11,72–74]

CLINICAL PEARL

Terret[75] proposed the following mnemonic for the signs and symptoms associated with VBI: five D's and 3 N's

- Dizziness
- Drop attacks
- Diplopia
- Dysarthria
- Dysphagia
- Ataxia of gait
- Nausea
- Numbness
- Nystagmus

Vertigo

Vertigo or dizziness is a commonly reported symptom in the physical therapy clinic.[11,73,74] Owing to the different areas of the brain that the VA and its branching arteries supply, dizziness, although the most common and usual symptom of VBI, is rarely an isolated symptom, especially in advanced stages of the condition. Tatlow and Bammer[16] proved that the cause of vertigo in patients with VBI was cervical rather than vestibular. This was accomplished by placing symptomatic patients into a Stryker bed to determine whether the vertigo symptoms were being elicited by the movement of the entire body or by the movement of the head relative to the torso. Each patient who was secured within the Stryker bed had the entire body rotated up to a full 360 degrees en bloc (without movement of the head and neck relative to the torso), and the patients reported no symptoms. However, when the torso was fixed in a still position but the head and neck was moved relative to the torso, symptoms were reproduced.

Nausea

Nausea is the accompanying symptom for many different conditions including VBI.

Headache

The headache associated with VBI is typically a unilateral occipital headache with associated vertigo and nausea.[43] The pain is usually sharp and acute in its onset located on the same side as the insufficiency.

In addition to those signs and symptoms already mentioned, the following have also been linked, both directly and indirectly, to VBI[43,76,77]:

- Wallenberg, Horner, and similar syndromes
- Bilateral or quadrilateral paresthesia
- Hemiparesthesia
- Scotoma (a permanent or temporary area of depressed or absent vision)
- Periodic loss of consciousness
- Lip/perioral anesthesia
- Hemifacial paralysis/anesthesia
- Hyperreflexia
- Positive Babinski, Hoffman, or Oppenheim signs
- Clonus
- Gait ataxia
- Dysphasia

Clinicians need to be aware of these signs and symptoms and consider VA dissection early in the differential diagnosis because of the potential devastating neurologic consequences and to decrease morbidity and mortality.[43]

Subclavian Steal Syndrome

The subclavian steal syndrome involves a proximal subclavian artery obstruction and reversed vertebral flow with resultant siphoning of blood from the brain and cerebrovascular symptoms.[78–80]

The subclavian steal syndrome can produce cerebral symptoms such as a "drop attack."[81] A headache, dizziness, and vertigo can occur while walking and turning the neck to look to the side or up.[82]

Imaging Studies

Conventional angiography has long been the gold standard in the diagnosis of arterial and venous pathology in the neck. Angiography can show the arterial lumen and allows extensive characterization of dissections of the carotid and vertebral arteries.[83] VA angiography is not, however, without risk. Magnetic resonance angiographic (MRA) techniques are less invasive and are supplanting conventional angiography as the gold standard in the diagnosis of dissections of the carotid and vertebral arteries. MRA is highly sensitive and specific in identifying stenoses and occlusions and can show the intramural hematoma itself.[84]

Ultrasonographic techniques are useful in the initial assessment of patients who are thought to have a dissection of the carotid artery.[85] Doppler sonography allows a direct visualization of the vascular tree while assessing blood flow velocity and pressure waveforms. Although the site of dissection generally is not seen, an abnormal pattern of flow is identified in more than 90% of patients.[85]

Physical Therapy Examination of the Vertebral Artery

Screening procedures to identify patients at risk for VBI prior to manual therapy interventions have been widely advocated

and routinely used by physical therapists for many years, being first described by Maitland in 1968.[86] It is widely recognized that passive therapeutic maneuvers applied to the cervical spine carry a small risk of developing iatrogenic stroke. T is is especially pertinent with regard to cervical manipulations (high-velocity thrust or grade V techniques). It is therefore generally advised that all patients with neck pain receive a subjective screening examination for VBI and be evaluated for their ability to perform active neck movements.[87] T e initial test consists of having the patient rotate the head to each side while in the sitting position. T e longus colli and scalene muscles rotate the cervical spine and can squeeze the VA on the side contralateral to the rotation.[11] T e presence of muscular compression of the artery can be further tested by combining cervical flexion with rotation to place the inferior oblique capitis on stretch.[11] If dizziness is provoked by rotation, it is sometimes possible to implicate or exclude the vestibular apparatus of the inner ear as the source of dizziness.[88] In a standing position, the clinician holds the patient's head steady as the patient turns the trunk while keeping the feet fixed, thus producing sustained end-range cervical spine rotation.[89] Because the semicircular canal fluid is not disturbed by this test, a positive response theoretically excludes the labyrinth of the inner ear.[88]

CLINICAL PEARL

Following positive responses in the history or initial test, the patient must be handled very carefully and further intervention, particularly manipulation of the cervical spine, should not be delivered. The patient should not, under any circumstance, be allowed to leave the clinic until his or her physician has been contacted, and until the necessary arrangements have been made for the safe transport of the patient to an appropriate facility.

T ose patients who demonstrate symptoms associated with VBI should certainly be referred for further investigation. T eoretically, patients with a negative subjective history and negative findings with the initial test should undergo additional passive physical examination procedures in the form of stress tests for the vertebrobasilar system to further assess the potential for VBI.[90] Traditionally, this has involved the use of manual premanipulative tests to determine the appropriateness of a grade V technique.

In those cases in which the clinician is to perform cervical mobilizations of grades I–IV rather than a grade V thrust technique, the Australian Physiotherapy Association's Protocol for Premanipulative Testing of the Cervical Spine continues to be recommended, although this cannot be viewed as a prescriptive guideline.[87] T e protocol recommends that the clinician should maintain the immediate premobilization position for a minimum of 10 seconds to test the patency of the vertebrobasilar system. Others recommend assessing the patient's responses for a further 10 seconds to note any latent response.[17,40] Clinical testing of the VA should stop once positive signs or symptoms are noted. T roughout the tests, the clinician should observe the patient's eyes for possible nystagmus or changes in pupil size and should have the patient count backward to assess his or her quality of speech. T e patient is asked to report any changes in symptoms, however, insignificant he or she may feel the changes to be.

Unfortunately, it is not clear how sensitive these premanipulative protocols are.[88,91] For example, studies by Haynes[92] and Cote et al.,[93] the latter of which found these protocols to have poor prediction value. Other studies have shown that the results of these tests are inconsistent[94] and inaccurate, [95] suggesting that the VA tests have very little, if any, diagnostic value. In addition, many of these premanipulative screening protocols involve the same combination of positions that have been suspected of causing spontaneous arterial dissections (cervical extension and rotation).

CLINICAL PEARL

A positive VA test is one in which signs or symptoms change, especially if the changes evoked include those previously mentioned. More subtle examination findings can include a significant delay in verbal responses to questions of orientation with some inconsistency of answers; changes in pupil size; and nystagmus.[15]

Although one could argue that if the VA was damaged or compromised, the patient would surely have signs and/or symptoms indicating this, the logical question still becomes, "How does one proceed in the absence of certainty?"[90] It would seem extremely prudent to avoid cervical thrust techniques on a patient with any degree of uncertainty. Even in the absence of any symptoms, it would be wise to either introduce the application of incrementally greater movements and loads or investigate VA flow using Doppler sonography or an MRA scan before performing a grade V technique in the cervical spine.[96] In addition to the specific tests of blood flow, the clinician should use a combination of the patient's description of the symptoms and medical history, and those considerations in Table 24-1, before reaching a conclusion.[97] Alternatively, the clinician should consider avoiding placing the patient's cervical spine in the extremes of rotation and

TABLE 24-1 Nine Factors to Consider with Vertebral Artery Testing

1. Inherent redundancy of blood supply—collateral circulation
2. Morphology of the vertebral artery at the atlantoaxial level
3. Biomechanics of upper cervical spine—concurrent contralateral side bending with cervical rotation
4. The nonvascular causes of dizziness (cervicogenic dizziness and benign paroxysmal positional vertigo)
5. The amount of cervical rotation to be used
6. Medical history (transient ischemic attack, cerebrovascular accident, cardiac risk factors, cervical spondylosis)
7. Psychometric properties of vertebral artery testing (0% sensitivity)
8. Force to be applied
9. Potential risk of injury with manipulation (thrust, rotational techniques vs. nonthrust, nonrotational techniques)

Data from Vidal PG. Vertebral artery testing as a clinical screen for vertebrobasilar insufficiency: Is there any diagnostic value? Orthop Pract. 2004;16:7–12.

CLINICAL PEARL

Grade V techniques should never be performed when slow blood flow of the VA is displayed on neck Doppler sonography or MRA scan.[97]

side bending in both the examination and the subsequent intervention, which would obviate the need for these tests.

The following case study[45] illustrates the problems associated when encountering a patient with a VBA insufficiency.

CASE STUDY

62-YEAR-OLD FEMALE WITH COMPLAINTS OF DIZZINESS

HISTORY

A 62-year-old woman with no history of vertigo or dizziness reported to the clinic for her scheduled physical therapy session for cervical degenerative joint disease. During the course of conversation, the patient reported experiencing dizziness after a shampoo treatment of her hair at a hairdressing salon. She had visited her hairdresser earlier that day and reported severe vertigo, occipital pain, difficulty in standing, and a periodic numbness of the right arm and leg. The patient also reported hypesthesia in a glove-and-stocking type of distribution.

Tests and Measures

Most of the findings of the physical therapy examination were negative. Although muscle stretch reflexes and muscle power were normal, disturbances of equilibrium were noted and nystagmus was present.[94] Given the presence of the nystagmus, the patient was referred back to her physician for further testing.

Following MRA, a diagnosis was made of VBA insufficiency with cerebellar infarction caused by neck hyperextension in the hairdressing salon. The patient was treated conservatively with rest and medication, and the vertigo improved 1 week after injury, enabling the patient to walk without assistance.

CHAPTER 25

The Cervical Spine

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the anatomy of the vertebrae, ligaments, muscles, and blood and nerve supply that comprise the cervical intervertebral segment.
2. Describe the biomechanics of the cervical spine, including coupled movements, normal and abnormal joint barriers, kinesiology, and reactions to various stresses.
3. Perform a detailed objective examination of the cervical musculoskeletal system, including palpation of the articular and soft tissue structures, specific passive mobility tests, passive articular mobility tests, and stability tests.
4. Perform and interpret the results from combined motion testing.
5. Assess the static and dynamic postures of the cervical spine and implement the appropriate intervention.
6. Apply manual therapy techniques using the correct grade, intensity, direction, and duration.
7. Evaluate intervention effectiveness in order to progress or modify the intervention.
8. Plan an effective home program, including spinal care, and instruct the patient in this program.
9. Help the patient to develop self-reliant intervention strategies.

OVERVIEW

The cervical spine (Fig. 25-1), which consists of 37 joints, permits more motion than any other region of the spine. The majority of the anatomy of the cervical spine can be explained by reference to the functions that the head and neck perform on a daily basis. The head has to be able to perform extensive, detailed, and, at times, very quick motions during everyday tasks. These motions allow for precise positioning of the eyes and the ability to respond to a host of postural changes that result from stimulation of the vestibular system (see Chapter 3).[1] In addition to providing this amount of mobility, the cervical spine has to afford some protection to several vital structures, including the spinal cord and the vertebral and carotid arteries. However, with stability being sacrificed for mobility, the cervical spine is rendered more vulnerable to both direct and indirect trauma.[2]

Neck and upper extremity pain are common in the general population. Almost everyone experiences neck pain at some point in their life,[3] and approximately 54% of individuals have experienced neck pain within the last 6 months.[4] In the younger population, cervical pathology is most commonly due to a ligament sprain or muscle strain, whereas in the elderly cervical injuries are more commonly due to cervical spondylosis and/or spinal stenosis. Neck pain, which is characterized by episodes of exacerbation and recovery, has a large financial impact on a number of industrial countries.[5] Neck pain may also coexist with signs and symptoms of distal involvement, including pain radiating down the arms and weakness or numbness in the upper extremity.[6] Most individuals with cervical dysfunction are labeled as having nonspecific neck pain caused by a neuromuscular or articular dysfunction.[7]

ANATOMY

Anatomically and biomechanically, the cervical spine can be divided into three regions: craniovertebral (the upper two vertebrae), the cervical spine proper (vertebrae 3–6), and the cervicothoracic junction (the seventh cervical vertebra and the first thoracic vertebra). For the sake of simplicity, these units are described separately. The craniovertebral region is described in Chapter 23, while the remaining cervical vertebrae are described in this chapter.

Vertebrae

Compared with the rest of the spine, the vertebral bodies of the cervical spine are small and consist predominantly of trabecular (cancellous) bone.[1] The third to sixth cervical vertebrae can be considered typical, whereas the seventh is atypical. The third, fourth, and fifth vertebrae are almost identical,

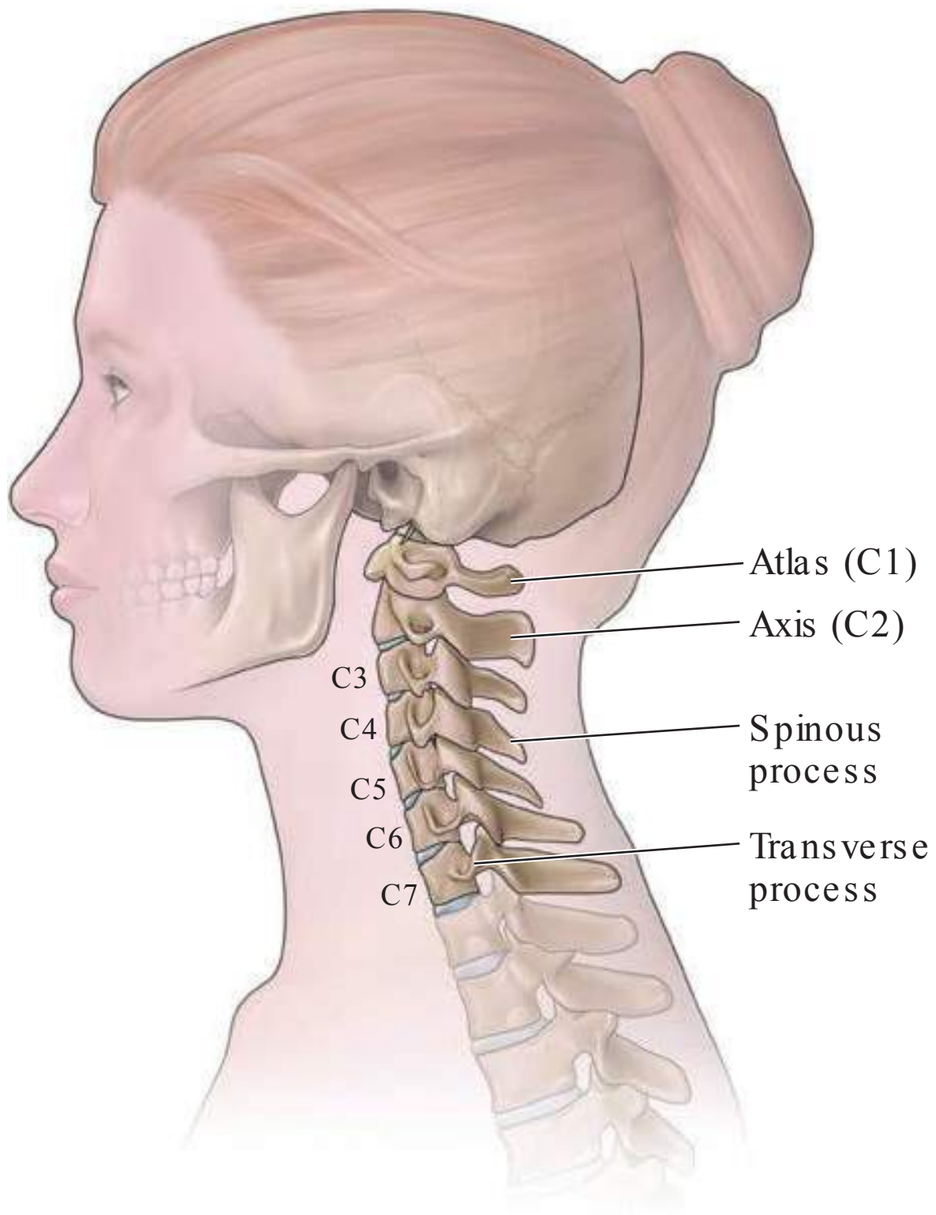

FIGURE 25-1 Cervical vertebra.

whereas the sixth has enough minor differences to distinguish it from the others.

The typical cervical vertebra has a larger transverse than anteroposterior dimension. The superior aspect of the centrum is concave transversely and convex anteroposteriorly, forming a sellar surface that reciprocates with the inferior surface of the centrum, superior to it.[1] The superior surface of the vertebral body is characterized by superiorly projecting processes on their superolateral aspects. Each of these hook-shaped processes is called an uncinate process and is composed of the raised lip of the superolateral aspect of the body, which articulates with a reciprocally curved surface at the synovial uncovertebral joint.

The transverse processes of vertebrae C3–6 are posterior and lateral to the transverse foramina, through which the vertebral artery, accessory vertebral vein, and the vertebral nerve all pass. Notable structural changes occur in the lower cervical vertebrae and include spinous processes that are more elongated, point inferiorly, and lose the characteristic bifid appearance of the cervical spine. The transverse processes are short and project anterolaterally and slightly inferiorly. The costotransverse and costovertebral articulations are found in the inferior aspect of the cervicothoracic region (see Chapter 27).

With the exception of the C2 vertebra (see Chapter 23), the superior aspect of the transverse process has a deep groove that mimics the orientation of the transverse process and the spinal nerve, both of which are parallel with the intervertebral foramen. The inferolateral orientation of the transverse process and the fact that the spinal nerves are firmly anchored in the groove make the nerves vulnerable to a stretch injury around the distal end of the transverse process.[1]

The articular pillars and zygapophyseal (facet) joints of vertebrae C2–7 are located approximately 1 inch lateral to the spinous processes. The articular pillar is formed by the superior and inferior articular processes of the zygapophyseal joint, which bulge laterally at the pedicle–lamina junction. The articular facets on the superior articular process are concave and face superolaterally to articulate with the reciprocally curved and orientated facet on the inferior articular process of the vertebra above. The articular pillars bear a significant proportion of axial loading.[8]

CLINICAL PEARL

The cervicothoracic junction (C7–T1) is located between the cervical spine with its great mobility and the limited motion of the superior thoracic spine.

- It is the area where the powerful muscles of the upper extremities and shoulder girdle insert.
- It is also the area through which the neurovascular structures of the upper extremities pass.

As in the rest of the spine, the pedicles and laminae form the neural arch, which encloses the vertebral foramen. The pedicles project backward and laterally, whereas the long, narrow laminae run posteriorly and medially, to terminate in a short bifid spinous process, which projects slightly inferiorly.[1] The seventh cervical vertebra varies from the typical cervical vertebra. In addition to possessing a much longer and monoid spinous process to which the ligamentum nuchae attaches, the seventh vertebra has wider transverse processes, no inferior uncinate facet, and no transverse foramen.

Intervertebral Disk

In the cervical spine, there are five disks, with the first disk being located between C2 and C3. The cervical disks (Fig. 25-2) are named after the vertebra above (C4 disk lies between C4 and C5). The anatomy of the cervical disk is distinctly different from that of the lumbar intervertebral disk (IVD). The cervical nucleus pulposus (NP) at birth constitutes no more than 25% of the entire disk, not 50% as in lumbar disks.[9]

The IVD height-to-vertebral body height ratio (2:5) is the greatest in the cervical spine, and the IVDs make up approximately 25% of the superior-to-inferior height of the cervical spine.[10] This increase in height ratio allows for the greatest possible range of motion. The NP sits in, or near, the center of the disk, lying slightly more posteriorly than anteriorly. The inferior surface of the cervical IVD is concave, and the inferior–anterior surface of the centrum projects downward to partly cover the anterior aspect. The anterior margin of the IVD is attached to the anterior longitudinal ligament (ALL). This surface can be palpated by the clinician and is often tender in the presence of intervertebral instability. The diskal margins of the posterior surface of the vertebral body give rise to the posterior longitudinal ligament (PLL).

CLINICAL PEARL

The cervical IVD and its development are distinctly different from that of the lumbar disk.

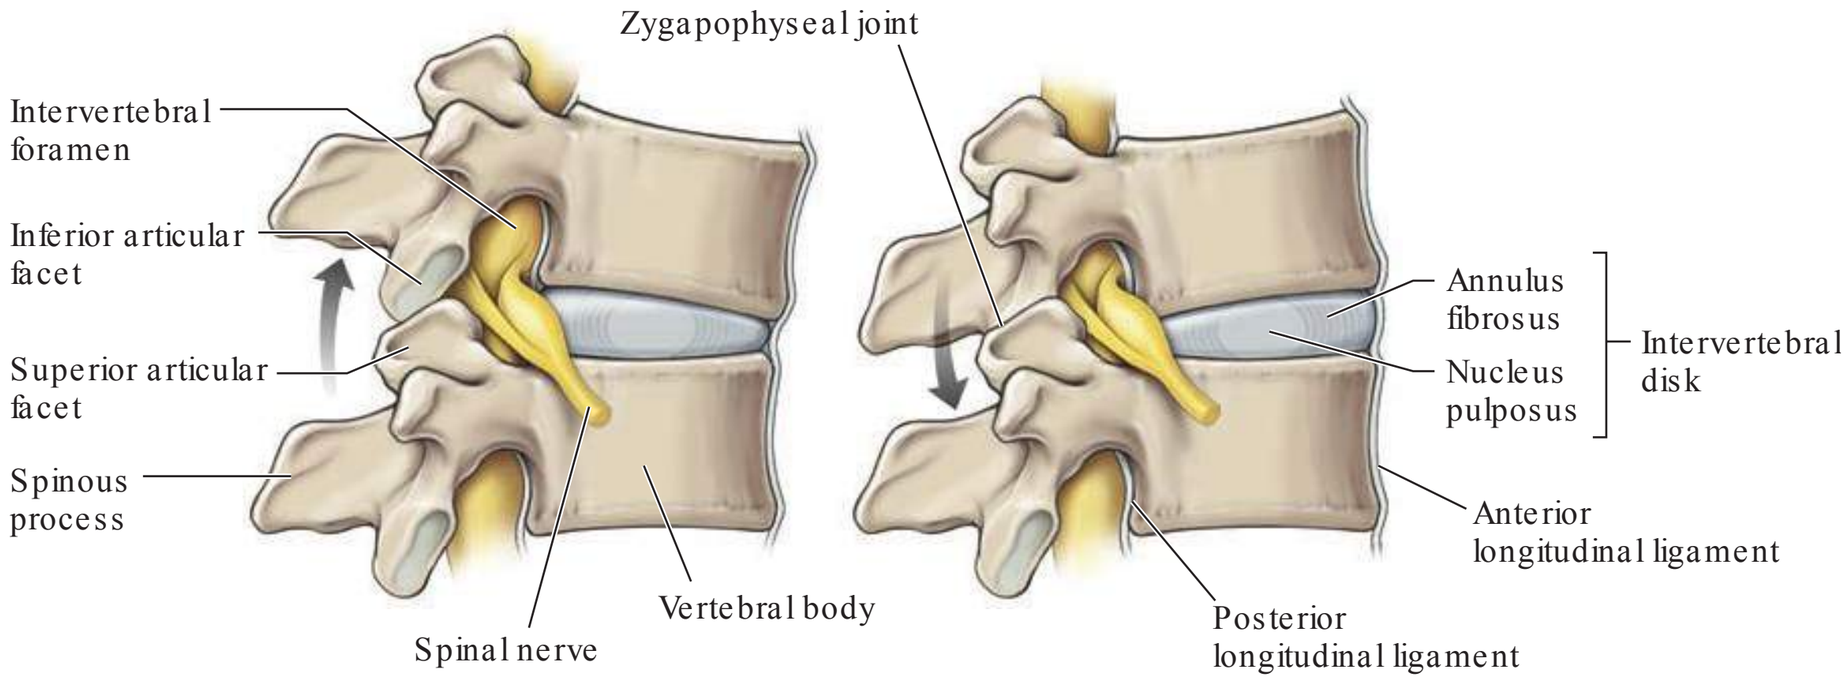

FIGURE 25-2 The intervertebral disk, articulations, ligaments, and neurologic structures. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

A number of features distinguish the cervical disk from the lumbar disk[11]:

- Anteriorly, the cervical annulus fibrosus (AF) consists of interwoven alar fibers, whereas posteriorly, the AF lacks any oblique fibers and consists exclusively of vertically orientated fibers.
- Essentially, the cervical AF has the structure of a dense anterior interosseous ligament, with few fibers to contain the NP posteriorly.
- In no region of the cervical AF do successive lamellae exhibit alternating orientations. In fact, only in the anterior portion of the AF—where obliquely orientated fibers, upward and medially, interweave with one another—does a cruciate pattern occur.
- Posterolaterally, the NP is contained only by the alar fibers of the PLL, under or through which the nuclear material must pass if it is to herniate. Further protection against disk herniation is afforded by the uncovertebral joints, which reinforce the posterolateral aspect of the IVD.
- The absence of an AF over the uncovertebral region. In this region, collagen fibers are torn during the first 7–15 years of life, leaving clefts that progressively extend across the back of the disk. Rather than an incidental age change, this disruption has been interpreted either as enabling[12] or resulting from[13] rotatory movements of the cervical vertebrae (see next section).
- Axial rotation of a typical cervical vertebra occurs around an oblique axis perpendicular to the plane of its facets.[13]

As in the rest of the spine, the cervical IVD functions as a closed but dynamic system, distributing the changes in pressure equally to all components of the container (i.e., the end plates and the AF) and across the surface of the vertebral body. It has been observed that in the first and second decades of life, before complete ossification occurs, lateral tears occur in the AF, most probably induced by the motion of the cervical spine in the bipedal posture.[14] The tears in the lateral part of the disk tend to enlarge toward the medial aspect of the IVD. The development of such tears through both sides may result in a complete transverse splitting of the disk. Such a process can be observed in the second and third decades of life in the lower cervical spine when the IVD is split in the middle into equal halves.[14] With this aging process, the NP rapidly undergoes fibrosis such that, by the third decade, it is fibrocartilaginous in nature.[15] Almost everyone older than 40 years of age has evidence of cervical disk degeneration.[16] According to Töndury and Theiler,[17] in the fourth and fifth decades of life, the NP usually dries out, and acute extrusion is not expected then. This development can be visualized on conventional radiographs as a flattening of the uncovertebral processes and a narrowing of the IVD space.[18] This may lead to a loss of elasticity and increased stresses on the vertebral end plates.

These age-related changes are evident chemically and morphologically and are much more evident in the NP than in the AF. Degenerative disk disease (DDD) in this region results in diminished disk height, subjecting the bony elements to increased load.[10] The splitting of the IVD in the second and third decades of life may result in segmental instability.[14] Also, such splitting of the IVD can allow the NP to move toward the spinal canal, ultimately causing disk protrusion or extrusion and resulting in nerve root compression.[14]

In general, compression of the cervical nerve roots occurs at the entrance zone of the intervertebral foramina.[19] Anteriorly, compression of the nerve roots is likely caused by protruding disks and osteophytes of the uncovertebral region, whereas the superior articular process, the ligamentum flavum, and the periradicular fibrous tissues often affect the nerve posteriorly.[19–22] Osteophytes develop in response to this increased stress and from degenerative changes of the zygapophyseal and uncovertebral joints. The osteophytes effectively increase the available surface area and decrease the overall force on the end plates.[23] Radicular arteries within the dural root sleeves may become compressed by osteophytes, leading to spasm and decreased vascular perfusion.[23] In addition, venous obstruction may occur, resulting in edema and additional reduction in nerve root perfusion.[23]

The nerve root is divided into the anterior (ventral) and posterior (dorsal) roots (Fig. 25-2), which are responsible for motor and sensory functions, respectively. Ebraheim et al.[24] described the quantitative anatomy of the cervical nerve root groove and divided it into three zones: medial zone (pedicle), middle zone (vertebral artery foramen), and lateral zone. The medial zone of the cervical nerve root groove corresponds to the intervertebral

foramen, and this zone is believed to play an important role in the etiology of cervical radiculopathy.[19] T e intervertebral foramen, which can be further divided into an entrance zone (medial) and an exit zone (lateral), resembles a funnel in shape. T e entrance zone corresponds to the narrow part of the funnel, and the shape of the radicular sheath is conical, with its takeoff points from the central dural sac being the largest part.[19] Consequently, nerve root compression occurs mostly in the entrance zone of the intervertebral foramina. Whether compression of the anterior (ventral) roots, posterior (dorsal) roots, or both occurs depends on various anatomic structures around the nerve roots. Anteriorly, compression of the nerve roots is likely caused by protruding disks and osteophytes of the uncovertebral region, whereas the superior articular process, the ligamentum flavum, and the periradicular fibrous tissues ot en affect the nerve posteriorly.[19–22] Osteophytes may develop in response to this increased stress and form degenerative changes of the zygapophyseal and uncovertebral joints. T e osteophytes effectively increase the available surface area and decrease the overall force on the end plates.[23] Radicular arteries within the dural root sleeves may become compressed by osteophytes, leading to spasm and decreased vascular perfusion.[23] In addition, venous obstruction may occur, resulting in edema and additional reduction in nerve root perfusion.[23]

Articulations

T e structure of the cervical vertebrae, combined with the orientation of the zygapophyseal facets, provides very little bony stability, and the lax sot tissue restraints permit large excursions of motion.[1] A narrow space exists between the spinal cord and the vertebral canal walls in this region. T ere is also a very small amount of extra space in the intervertebral foramina. T us, a relatively small change in either the vertebral canal or the dimensions of the intervertebral foramen can result in significant compression of the spinal cord or the spinal nerve, respectively.[25]

Each pair of vertebrae in this region is connected by a number of articulations: a pair of zygapophyseal joints, two uncovertebral joints, and the IVD.

Zygapophyseal Joints

T ere are 14 zygapophyseal joints (Fig. 25-2) from the occiput to the first thoracic vertebra (C1–7). T ese joints are typical synovial joints and are covered with hyaline cartilage. T e articular facets are teardrop shaped, with the superior facet facing upward and posteriorly while the inferior one faces downward and anteriorly. In the middle to lower cervical regions, the dual requirements of stability and mobility are provisioned through zygapophyseal joints, with C5–6 contributing the greatest segmental mobility. T e average horizontal angle of the joint planes of the middle segments is approximately 45 degrees between the frontal and transverse planes[26,27] with the upper cervical levels being closer to 35 degrees, and the lower levels at approximately 65 degrees.

CLINICAL PEARL

Clinically, the orientation of the zygapophyseal joint planes can be thought of as passing through the patient's nose.

T e orientation of the zygapophyseal joint planes in the midcervical spine permits considerable flexibility in the motions of flexion and extension and encourages the coupling motions of rotation and side bending to the same side in the upper segments (see Chapter 22). However, the more caudal segments approaching the cervicothoracic junction show a tendency for a smaller range of motion—it is here that axial loading is higher, and the segmental mobility becomes markedly diminished as the thoracic cage commences.[28]

T e anterior joint capsule is strong, but it is lax in neutral and extension.[29] T e posterior capsule is thin and weak. T is laxity allows for translation between facets. T e major constraints and supports of these joints are the ligaments of the vertebral column and the IVD.

Vascular, fat-filled, synovial intra-articular inclusions[30] have been observed in these joints. T ese structures have been described as fibroadipose meniscoids, synovial folds, and capsular rims. T e meniscoids consist of connective and fatty tissue that is highly vascularized and innervated.[14] In the cervical spine, the meniscoids function as space fillers for the uneven articular surfaces, especially in regions where the elasticity of the relatively thin cartilage is not suf cient.[14] T ese inclusions, which are theorized to play some role in protecting the articular surfaces as they are sucked in or expelled during movements, are prone to entrapment and can play a potential role in intra-articular fibrosis and cervical spine pain.[31] Töndury and T eiler[17] have observed that the meniscoids atrophy and virtually disappear with increasing age.

T e zygapophyseal joint receives its nerve supply from the medial branches of the posterior cervical rami from C2 to C8 and the recurrent meningeal (sinuvertebral) nerve. T e recurrent meningeal (sinuvertebral) nerve also innervates the anterior dural sac, the posterior AF, and the PLL. T e capsular pattern of the zygapophyseal joint is a limitation of extension and equal loss of rotation and side bending, with flexion being unaffected.

Uncovertebral Joints

From C3 to T1, there usually are a total of 10 saddle-shaped, diarthrodial articulations. T ese articulations, known as joints *of* Luschka, uncinate processes, or uncovertebral joints, are formed between the uncinate process found on the lateral aspect of the superior surface of the inferior vertebra and the beveled inferolateral aspect of the superior vertebra.[32] T e uncovertebral joints develop within the first 12 years of life, as a result of loading from the head, and become fully developed by about 33 years of age.[33,34] Two of these uncovertebral joints are found between each pair of adjacent vertebrae in the cervical spine proper (C2–3 to C6–7). T e uncovertebral joint maintains a synovial compartment and creates the posterior lateral border of the IVD.[35]

T e biomechanical role of the uncovertebral joint is thought to be that of a sagittally oriented guiding rail during cervical flexion and extension that acts to transfer rotation forces into side-bending and posterior translation motions.[32,36,37] T is function is accomplished while simultaneously ensuring that the translation and, to some extent, the side bending (lateral flexion) between adjacent vertebral bodies are limited to the sagittal plane.[32,36,37] T is stabilizing feature develops and changes with age and is based on alterations in the uncinate processes.[38]

CLINICAL PEARL

The uncovertebral joints serve to

- guide cervical flexion and extension;
- reduce side bending of the cervical spine;
- prevent posterior translation of neighboring vertebrae;
- reinforce the posterolateral aspect of the IVD.

Penning and Wilmink[39] highlighted a possible correlation between uncovertebral joint configuration and the coupled cervical segmental motion of side bending and axial rotation. A more recent study of the C5–6 segment level by Clausen et al.[40] found that both the zygapophyseal joints and the uncovertebral joints are the major contributors to coupled motion in the lower cervical spine and that the uncinate processes effectively reduce motion coupling and primary cervical motion (motion in the same direction as load application), especially in response to axial rotation and side-bending loads.[40]

The onset of degenerative changes in the cervical spine has been shown to occur more commonly at the midcervical level than at the lower cervical level.[41] The reasons for the different degrees of involvement are not clear. The degenerative changes result in the substitution of a hinge-like motion, with the pivot point on the contralateral side, in place of the normal gliding motion at the uncovertebral joints.[1] This is alteration effectively transforms the cervical segment into a sellar joint.[17,39,42]

CLINICAL PEARL

With a loss of disk height as a result of degeneration or degradation of the IVD, the potential for repeated contact between the bony surfaces of the uncovertebral joint increases. This repetitive contact may result in hypertrophic changes in the bone in the form of osteophytes.[1]

The nerve roots in the midcervical level are more predisposed to osteophytic compression because of a combination of

- higher uncinate process;
- the smaller anteroposterior diameter of the intervertebral foramina;
- a longer course of nerve roots in close proximity to the uncovertebral joints at C4–6 levels;
- greatest segmental mobility at C5 and C6.

The vertebral artery may also be compromised in the degenerative cervical spondylotic process. When involved, the vertebral artery (see Chapter 24) is usually compromised at the level of the inferior aspect of the superior vertebra, where the apical posterolateral uncovertebral osteophytes are present.

Intervertebral Foramina

The intervertebral foramina are found between all vertebrae of the spine, except in the upper cervical spine. Although there are seven cervical vertebrae, there are eight intervertebral foramina. This is difference occurs because there is a nerve root existing between the occiput and the atlas (C1) that is designated to the C1 nerve root. The cervical intervertebral foramina are 4–5 mm long and 8–9 mm high. They extend obliquely anteriorly and inferiorly from the spinal canal at an angle of 45 degrees in the coronal plane.[43] The anterior boundary of the foramen is formed by the IVD and by portions of both vertebral bodies, with the zygapophyseal joints serving as the posterior boundaries. The pedicles form the superior and inferior boundaries. The medial to lateral depth of the posterior wall is formed by the lateral aspect of the ligamentum flavum.

The intervertebral foramina serve as the principal routes of entry and exit for the neurovascular systems to and from the vertebral canal. Within each foramen are

- a segmental mixed spinal nerve;
- from two to four recurrent meningeal nerves or sinuvertebral nerves;
- various spinal arteries;
- plexiform venous connections.

Because they contribute to the innervation of the upper limb, the lower cervical spinal nerves are quite large in diameter and nearly fill the foramina. This is region is vulnerable to narrowing with certain motions, or with osteophyte growth. The dimensions of the intervertebral foramina decrease with full extension and ipsilateral side bending of the cervical spine such that uncovertebral osteophytes may compress the nerve root and cervical cord posteriorly.

The spinal nerves also are in close proximity to both the ligamentum flavum and the zygapophyseal joint. Thus, zygapophyseal joint arthritis or a hypertrophic ligamentum flavum can cause posterior impingement of these nerves.

Vertebral Canal

In the cervical region, the vertebral canal contains the entire cervical part of the spinal cord, as well as the upper part of the first thoracic spinal cord segment. There are eight cervical spinal cord segments, and thus eight cervical spinal nerves (see Chapter 3) on each side, but only seven cervical vertebrae.

Ligaments

Both the function and the location of the ligaments in this region are similar to that of the rest of the spine. For the purposes of these descriptions, the short ligaments that interconnect the adjacent vertebrae are classified as segmental, whereas those that attach to the peripheral aspects of all of the vertebrae are classified as continuous.

Continuous Ligaments

Anterior Longitudinal Ligament. The ALL (Fig. 25-2) is a strong band, extending along the anterior surfaces of the vertebral bodies and IVDs, from the front of the sacrum to the anterior aspect of C2. The ALL is narrower in the upper cervical spine but is wider in the lower cervical spine than it is in the thoracic region. It is firmly attached to the superior and inferior end plates of the cervical vertebrae, but not to the cervical disks. At the waist of the centrum, the ligament thickens to fill in the concavity of the body. The ALL functions to

restrict spinal extension and is thus vulnerable to hyperextension trauma.

Posterior Longitudinal Ligament

Lying on the anterior aspect of the vertebral canal, the PLL extends from the sacrum to the body of the axis (C2), where it is continuous with the tectorial membrane (Fig. 25-2). T e PLL travels over the posterior aspect of the centrum, attaching to the superior and inferior margins of the body, but is separated from the waist of the body by a fat pad and the basivertebral veins. In addition, this ligament attaches firmly to the posterior aspect of the IVDs, laminae of hyaline cartilage, and adjacent margins of vertebral bodies. T e PLL is broader and considerably thicker in the cervical region than in the thoracic and lumbar regions.[44] T e PLL functions to prevent disk protrusions and also acts as a restraint to segmental flexion of the vertebral column.

T e dura mater is strongly adherent to the PLL at the level of C3 and higher, but this attachment diminishes at lower levels.

Ligamentum Nuchae (Nuchal Ligament)

T is bilaminar fibroelastic intermuscular septum spans the entire cervical spine, extending from the external occipital protuberance to the spinous process of the seventh cervical vertebra.[45] Some consider the ligament to be an extension or a replacement of the supraspinous and interspinous ligaments.[46,47] However, an observational study by Allia and Gorniak[48] suggests that it is a distinct ligamentous structure comprised of four portions formed by aponeurotic fibers from the trapezius, splenius capitis, rhomboid minor, and the serratus posterior superior.[47] T e ligament is described as being a strong, thick band of elastic tissue that aids in the suspension of the head and neck.[47] However, the function of the nuchal ligament is controversial. While Mercer[49] suggests that the only contribution of the ligament to stability is at C7 and the occiput, others have proposed that the ligament may play a more important role in cervical stability,[48,50] while still others have proposed that it many play a role in posterior dural stretching and cervicogenic headaches. Studies[47–49] have shown that when the occipitoatlantal joint is flexed, the superficial fibers of the ligament tighten and pull on the deep laminae and muscular attachments, which, in turn, pull the vertebrae posteriorly, limiting the anterior translation of flexion and, therefore, flexion itself.

Segmental Ligaments

T e interspinous ligaments are thin and almost membranous, interconnecting the spinous processes. T e ligament is poorly developed in the upper cervical spine but well developed in the lower.[44]

T e ligamentum flavum runs perpendicularly to the spine from C1 and C2, where it is referred to as the posterior atlantoaxial ligament, to L5 and S1. T is ligament connects the laminae of successive vertebrae, from the zygapophyseal joint to the root of the spinous process. It is formed by collagen and yellow elastic tissue and, therefore, differs from all other ligaments of the cervical spine. T e ligamentum flavum of the cervical spine is fairly long, allowing an appreciable amount of flexion to occur while maintaining tension when the head and neck are in neutral. Scarring or fatty infiltration to the ligament in this region can compromise the degree of elasticity, making the ligament lax, particularly with cervical extension. T is laxity increases the potential for the contents of the vertebral canal to be compressed by the buckling ligament.[51] Any enlargement of the ligament increases the likelihood that a spinal nerve or its posterior root will become impinged.[9] T e ligament appears to function as a restrictor of flexion of the neck.

Muscles

T e neck muscles are characteristically grouped in layers[52]:

- T e superficial layer consists of muscles that connect the skull and shoulder girdle and include the trapezius (Fig. 25-3) and sternocleidomastoid (SCM) (Fig. 25-3). Other superficial muscles, which connect the scapula with the vertebral column, include the levator scapulae and the rhomboids. T e scalene muscle group (Fig. 25-4) provides a relationship between the cervical spine and the first and second ribs.
- A deeper layer links the skull and vertebral column and includes long posterior (dorsal), splenius capitis (Fig. 25-5), semispinalis capitis, and longissimus capitis.
- T e deepest layers consist of muscles that link the cervical and thoracic vertebrae, splenius cervicis, semispinalis cervicis, and longissimus cervicis.

For the most part, the muscles of the neck function to support and move the head. Given the number of degrees of freedom available at the neck, it is likely that the muscles are organized as functional synergies. Muscle synergies are conceptualized as units of control, incorporating the muscles around the joint that will act together in a functional fashion.[52] Under this concept, the central nervous system (CNS) needs only trigger a synergic unit to produce a specific movement, instead of communicating with each individual muscle.[52] Synergistic movements incorporate both agonist and antagonist muscle groups, which results in a greater level of control.

Superficial Muscles

Trapezius

T e trapezius muscle (Fig. 25-3) is the most superficial back muscle. It is a flat triangular muscle that runs from the superior nuchal line and external occipital protuberance of the occipital bone to the spinous process of T12 and is the largest muscle attachment in the body. Its insertion can be traced from the entire superior aspect of the spine of the scapula, the medial aspect of the acromion, and the posterior aspect of the lateral third of the clavicle.

T is muscle is traditionally divided into middle, upper, and lower parts, according to anatomy and function.

- T e middle part originates from C7 and forms the cervicothoracic part of the muscle.
- T e lower part, attaching to the apex of the scapular spine, is relatively thin.

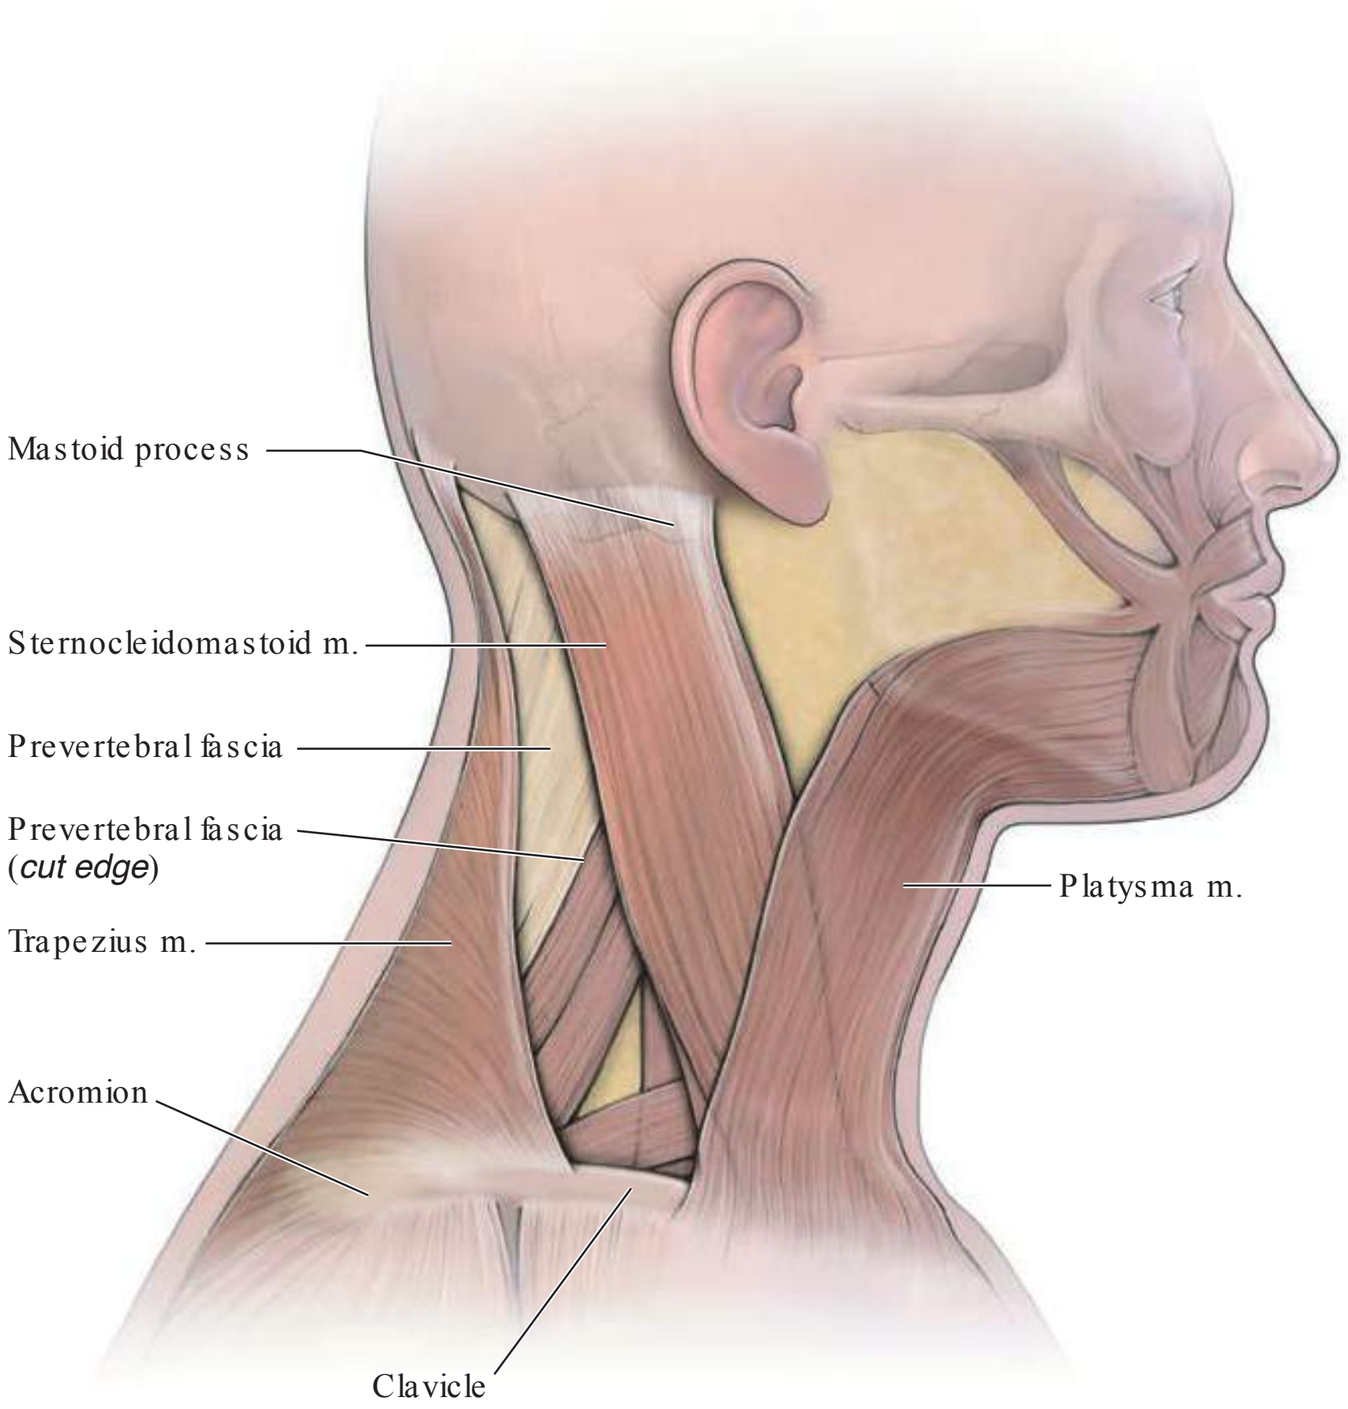

FIGURE 25-3 Muscles of the lateral and posterior cervical spine. (Reproduced, with permission, from Chapter 25. Overview of the Neck. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

The upper part (Table 25-1) is very thin, and yet it has the most mechanical and clinical importance to the cervical spine.[53]

The innervation of the trapezius comes from the accessory nerve (CN XI) and fibers from the anterior (ventral) rami of the third and fourth cervical spinal nerves, with the former being speculated to provide the motor innervation and the latter supplying the sensory information.[54–58] The greater occipital nerve occasionally travels through the trapezius near its superior border to reach the scalp and can become entrapped by an adaptive shortening of the upper trapezius muscle or be traumatized by a blunt force.[58–60]

The different parts of this muscle provide a variety of actions on the shoulder girdle, including elevation and retraction of the scapula. When the shoulder girdle is fixed, the trapezius can produce ipsilateral side bending and contralateral rotation of the head and neck. Working together, the trapezius muscles can produce symmetric extension of the neck and head.[61] In addition, the trapezius muscle can produce scapular adduction (all three parts), and upward rotation of the scapula (primarily the superior and inferior parts). The importance of the trapezius to the shoulder joint is discussed in Chapter 16.

Sternocleidomastoid

The SCM (Fig. 25-3) is a fusiform muscle that descends obliquely across the side of the neck, forming a distinct landmark for palpatory purposes. It is the largest muscle in the anterior neck. It is attached inferiorly by two heads, arising from the posterior aspect of the medial third of the clavicle and the manubrium of the sternum. From here, it passes superiorly and posteriorly to attach to the mastoid process of the temporal bone. The motor supply for this muscle is from the accessory nerve (CN XI), whereas the sensory innervation is supplied by the anterior (ventral) rami of C2 and C3.[62] This muscle can provide the clinician with information regarding the severity of symptoms, and postural impairments, because of its tendency to become prominent when hypertonic. The SCM is also involved with a condition called torticollis, a postural deformity of the neck (see Chapter 5 and later).

In broad terms, the actions of this muscle are flexion, side bending, and contralateral rotation of the head and neck.[61] The two muscles act together to draw the head forward and can also raise the head when the body is supine. This head-raising action is a combination of upper cervical extension and lower cervical flexion. The muscle is also active on resisted neck flexion. With the head fixed, it is also an accessory muscle of forced inspiration.

Levator Scapulae

The levator scapulae (Fig. 16-5) is a slender muscle attached by tendinous slips to the posterior tubercles of the transverse processes of the upper cervical vertebrae (C1–4). The levator,

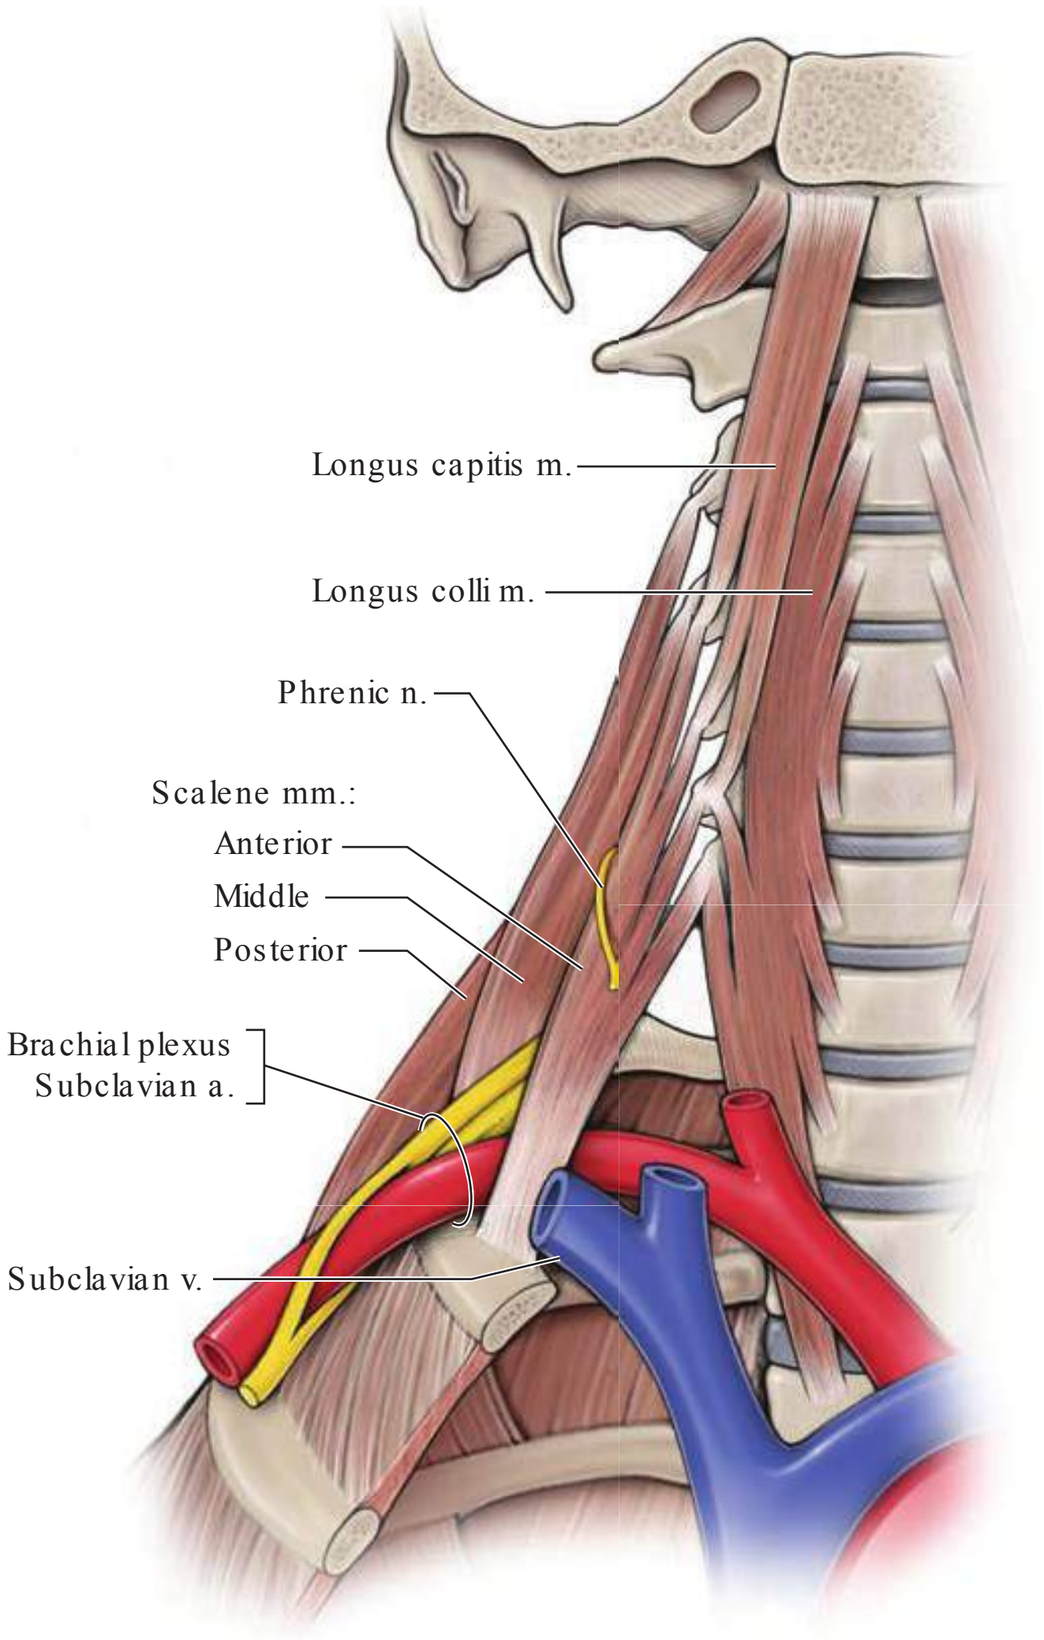

FIGURE 25-4 Muscles of the anterior cervical spine. (Reproduced, with permission, from Chapter 25. Overview of the Neck. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

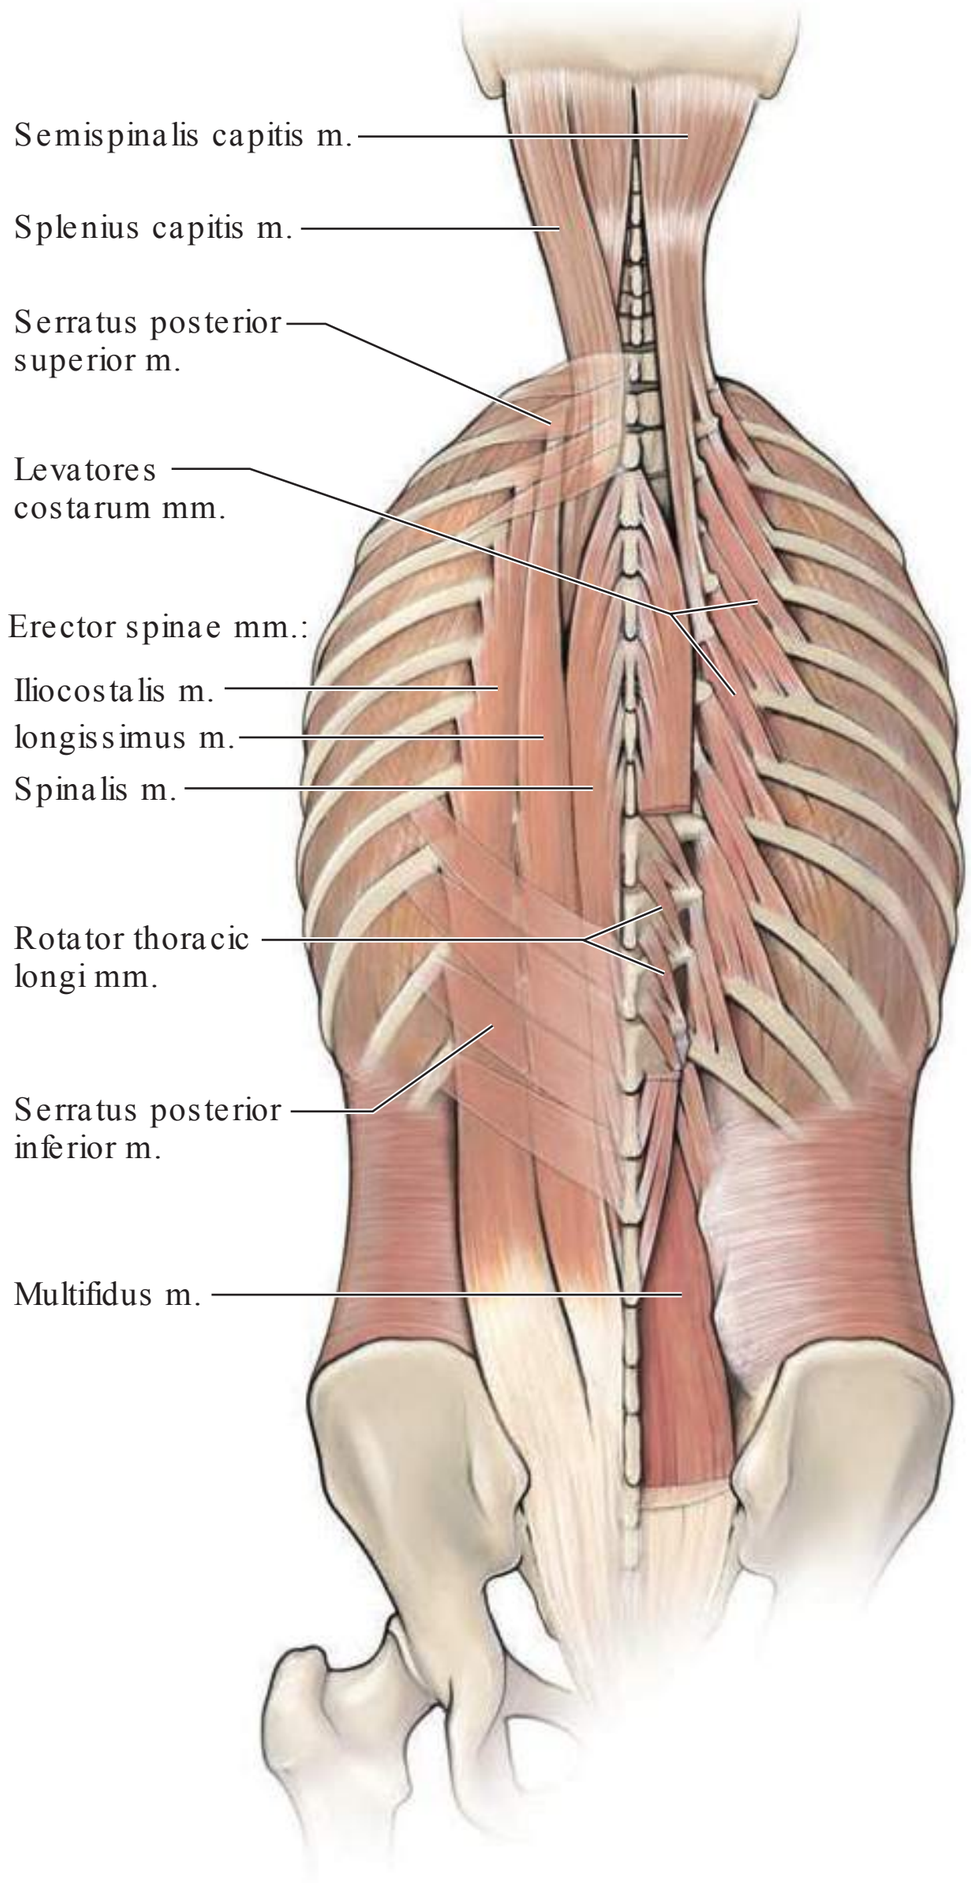

FIGURE 25-5 Deep cervical muscles. (Reproduced, with permission, from Chapter 1. Back. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

located deep to both the upper and the middle parts of the trapezius, can be palpated just deep to the superior border of the trapezius. It descends posteriorly, inferiorly, and laterally to the superior angle and medial border of the scapula, between the superior angle and the base of the spine (Table 25-1). T e levator is the major stabilizer and elevator of the superior angle of the scapula. With the scapula stabilized, the levator produces rotation and side bending of the neck to the same side; when acting bilaterally, cervical extension is produced. With a forward head posture, the potential for this extension moment increases.[1] T is abnormal anterior translation is resisted by tension within the levator scapulae and the ligamentum nuchae.[63]

CLINICAL PEARL

If the levator scapulae is shorter on one side, it may provoke contralateral suboccipital muscle spasms and subsequent headaches.[1]

T e levator is supplied by direct branches of the C3 and C4 cervical spinal nerves and from C5 through the posterior (dorsal) scapular nerve. It is heavily innervated with muscle spindles.

TABLE 25-1 Attachments of Upper Trapezius and Levator Scapulae Muscles

Muscle	Proximal	Distal	Innervation
Upper trapezius	Superior nuchal line Ligamentum nuchae	Lateral third of clavicle and the acromion process	Spinal accessory
Levator scapulae	Transverse processes of upper four cervical vertebrae	Medial border of scapula at level of scapular superior angle	Posterior (dorsal) scapular C5 (C3 and C4)

Rhomboids

The rhomboid major is a quadrilateral sheet of muscle, and the rhomboid minor muscle is small and cylindrical (see Chapter 16). Together they form a thin sheet of muscle that fills much of the interval between the medial border of the scapula and the midline. Although the rhomboid minor, with its attachment to the spinous processes of C7 and T1, has a slight association with the cervical spine, the rhomboid major, arising from the spinous processes of T1–5, is inactive during isolated head and neck movements. The two muscles descend from their points of origin, passing laterally to the posterior aspect of the vertebral border of the scapula, from the base of the spine to the inferior angle. Both these muscles receive their nerve supply from the posterior (dorsal) scapular nerve (anterior [ventral] ramus of C4–5). The principal action of these muscles is to work with the levator scapulae to control the position and movement of the scapula. Both the muscles are involved with concentric contractions during rowing exercises or other activities involving scapular retraction.

Scalenes

The scalenes (Fig. 25-4) extend obliquely like ladders (scala means ladder in Latin) and share a critical relationship with the subclavian artery. Tightness of these muscles will affect the mobility of the upper cervical spine. In addition, because of their distal attachments to the first and second ribs (Table 25-2), they can, if in spasm, elevate the ribs and be implicated in thoracic outlet syndrome (TOS).[64,65]

Scalenus Anterior. The scalenus anterior (see Fig. 25-4) runs vertically, behind the SCM on the lateral aspect of the neck. Arising from the anterior tubercles of the C3–6 transverse processes, it travels to the scalene tubercle on the inner border of the first rib. The osteal portion of the vertebral artery and the stellate ganglion are located lateral to the scalenus anterior. Acting from above, the scalenus anterior, like the rest of the scalenes, is an inspiratory muscle, even with quiet breathing.[66] Working bilaterally from below, it flexes the spine. Unilaterally, it side bends the spine ipsilaterally and rotates the spine contralaterally. It is supplied by the anterior (ventral) rami of C3-8.

Scalenus Medius. The scalenus medius (see Fig. 25-4) is the largest and longest of the group, attaching to the transverse processes of all cervical vertebrae except the atlas (although it often attaches to this) and running to the upper border of the first rib. It is separated from the anterior scalene by the carotid artery, and cervical nerve, and is pierced by the nerve to the rhomboids (posterior [dorsal] scapular) and the upper two roots of the nerve to the serratus anterior (long thoracic). When working unilaterally on the cervical spine, the scalenus medius is an ipsilateral side bender of the neck. When working bilaterally, it is a cervical flexor.

Scalenus Posterior. The scalenus posterior (Fig. 25-4) is the smallest and deepest of the group, running from the posterior tubercles of the C4–6 transverse processes to attach to the outer aspect of the second rib. It functions to elevate or fix the second rib and side bends the neck ipsilaterally. It is innervated by the anterior (ventral) rami of C3-8.

Scalenus Minimus (Pleuralis). The scalenus minimus is a small muscle slip, running from the transverse process of C7 to the inner aspect of the first rib and the dome of the pleura. It is a suprapleural membrane that is often considered to be the expansion of the tendon of this muscle. The muscle functions to elevate the dome of the pleura during inspiration and is innervated by the anterior (ventral) ramus of C7.

Platysma. The broad sheet of the platysma muscle is the most superficial muscle in the cervical region (Fig. 25-3). The platysma covers most of the anterolateral aspect of the neck, the upper parts of the pectoralis major, and deltoid, extending superiorly to the inferior margin of the body of the mandible. As a muscle of facial expression, it cannot affect bony motion, except perhaps as a passive restraint to head extension. It is supplied by the cervical branch of CN VII (facial).

Deeper Muscles of the Back

The deep or intrinsic muscles of the back are the primary movers of the vertebral column and head and are located deep to the thoracolumbar fascia. The muscles in all of these groups are segmentally innervated by the lateral branches of the posterior (dorsal) rami of the spinal nerves.

Splenius Capitis

The splenius capitis (Fig. 25-5) extends upward and laterally, from the posterior (dorsal) edge of the nuchal ligament and

TABLE 25-2 Attachments of Scalene, Longus Colli, and Longus Capitis Muscles

Muscle	Proximal	Distal	Innervation

Splenius cervicis	Spinous processes of T3–6 vertebrae	Posterior tubercles of C1–3	Posterior (dorsal) primary rami of C5, 6

the spinous processes of the lower cervical and upper thoracic vertebrae (T4–C7) to the mastoid process of the occipital bone just inferior to the superior nuchal line and deep to the SCM muscle.

Splenius Cervicis

The splenius cervicis is just inferior and appears continuous with the capitis, extending from the spines of the third to the sixth thoracic vertebrae to the posterior tubercles of the transverse processes of the upper cervical vertebrae.

The splenius capitis and splenius cervicis muscles are two important head and neck rotators. From their attachments (Table 25-3), it is clear that these two muscles are capable of producing ipsilateral rotation, side bending, and extension at the spinal joints they cross.

Cervical Erector Spinae

The erector spinae complex spans multiple segments, forming a large musculotendinous mass (Fig. 25-6) consisting of the iliocostalis, longissimus, and spinalis muscles (Tables 25-4 and 25-5).

- The iliocostalis cervicis appears to function as a stabilizer of the cervicothoracic junction and lower cervical spine.
- The semispinalis has thoracis, cervicis, and capitis divisions. The obliquus capitis superior (superior oblique) and inferior (inferior oblique) and the rectus capitis posterior major and minor (see Chapter 23) lie underneath the semispinalis capitis and splenius capitis muscles.[67] The semispinalis cervicis is a stout muscle that extends superiorly to the spinous process of vertebra C2, functioning as a strong extensor of the lower cervical spine.[1]
- The interspinales and intertransversarii, which interconnect the processes for which they are named, produce only minimal motion because they can influence only one motion segment and are more likely to function as sensory organs for reflexes and proprioception.[68]

Deep Neck Flexors

The prevertebral muscles of the neck consist of:

- Longus colli. The longus colli (Fig. 25-4) consists of a vertical portion that originates from the bodies of the first

three thoracic and last three cervical vertebrae, an inferior oblique portion that originates from the bodies of the first three thoracic vertebrae, and the superior oblique portion that originates from anterior tubercles of the transverse processes of C3–5. The various portions of the longus colli insert into the bodies of C2–4, the anterior tubercles of the transverse processes of C5–6, and the anterior tubercle of the atlas. The longus colli functions to flex (and assists in rotating) the cervical vertebrae and head. Acting singly, the longus colli side bends the vertebral column. The longus colli is innervated by branches of the anterior primary rami of C2–8.

- Longus capitis. The longus capitis (Fig. 25-4) originates from the anterior tubercles of the transverse processes of C3–6 and inserts onto the inferior surface of the basilar part of the occipital bone. The longus capitis functions to flex (and assists in rotating) the cervical vertebrae and head. It is innervated by the muscular branches of C1–4.
- Rectus capitis anterior. The rectus capitis anterior (RCA) originates from the lateral mass of the atlas and inserts onto the base of the occipital bone anterior to the foramen magnum. The RCA flexes and rotates the head and is innervated by the muscular branches of C1–2.
- Rectus capitis lateralis. The rectus capitis lateralis (RCL) originates from the upper surface of the transverse process of the atlas and inserts onto the inferior surface of the jugular process of the occipital bone. The RCL side bends the head to the ipsilateral side and is innervated by branches of the anterior rami of C1–2.

CLINICAL PEARL

The longus colli and longus capitis play an important role in cervical stabilization (see "Muscle Control" section).

Neurology

The cervical spine is the only region that has more nerve roots than vertebral levels.[8]

In general, structures supplied by the upper three cervical nerves can cause neck and head pain (see Table 23-1), whereas the mid to lower cervical nerves can refer symptoms to the shoulder, anterior chest, upper limb, and scapular area.[69]

Cervical proprioceptive input has considerable influence on posture through the tonic neck reflex and on eye movement and accommodation through the cervico-ocular and vestibulo-ocular reflexes (see Chapter 3).[69–71] It is probably no accident that the two largest postural muscles of the head and neck, the trapezius, and the SCM muscles, are partly innervated by the accessory nerve (CN XI).

Vascular Supply

The middle cervical segments are supplied by radicular branches off the extradural vertebral artery and are the most common segments to be affected in vertebral artery disease.[72] The vertebral artery is detailed in Chapter 24.

The common carotid artery bifurcates at the middle to upper cervical level into the internal and external carotid arteries. The carotid body, a specialized structure that senses oxygen and carbon dioxide levels in the blood, is located at this bifurcation.[10] The carotid sinus, which contains baroreceptors that monitor blood pressure, is located at a point before the bifurcation.[10]

Cervical Lordosis

The amount of cervical lordosis is a factor of the zygapophyseal joint planes and the cervical IVDs. Under normal conditions, the C4–5 interspace is considered the midpoint of the curve, and the center of gravity (COG) for the skull lies anterior to the foramen magnum. The longus colli has been shown to have an important supporting role on the cervical curve.[73]

A reduction in the cervical lordotic curve because of injury or abnormal posture results in more weight being borne by the vertebral bodies and IVDs, whereas an increase in the lordosis increases the compressive load on the zygapophyseal joints and posterior elements. Watson and Trout[74] have demonstrated a link between a lack of endurance capacity of the upper cervical and deep neck flexors and the forward head posture (see later).

Cervicothoracic Junction

T e cervicothoracic junction comprises the C7–T1 segment, although functionally it includes the seventh cervical vertebra, the first two thoracic vertebrae, the first and second ribs, and the manubrium. In addition, the cervicothoracic junction forms the thoracic outlet, through which the neurovascular structures of the upper extremities pass. Lewit[75] considers the cervicothoracic junction to be the third major area of the spine for musculoskeletal problems, with the craniovertebral area and the lumbosacral junction being first and second, respectively.

BIOMECHANICS

T e motions that occur in the cervical spine correspond to motions of the head, although the range of head movement bears little relation to the range of neck movement and that the total range is the sum of both the head and the neck motions.[76]

T e cervical spine is a complex mechanical linkage composed of multiple degrees of freedom of movement about each of its joints and at least 20 pairs of muscles, many of which are capable of performing similar actions.[52] It is estimated that the osseoligamentous system contributes 20% to the mechanical stability of the cervical spine while 80% is provided by the surrounding neck musculature.[77] T e role of the ligaments in stabilization occurs mainly at the end-of-range postures,[78] while the muscles supply dynamic support in activities around neutral- and midrange postures.[79]

At the zygapophyseal joints, there is a sagittal range of 50–80 degrees in each direction of flexion and extension.[80] T e only significant arthrokinematic motions available to the zygapophyseal joint are an inferior, medial glide of the inferior articular process of the superior facet during extension and a superior, lateral glide during flexion. Segmental side bending is, therefore, an extension of the ipsilateral joint and flexion of the contralateral joint. Rotation, coupled with ipsilateral side bending, also involves the extension of the ipsilateral joint and flexion of the contralateral. Because of their multiple insertions, many of the neck muscles have multiple functions or can change their function depending on the initial position of each vertebral joint and the degree to which the joints are free to move in each of the planes of motion.[52] T us, a voluntary motor task of the head and neck can be accomplished through a variety of combinations of kinematic and muscle actions. Considering that most functional daily tasks are performed in and around midrange postures, the muscles controlling the cervical spine are subject to constant external and internal forces.[79]

CLINICAL PEARL

The cervicothoracic junction is an area subject to many forces, usually rotational and is also vulnerable to postural impairments.

Flexion

Flexion may be divided into three sequential phases.[81,82] T e initial phase begins in the lower cervical spine (C4–7) where C6–7 makes its maximum contribution followed by the C5–6 segment and then by C4–5. Motion in the second phase occurs initially at C0–2, followed by C2–3 and C3–4. T e first phase of motion occurs again at the lower cervical spine (C4–7) initially, with the C4–5 segment followed by C5–6 then the C6–7 segments.[81,82]

At the segmental level, flexion is described as an anterior osteokinematic rock tilt of the superior vertebra in the sagittal plane, a superoanterior glide of both superior facets of the zygapophyseal joints, and an anterior translation slide of the superior vertebra on the IVD (see Fig. 25-7). T is produces an anterior (ventral) compression and a posterior (dorsal) distraction of the cervical disk. T e uncovertebral joint lies on, or very near to, the axis of rotation of flexion and extension. Consequently, the main arthrokinematic motion that seems likely to be occurring here is an anterior spin (or very near spin).[83] T is arthrokinematic spin appears especially probable, as impairments of the uncovertebral joint seem to be unaffected by flexion or extension. T us, uncovertebral restrictions may be detected in all cervical positions, although flexion partly disengages the joint because of its posterior position on the vertebra.[83]

Although all the following anatomic movement restrictors act to some degree on most of the components of flexion, they act particularly on the associated movement component.

- Anterior osteokinematic motion is restrained by the extensor muscles and the posterior ligaments (posterior longitudinal, interspinous, and ligamentum flavum).
- Superoanterior arthrokinematic is restrained by the joint capsule, whereas translation is restrained by the disk and the nuchal ligament.

Extension

Extension is described as a posterior osteokinematic sagittal rock, an inferoposterior glide and approximation of the superior facets of the zygapophyseal joints, and a posterior translation of the vertebra on the disk (see Fig. 25-8). T e uncovertebral joint undergoes a posterior arthrokinematic spin. T e osteokinematic motion of extension is restricted by the anterior prevertebral muscles and the ALL. T e arthrokinematic motion is restricted by the zygapophyseal joint capsule.[83] T e IVD restrains the posterior translation.

CLINICAL PEARL

Forward flexion occurs with rotation below the C5–6 level, and extension occurs with rotation above the C4–5 level. The net result is that whenever cervical spine rotation occurs, the greatest degree of weight bearing is on the anterior edge of the vertebral bodies below the C5–6 segments and on the posterior edge above C4–5 (this factor has been implicated in the cause of spondylosis in these areas).[1]

The greatest amount of cervical motion occurs at the C5–6 segment, with the C4–5 and C6–7 segments a close second.[80] A coupled translation of between 2 and 3.5 mm occurs with flexion and extension. Significant flexion occurs at C5–6, and extension around C6–7.[27] Side bending averages about 10 degrees to each side in the midcervical segments, decreasing in the caudal segments.[27]

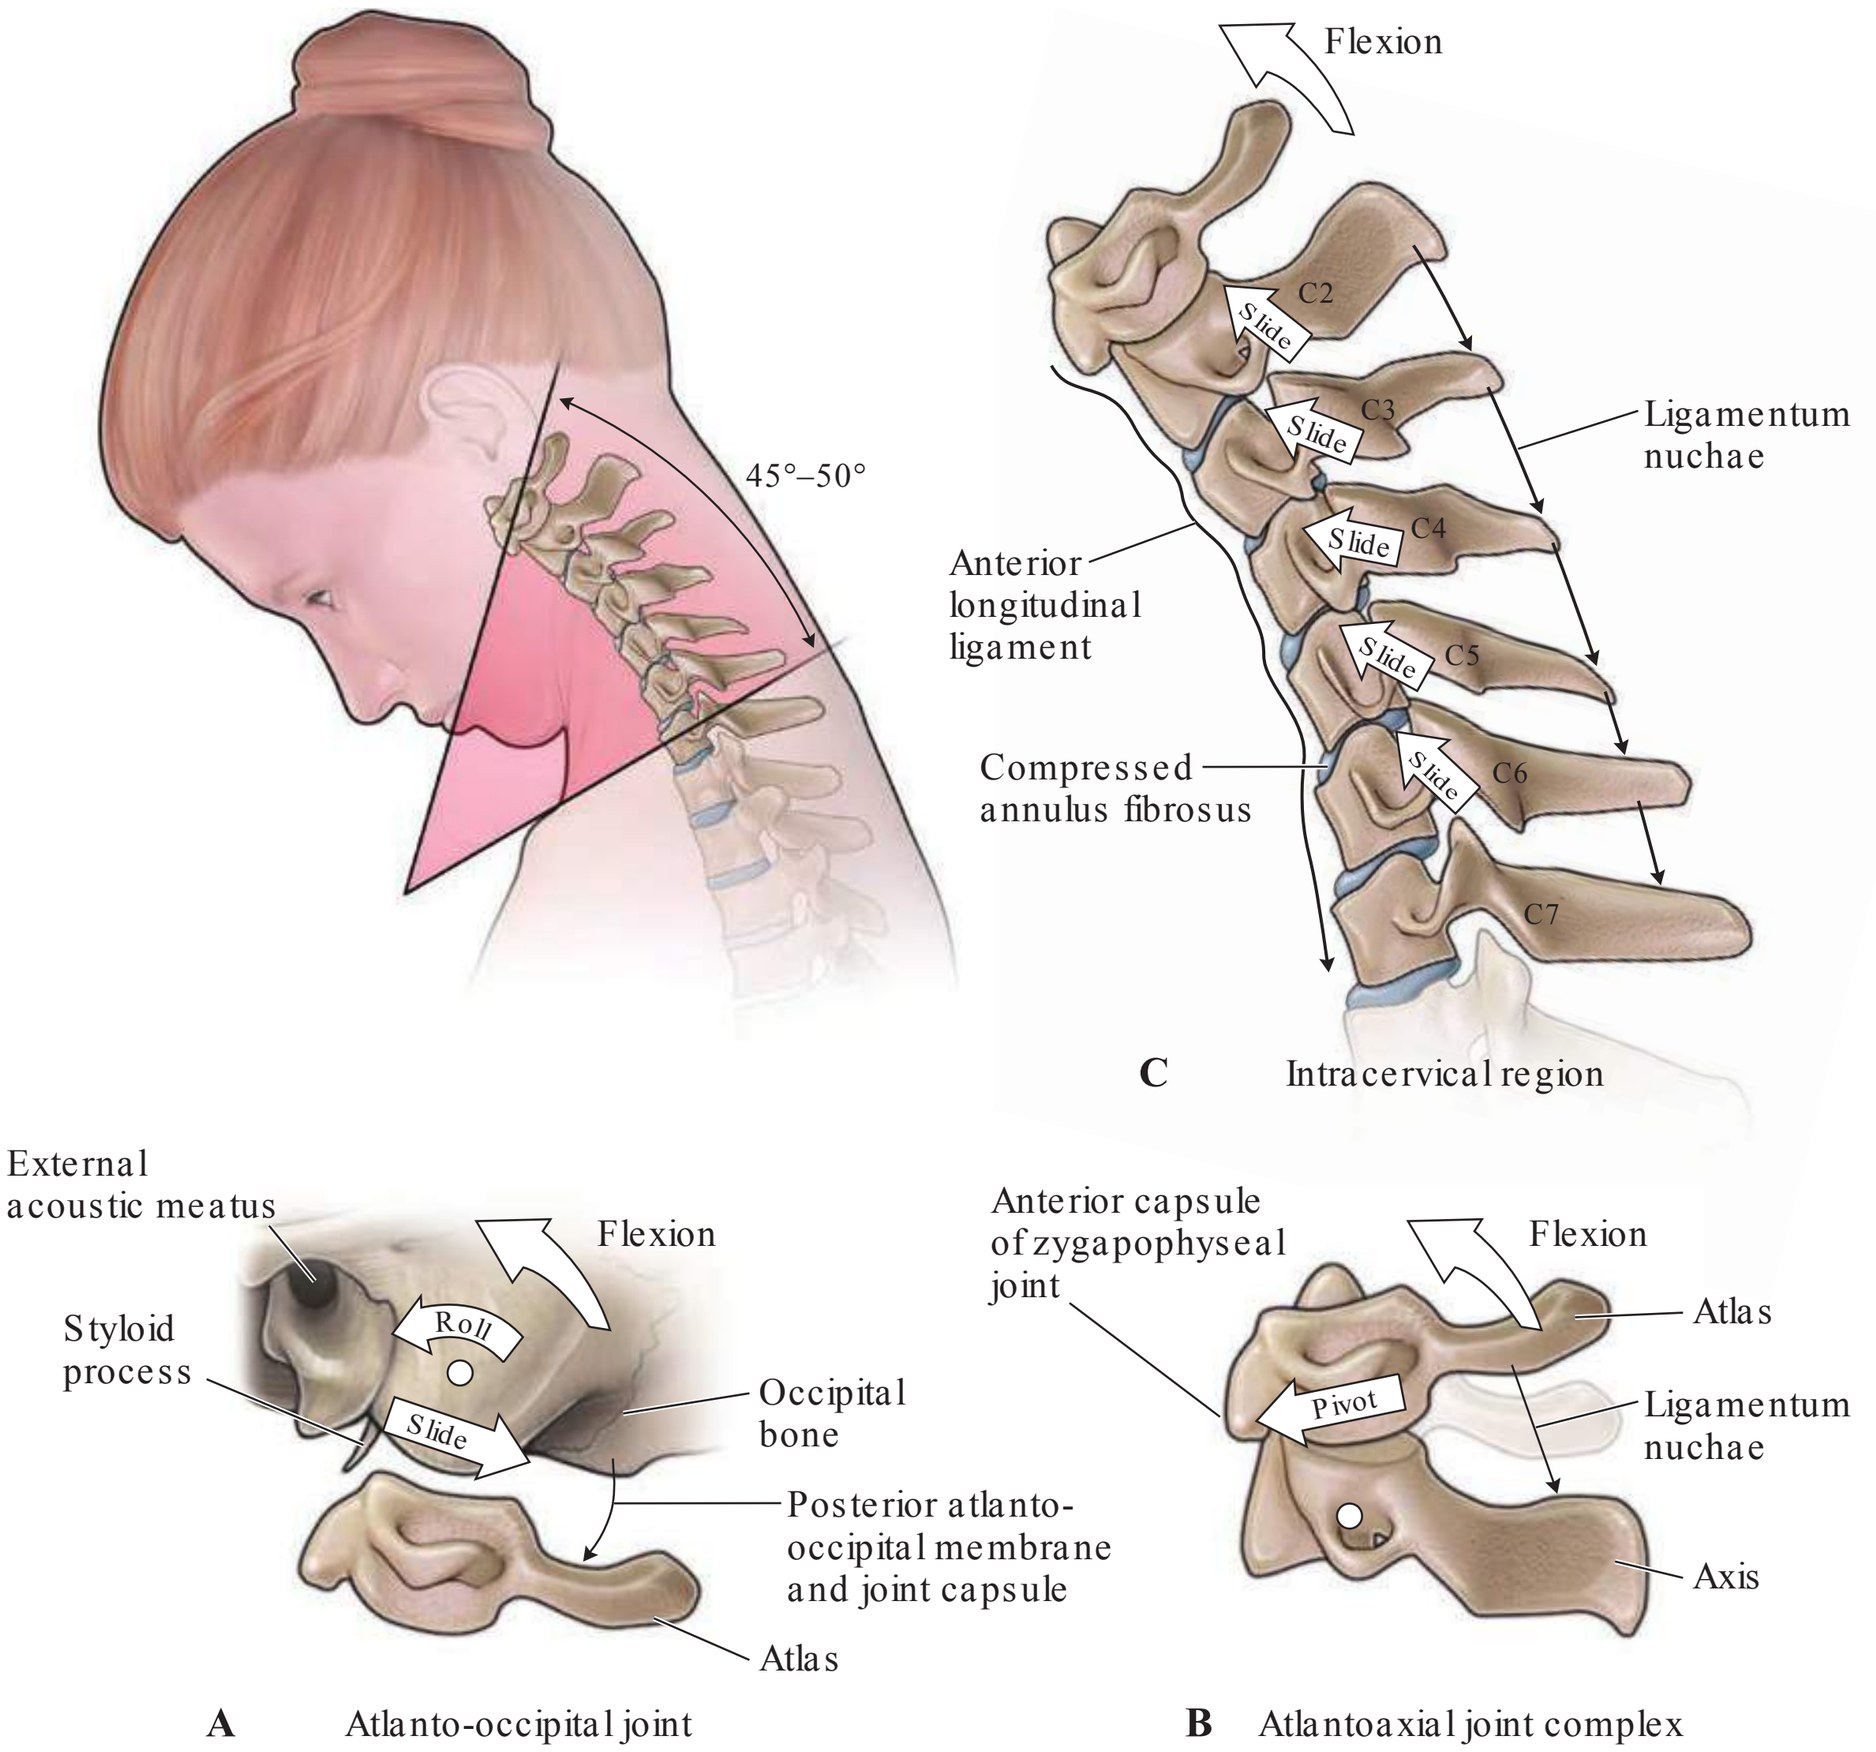

FIGURE 25-7 Kinematics of craniocervical flexion.

Side Bending

Side bending (lateral flexion) is an ipsilateral osteokinematic rock, a superoanterior glide of the contralateral superior facet, and a posteroinferior glide of the ipsilateral facet (see Fig. 25-9). In addition, there is a contralateral translation of the vertebra on the disk, an inferomedial glide of the ipsilateral uncovertebral joint, and a superolateral glide of the contralateral uncovertebral joint. A composite curved translation results. T is curve is formed by the superoinferior linear glides of the zygapophyseal joints, the oblique inferomedial and superomedial glides of the uncovertebral joints, and the linear translation across the disk.[83]

T e osteokinematic rock can be limited by the contralateral scalenes and intertransverse ligaments. T e uncovertebral and zygapophyseal arthrokinematic motions can be limited by the joint capsule, and the translation is limited by the IVD. If the side bending is limited, but the translation is okay, it is unlikely that the joint complex (the zygapophyseal joint, disk, or uncovertebral joint) is impaired; instead, these findings may implicate adaptive shortening of the sot tissues.[83]

However, if the translation is also limited, a problem with the joint complex also probably exists.

Rotation

Rotation is chiefly an osteokinematic motion of the vertebra about a vertical axis that is coupled with ipsilateral side bending (see Fig. 25-10). Presumably, the translation follows the side bending (i.e., contralateral), resulting in the same uncovertebral and zygapophyseal arthrokinematic motions as does side bending.[83]

CLINICAL PEARL

While the coupled motions of rotation and side bending are ipsilateral (occur to the same side) in the midcervical spine, the coupled motions at the cervicothoracic junction are more dif cult to discern due to the influence of the more rigid thoracic spine and ribcage.

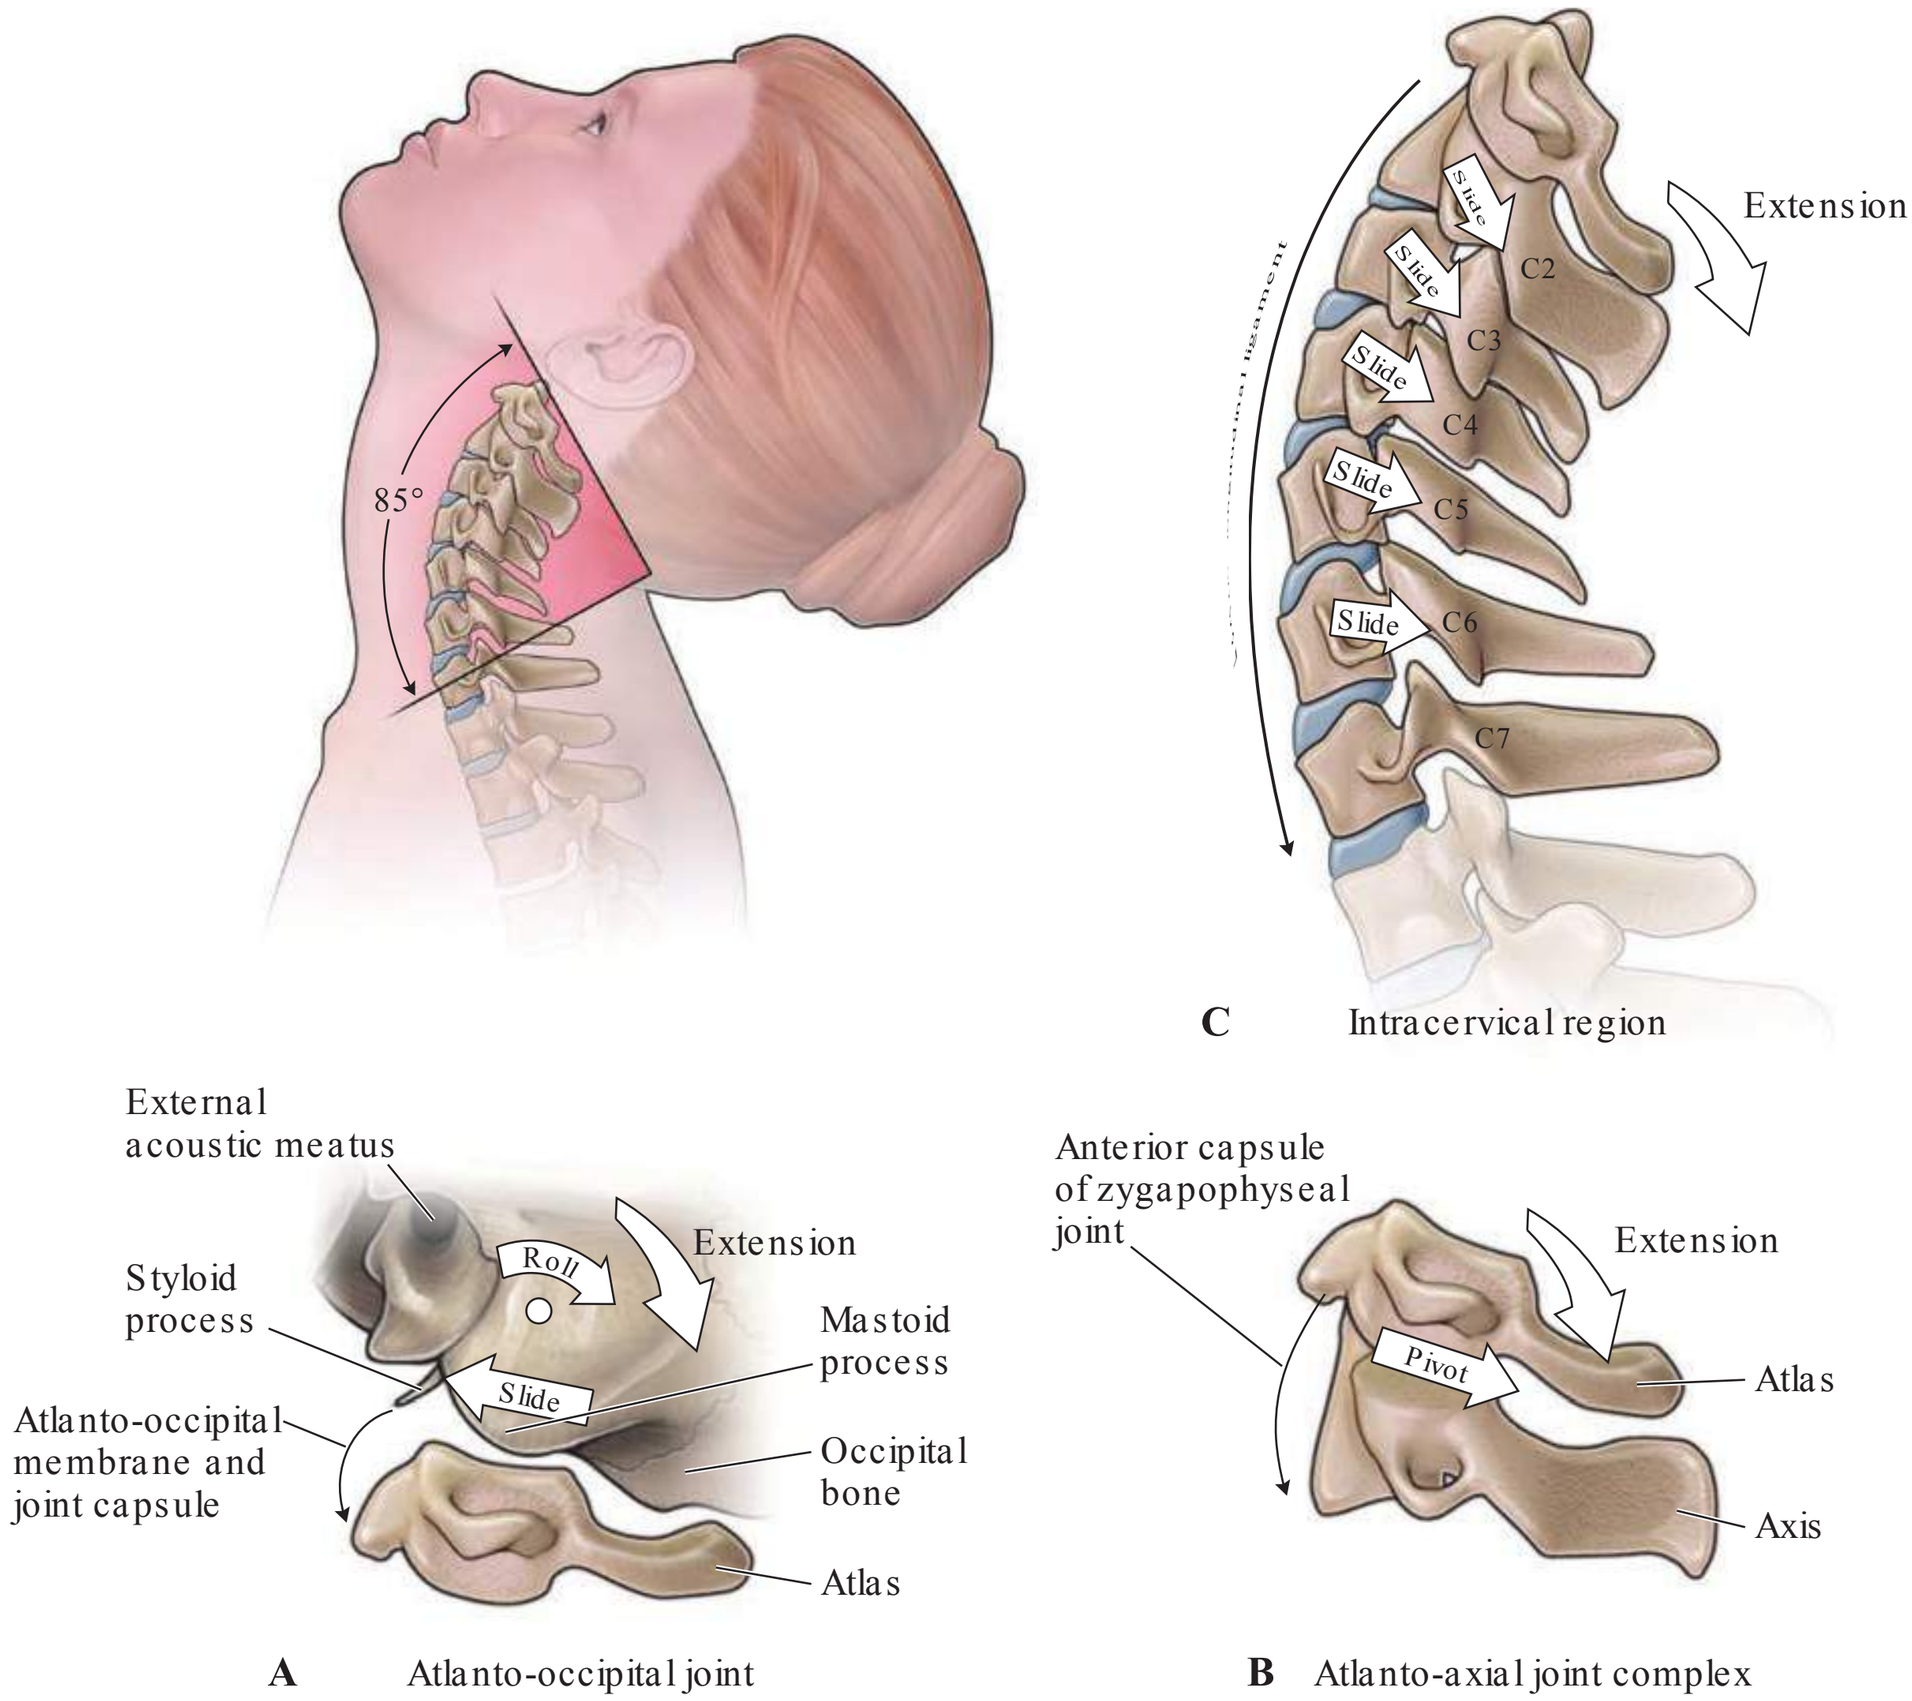

FIGURE 25-8 Kinematics of craniocervical extension.

Muscle Control

The control of head and neck postures and movements is a complex task, especially in the presence of pain or dysfunction. The muscle groups of the cervical region may be divided into those that sustain postures or stabilize the segments and those that produce movement.[84–86] Considerable biomechanical, physiological, and clinical research in both the cervical and lumbar regions has been undertaken which supports Bergmark's[86] model for a functional division between the deep and more superficial muscles in their relative contributions to spinal support and control.[79] According to this model, the more superficial multisegmental (global) muscles have the responsibility for maintaining equilibrium of external forces (torque production and control of the head) so that the load transmitted to the spinal segments can be controlled efficiently by the deep intersegmental (local) muscle system.[69,79,86]

The SCM (anteriorly) and the semispinalis capitis and splenius capitis (posteriorly) are thought to be the global muscles of the neck, whereas the local system is thought to comprise the longus capitis and colli (Table 25-2),[73] semispinalis cervicis, and multifidus.[87] The longus colli and posterior (dorsal) neck muscles form a muscle sleeve that surrounds the cervical column to support the cervical spinal segments in functional movements.[73]

Patients with neck pain have been found to demonstrate generally less torque production (strength and endurance) in all planes, with a greater loss in the cervical flexors than extensors.[88] However, addressing strength alone in research and exercise programs may oversimplify the problems in the neuromuscular system associated with neck pain.[79] Recent research has recognized the vital role that activation of the deep neck flexor muscles plays in supporting the cervical segments and the cervical curve (see "Muscle Function Testing: Deep Neck Flexors" section later).[73,87,89] Indeed, impairment in the axioscapular-girdle muscles has been linked clinically to cervical pain syndromes.[84,90–94] The nature of the impairment in the cervical and cervicobrachial muscle systems indicates the need for careful and precise movement analysis and muscle testing to appreciate and accurately define the problem.[79]

EXAMINATION

The cervical spine is an area with a high potential for serious injury, which makes this a region of the body that needs to be examined with caution, especially when there is a history of acute and recent trauma of the neck, because of the potential for the examination itself to be harmful.[95] Although most

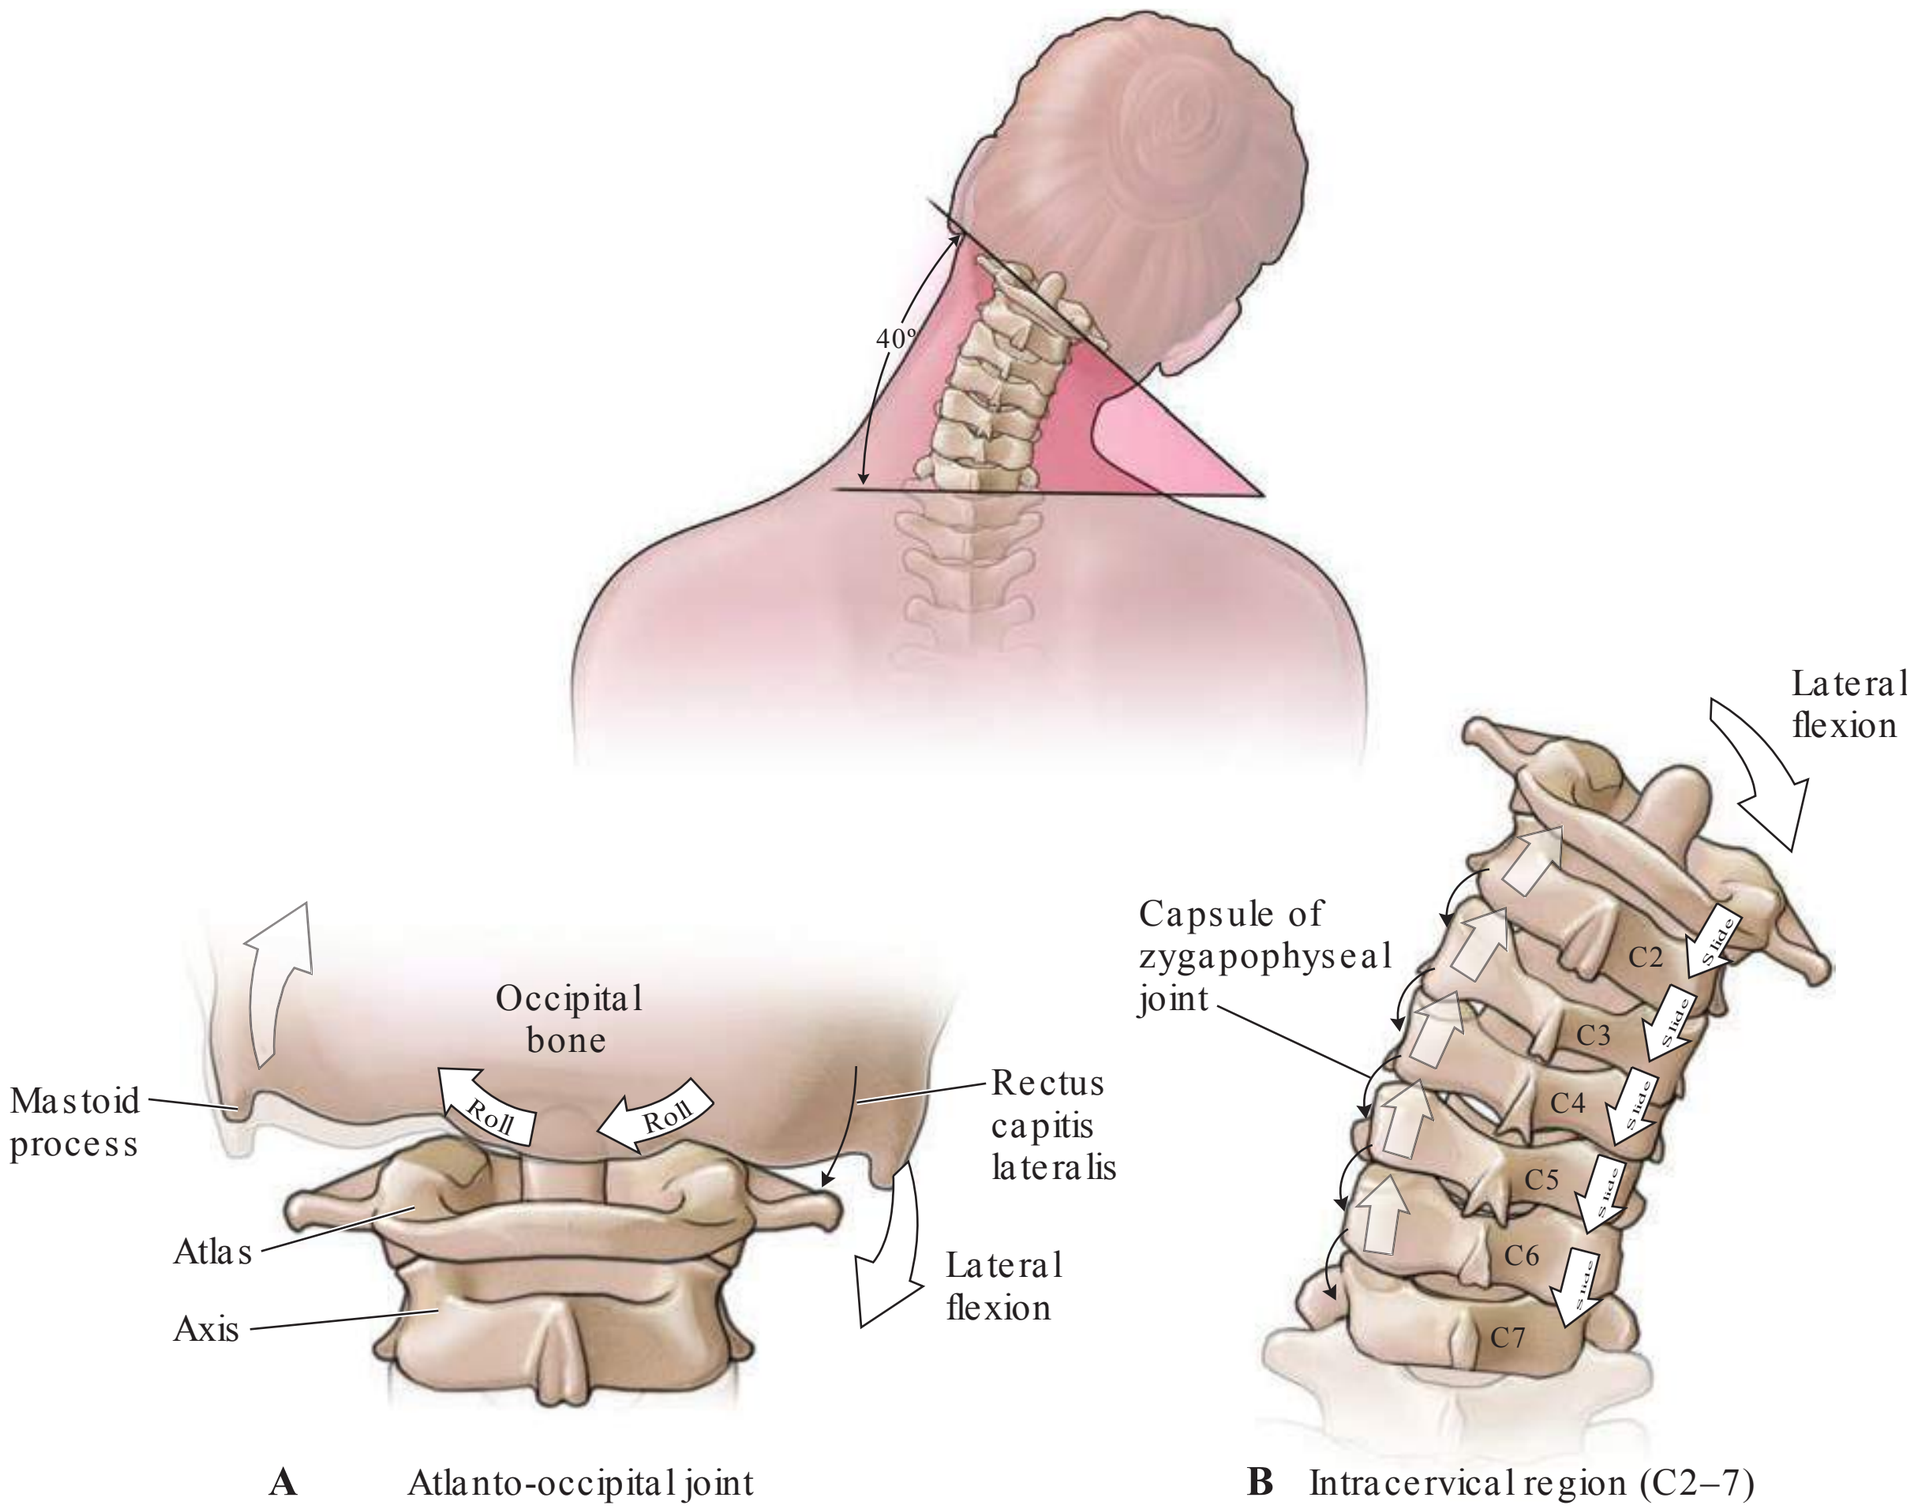

FIGURE 25-9 Kinematics of craniocervical side bending.

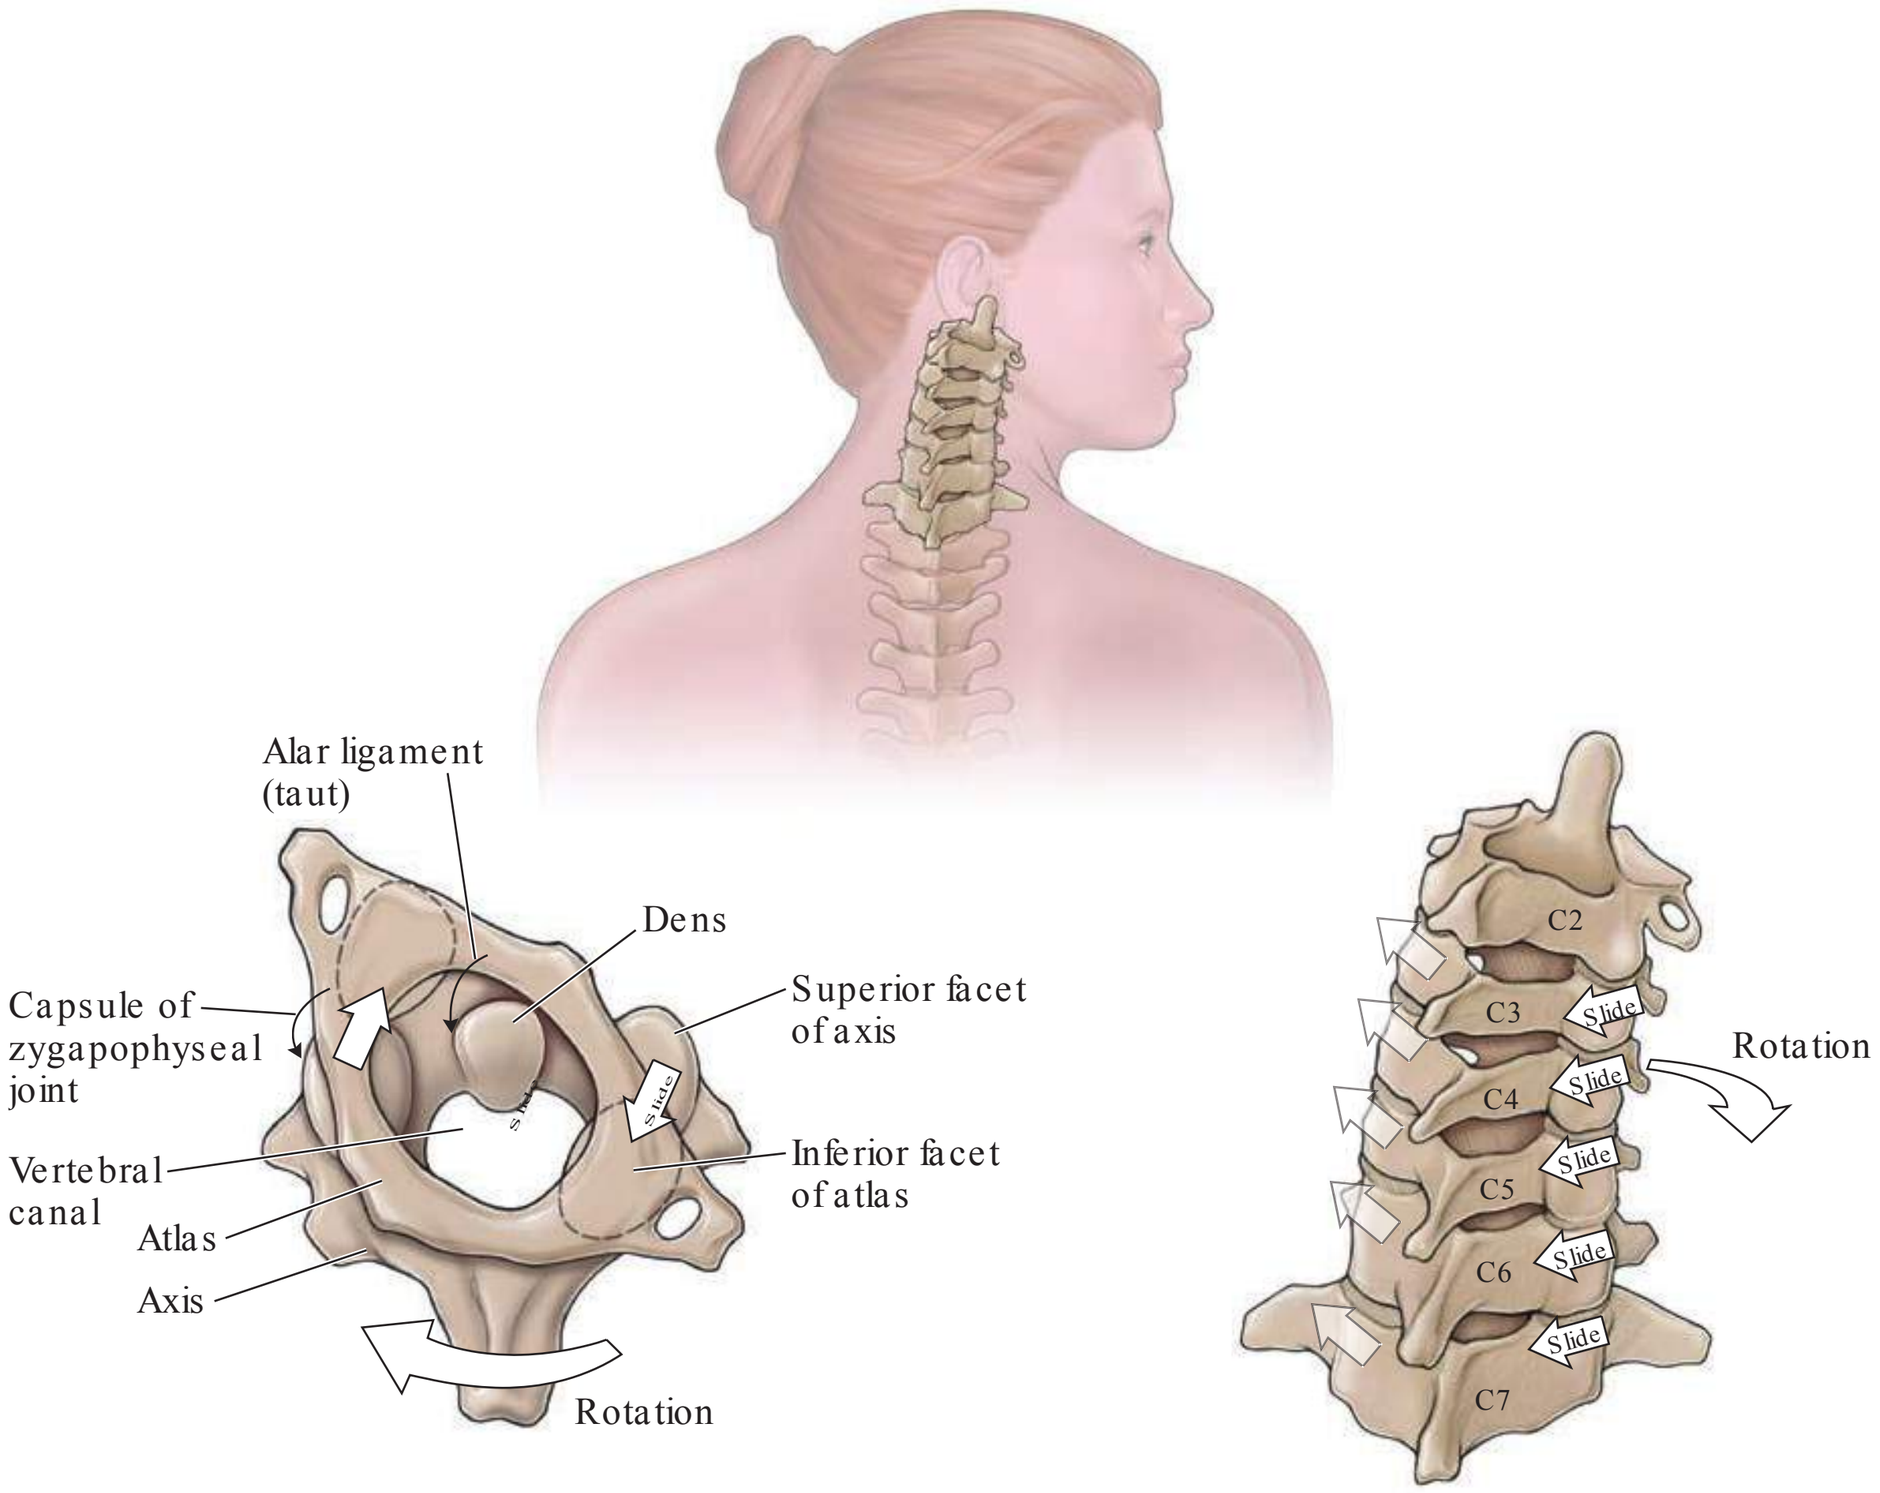

conditions involving the neck and upper limb symptoms can be diagnosed at er a careful history and physical examination, in cases of significant trauma, imaging studies may be required to exclude a fracture or instability. Where possible, the patient should be examined for central and/or peripheral neurologic deficit, neurovascular compromise, and serious skeletal injuries, such as fractures or craniovertebral ligamentous instability.

Winkel et al.[96] clinically categorize cervical disorders by the location of symptoms and the etiology of each condition:

- Local cervical syndrome (LCS). T is syndrome manifests with local neck complaints, resulting from cervical muscle strain, ligament sprain, or a primary or secondary disk-related condition.
- A primary disk-related LCS is characterized by symptoms that may result from a protrusion, prolapse, or extrusion of the disk.
- A secondary disk-related LCS is characterized by symptoms resulting from gradual changes in the cervical spine that have been generated by the previous degradation of the IVD. T ese changes include internal disk disruption and synovitis or irritation of the zygapophyseal and uncovertebral joints. In the cervical spine, myofascial pain may be a secondary tissue response to an IVD or zygapophyseal joint injury.[97] T e cervical zygapophyseal (facet) joints can be responsible for a significant portion of chronic neck pain. Established referral zones for the cervical zygapophyseal joint[98,99] overlap both myofascial and dermatomal pain patterns. Cervical zygapophyseal joint pain is typically unilateral and is described by the patient as a dull ache. Occasionally, the pain can be referred to the craniovertebral or interscapular regions.
- Cervicobrachial syndrome. T is syndrome includes symptoms in the local cervical region, as well as in one or both upper extremities, as a result of nerve root irritation by compression or tension of the nerve root.
- Cervicocephalic syndrome. T is syndrome is characterized by complaints in both the neck and the head and includes symptoms such as dizziness, tinnitus, and headache. T ese symptoms may result from articular, ligamentous, neurologic, organic, or vascular sources.
- Cervicomedullary syndrome. T is syndrome is characterized by spinal cord symptoms associated with cord compression at the cervical spine (cervical myelopathy).

Clearing tests for the cervical spine include

- vertebral artery tests;
- Sharp–Purser test;
- articular stability tests;

A Atlantoaxial joint complex **B** Intracervical region (C2–7)

FIGURE 25-10 Kinematics of craniocervical rotation.

- transverse ligament test;
- alar ligament test; and
- temporomandibular joint (TMJ) assessment.

Once damage to the vertebral artery (see Chapter 24) and transverse ligament (see Chapter 23) has been ruled out, the most likely pain candidates are assessed first. These include the bone, muscles, ligaments, zygapophyseal joints, and IVD. In addition, because of its close proximity, a quick examination of the TMJ should be performed to rule out pain referral from this joint (see Chapter 26). The examination must be graduated and progressive so that the testing can be discontinued at the first signs of serious pathology.[94] An examination and treatment algorithm for the mid-lower cervical spine is outlined in Figure 25-11.

History

The most common symptoms of cervical disorders are ongoing or motion-induced neck or arm pain, or both, and suboccipital headache.[12] In addition to the questions listed under History in Chapter 4, the clinician should obtain the following information.

The clinician must determine whether the trauma occurred and the exact mechanism. In acute sprains and strains, patients typically relate an activity that precipitated the onset of their symptoms. This may be lifting or pulling a heavy object, an awkward sleeping position, a hyperextension injury, or prolonged static postures. In whiplash-associated disorders (WADs), patients generally describe an accident in which they were unexpectedly struck from the rear, front, or side. Rotational injuries may also occur. If there were neurologic symptoms following the trauma (paresthesias, dizziness, tinnitus, visual disturbances, or loss of consciousness), more severe damage should be suspected.[100] If the patient reports electric shock-like symptoms down the spine with neck flexion (Lhermitte's sign), the clinician should consider the possibility of inflammation or irritation of the meninges.[101–103] A traumatic mechanism of injury with complaints of nonspecific cervical symptoms that are exacerbated in the vertical position, and relieved with the head supported in the supine position, is suggestive of cervical instability, especially if the patient reports that dysesthesias of the face occur with neck movement.[104–106]

For the purposes of the examination, it is important to establish a baseline of symptoms so that the clinician is able to determine whether a particular movement aggravates or lessens the patient's symptoms. The history can provide the clinician with information as to the location of the patient's symptoms (head, neck, shoulder, arm, and hand), the nature

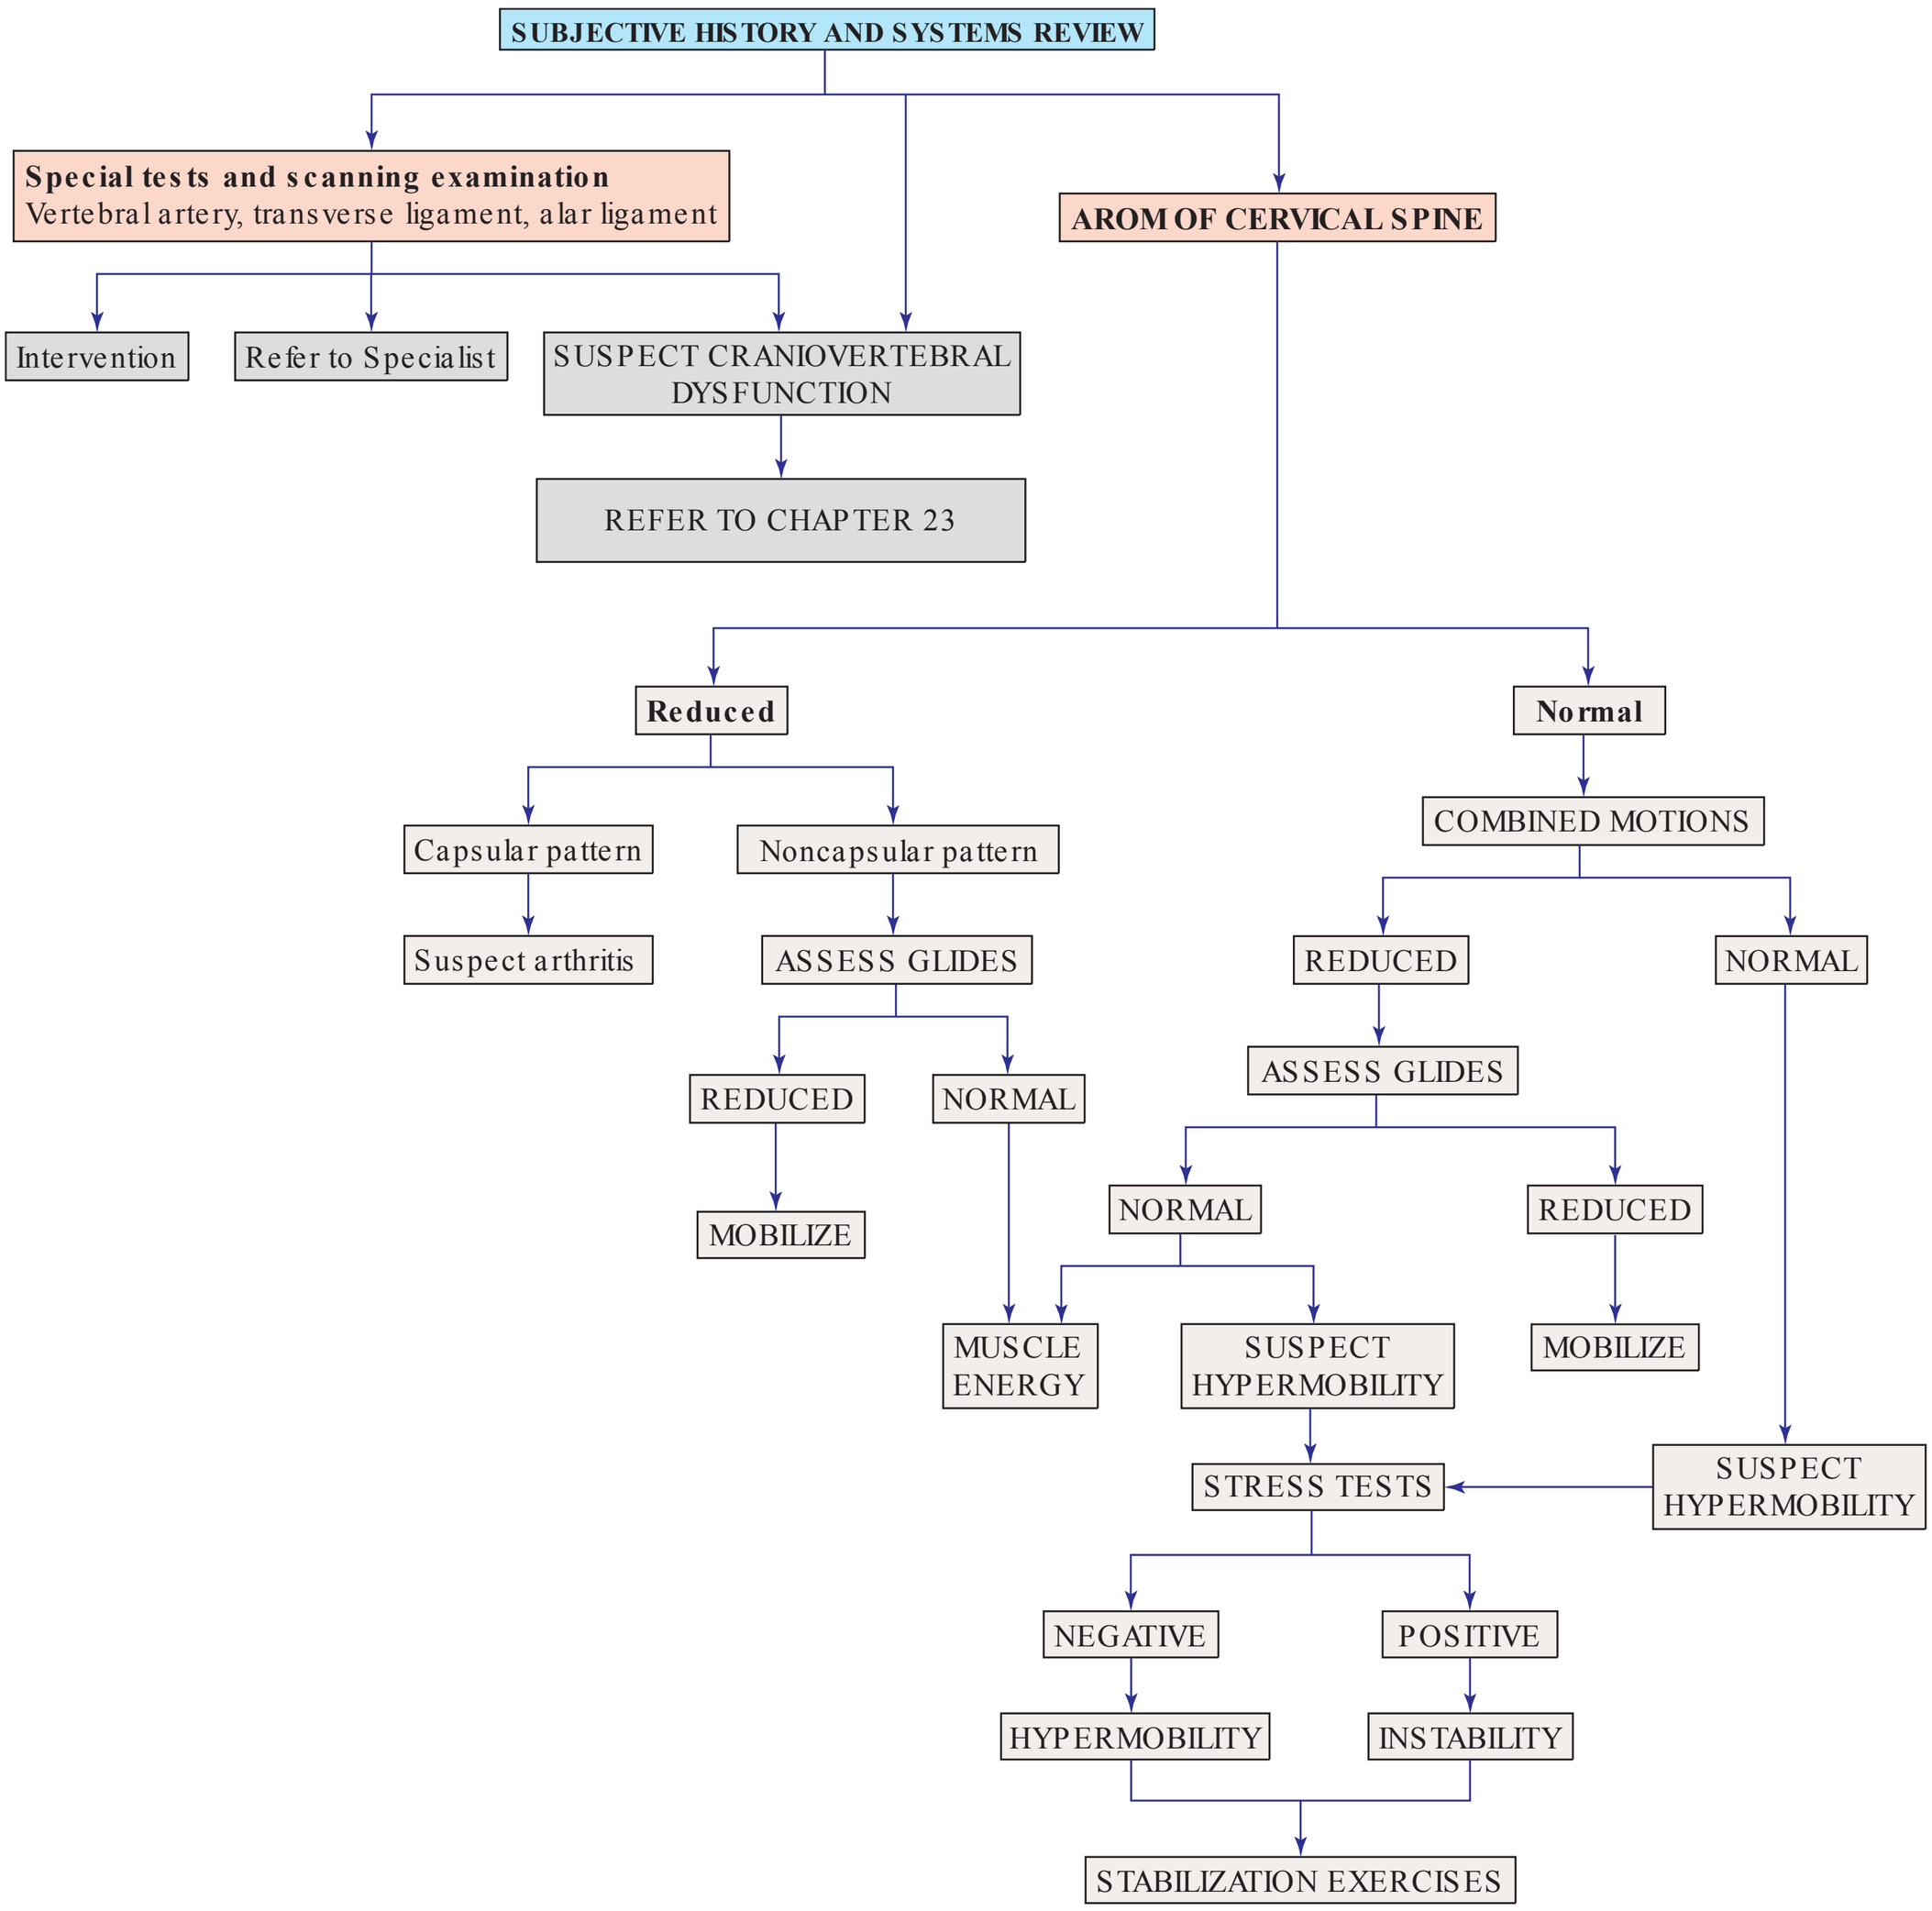

FIGURE 25-11 An examination and treatment algorithm for the mid-lower cervical spine.

of the symptoms (constant, intermittent, or variable), the type of symptoms (pain, paresthesia, numbness, weakness, and stiffness), the severity of the condition, and the activities or positions that appear to aggravate or improve the patient's condition. It is also important to determine the type of work the patient does and whether that work involves sustained postures, the potential for eye strain, repetitive motions of the head, neck, and upper extremity, or heavy lit ing. Symptoms associated with coughing and sneezing are ot en associated with disk pathology. Radicular pain may be accompanied by sensorimotor symptoms.[14]

T e patient's chief complaint should be determined. T e clinician should determine the location and boundaries of the symptoms. All symptoms present should be recorded on a body diagram, even those that may initially appear unrelated. If the pain is the major symptom, the clinician should attempt to quantify the pain using a pain rating scale. It is also appropriate at this time to establish the patient's goals.

Asking the patient to describe his or her symptoms over a 24-hour period can provide the clinician with valuable information about the severity, the positions and activities that aggravate or relieve the symptoms, and the duration of the symptoms. Patients who report dif culty in sleeping because of pain may have an inflammatory condition, but the more insidious causes of night pain, such as malignancy, must be ruled out. T e patient's sleeping position and habits should be investigated. Cervical symptoms are ot en increased when a foam or very firm pillow is used.[107] Sleeping in the prone position requires adequate cervical and upper thoracic rotation. Some degree of cervical extension is also required, depending on the number and type of pillow used. T e onset of symptoms may also provide clues as to the type of tissue involved. Muscle

or ligamentous pain may either occur immediately following trauma or be delayed for several hours or days. Bone pain usually occurs immediately.

T e reports of headaches or facial pain, depending on frequency and severity, warrant special attention (see section "Systems Review").

It is important for the clinician to determine whether the patient has had successive onsets of similar symptoms in the past because recurrent injury tends to have a detrimental effect on the potential for recovery. If the patient has had a recurrent injury, the clinician should note how ot en, and how easily, the injury has recurred and the success or failure of previous interventions.

T e clinician must determine whether there are musculoskeletal symptoms elsewhere. It is well established that the head, neck, upper thoracic regions, and upper extremities can be sites of referred pain. T oracic interscapular pain, at a point level with T4–5, is a very common complaint, especially in women.[2] T is pain is thought to be posture related.

CLINICAL PEARL

Referred symptoms that are cervical in origin can occur in the upper extremities, thoracic spine, scapula, and, occasionally, the upper chest. Pain may be referred to the tip of the acromion or scapular region via the cutaneous branches of the upper thoracic posterior (dorsal) rami.[108] The rib articulations of cervicothoracic region may produce local pain, or refer pain to the suprascapular fossa or shoulder.[109]

Neck pain accompanied by widespread musculoskeletal pain raises the strong possibility of fibromyalgia, whereas neck pain with synovitis of peripheral joints suggests an inflammatory arthropathy, such as rheumatoid arthritis.[110] Myofascial pain syndromes are characterized by generalized aching and the presence of trigger points (see Chapter 10). T e basic pathologic impairment in myofascial pain has yet to be substantiated.[111,112] Pain that is constant in nature and unrelated to rest or activity may be inflammatory in origin, in which case physical therapy and, specifically, manual therapy may be inappropriate.[113]

A report of diffuse nonspecific neck pain that is exacerbated by neck movements is suggestive of mechanical neck pain, cervical facet syndrome,[114] or a cervical strain/sprain.[115] Conditions that have a mechanical origin are usually improved with rest, although they may worsen initially on retiring.[116] Pain caused by sustained positions and postures, such as the upper crossed postural syndrome,[84] may awaken the patient at night but is usually relieved by a change of position.

CLINICAL PEARL

An insidious onset of symptoms could suggest postural (e.g., TOS), degenerative, or myofascial origins; or a disease process, such as ankylosing spondylitis, cervical spondylosis, or facet syndrome. An insidious onset may also indicate the presence of a serious pathology such as a tumor.

Systems Review

General health questions provide information about the status of the cardiopulmonary system, the presence or absence of systemic disease, and medications the patient may be taking that might affect the examination or intervention. Warning signs in the cervical region include the following:

- Unexplained weight loss;
- Evidence of compromise to two or three spinal nerve roots;
- A gradual increase in pain;
- Expansion of pain in terms of the regions involved;
- Spasm with passive range of motion of the neck;
- Visual disturbances;
- Painful and weak resistive testing;
- Hoarseness;
- Limited scapular elevation;
- Horner's syndrome;
- T1 palsy (weakness and atrophy of the intrinsic muscles of the hand);
- Arm pain in a patient who is younger than 35 years or in a patient for more than 6 months; and
- Side bending away from the painful side that causes pain (if this is the only motion that causes pain).

It must also be remembered that all cervical patients, especially the ones with a history of a hyperextension mechanism, are at potential risk of serious head and neck injuries, including vertebrobasilar injury (Chapter 24) and cervical myelopathy. Cervical myelopathy (Table 25-6), involving an injury to the spinal cord itself, is associated with multisegmental paresthesias and upper motor neuron (UMN) signs and symptoms such as spasticity, hyperreflexia, visual and balance disturbances, ataxia, and sudden changes in bowel and bladder function. Early indicators of this condition include reports of symptoms in multiple extremities and clumsiness when performing fine motor skills. Myelopathy may occur with compression of the spinal cord and is more likely to occur at the C5–6 level, because in this region the spinal cord is at its widest and the spinal canal at its narrowest.[117] Usually, narrowing of the spinal canal occurs during the end stages of a degenerative disease, although structural anomalies, such as a narrowed trefoil canal or shortened pedicles, can result in congenital stenosis.[10] Depending on the cause, the onset of myelopathy can be sudden or gradual.

T e following signs and symptoms demand a cautious approach or an appropriate referral:

- Recent trauma (occurring up to 6 weeks earlier);
- An acute capsular pattern;
- Severe movement loss, whether capsular or noncapsular;
- Strong spasm;
- Paresthesia;
- Segmental paresis;
- Segmental or multisegmental hyporeflexia or areflexia;
- UMN signs and symptoms (see Chapter 3); these can include reports of neck pain with bilateral upper extremity

TABLE 25-6 The Differential Diagnosis of Myelopathy

Compressive myelopathy
Cervical spondylosis with stenosis
Cervical disk herniation fracture
Spondylolisthesis
Tumor
▯ Vertebral column primary tumor
▯ Metastatic tumor infection
▯ Epidural abscess
▯ Diskitis or osteomyelitis with epidural extension
Epidural hematoma syringomyelia
Medical myelopathy
Idiopathic acute or subacute transverse myelitis
Postinfectious and postvaccination myelitis
Multiple sclerosis
Amyotrophic lateral sclerosis
Infectious myelitis: viral, bacterial, fungal, and parasitic
Arachnoiditis
Vascular disease of the spinal cord
▯ Atherosclerosis
▯ Epidural arteriovenous malformation
Connective tissue disease
Paraneoplastic myelopathy
Metabolic and nutritional disease of the spinal cord
▯ Vitamin B_{12} deficiency
▯ Chronic liver disease
Toxins
Decompression illness (Caisson's disease)
Electrical injury
Radiation injury (postradiation therapy)
Necrotic myelopathy of unknown cause

Data from Spivak JM, Zuckerman JD. Orthopaedics: A Study Guide. New York, NY: McGraw-Hill; 1999:349.

symptoms and occasional reports of loss of balance or lack of coordination of the lower extremities;

- Constant or continuous pain;
- Moderate-to-severe radiating pain;
- Moderate-to-severe headaches;
- Tinnitus;
- History of loss of consciousness;
- Memory loss or forgetfulness;
- Dif culties with problem solving;
- Reduced motivation;
- Irritability;
- Anxiety or depression; and
- Insomnia.

CLINICAL PEARL

Symptoms that respond to mechanical stimuli in a predictable manner are usually considered to have a mechanical source. Symptoms that show no predictable response to mechanical stimuli are unlikely to be mechanical in origin, and their presence should alert the clinician to the possibility of a more sinister disorder or one of central initiation, autonomic, or affective nature.[113]

Neurologic Symptoms

T e presence of neurologic symptoms, including sympathetic symptoms (e.g., blurred vision, sweating, tinnitus), deserves special attention. Many of the symptoms that occur in an upper limb have their origins in the neck. T e patient with neck trauma can report seemingly bizarre symptoms, but these need to be heeded until the clinician can rule out serious pathology. Cervical radiculitis is most commonly associated with spinal nerve root irritation. Peripheral symptoms can also be caused by a host of other conditions, including TOS or an isolated peripheral nerve lesion.[118]

T e systems review must include questions that will elicit any symptoms that might suggest a CNS condition or a vascular compromise to the brain. For example, lower limb symptoms associated with neck motions, dif culty walking, poor balance, or bowel or bladder dysfunction. One of the earlier indications of a balance disturbance can be elicited during the history or systems review with correct questioning. A simple question such as "Do you have dif culty with walking or with balance?" can provide the clinician with valuable information. Positive responses may indicate a cervical myelopathy or systemic neurologic impairment.[119] T e neurologic examination, if appropriate, attempts to differentiate between nerve root and spinal cord compression. T e presence of any UMN sign or symptom requires immediate medical referral.

Vascular Compromise

A history of dizziness, falling, faintness, or seizures always warrants further investigation. It is not always an easy task for the clinician to determine whether the presenting dizziness is the result of a disturbed afferent input from the cervical spine, which can be extremely rewarding to treat, or has a more serious cause.[95] For example, dizziness provoked by head movements may indicate an inner ear or vertebral artery problem. A history of falling without loss of consciousness (drop attack) is strongly suggestive of vertebral artery compromise.[120] Compromise of the vertebral artery (see Chapter 24) should be considered if the observation and history reveal any of the signs and symptoms that have been linked, directly or indirectly, to vertebral artery insuf ciency. T ese include the following:

- Wallenberg's, Horner's, and similar syndromes;
- Bilateral or quadrilateral paresthesia;
- Hemiparesthesia;
- Ataxia;
- Nystagmus;
- Drop attacks;
- Periodic loss of consciousness;
- Lip anesthesia;
- Hemifacial paresthesia or anesthesia;
- Dysphasia; and
- Dysarthria.

A Headache or Facial Pain

Does the patient have headaches and, if so, where? What are their frequency and intensity? Does a position alter the severity of the headache? If the patient reports relief of pain and referred symptoms with the placement of the hand or arm of the affected side on top of the head (shoulder abduction/Bakody's sign), this is usually indicative of a disk lesion of the C4 or C5 level.[121]

A history of headaches may or may not be benign, depending on the frequency and severity. Differential diagnosis is important, especially in light of the fact that there is considerable overlap in symptoms among tension headaches; cervicogenic headaches (see Chapter 23); cervical, trigeminal, and glossopharyngeal neuralgia (see Chapter 5); the headache associated with Lyme disease (see Chapter 5); migraines without aura (see Chapter 5); and TMJ dysfunction (see Chapter 26).[122] Cervicogenic headaches, which can be mild, moderate, or severe, tend to be unilateral and located in the suboccipital region, with a referral to the frontal, retro-orbital, and temporal areas.[70,123] The most serious causes of a headache without a history of trauma include spontaneous subarachnoid hemorrhage, vertebral artery compromise, meningitis, pituitary tumor, brain tumor, and encephalitis (see Chapter 5).

Facial pain can be the consequence of temporomandibular dysfunction, temporal arteritis, acute sinusitis, orbital disease, glaucoma, trigeminal neuralgia, referred pain, and herpes zoster (see Chapter 5).

TESTS AND MEASURES

Due to the complexity of this area, sufficient time must be allowed for a comprehensive examination to ensure that all causes of the signs and symptoms are determined.

Observation

Static observation of general posture, as well as the relationship of the neck on the trunk, and the head on the neck, is carried out while the patient is standing and sitting, both in the waiting area and in the examination room (see Chapter 6). Once in the examination room, the patient is asked to assume an upright neutral postural position from a relaxed sitting position. This can help the clinician to gain an idea of which muscle strategy the patient is using to support the natural spinal curves.[79] A major contributor to cervicogenic pain is a lack of postural control resulting from poor neuromuscular function.[85,122,124,125] Sustained postures, or fatigue overloading of the deep spinal and postural muscles, can result in increased joint compressive forces and inefficient movement strategies.[111,112,126,127] A good pattern when assuming an upright neutral postural position would involve the pelvis being brought into an neutral upright position, with the formation of a low lumbar lordosis (lumbar multifidus) rather than with thoracolumbar extension (thoracopelvic extensors).[79] Postural misalignment of the head on the trunk is associated with complaints of pain in the neck and shoulder region and TMJ dysfunction but is also observed in asymptomatic individuals.

The clinician should look for:

- Hair quality (i.e., brittle hair due to thyroid problems).
- The position of the patient's head. If it is shifted to one side, a disk protrusion may be present; if deviated, acute arthritis may be the cause. Severe or constant pain usually is manifested by the patient constantly changing his or her posture or remaining very still.
- Evidence of the patient being a mouth breather. Mouth breathing encourages forward head posture.
- Evidence of skin cancer, such as unusual looking moles.
- Torticollis.
- Sprengel's deformity, a congenital elevation and medial rotation of the scapula, which gives the patient the appearance of having no neck on one side, secondary to a high-riding scapula.
- Scars (long, transverse scars indicative of cervical surgery), lumps, rashes, thyroid enlargement (goiter), skin discoloration, or other lesions.
- Scoliosis of the thoracic spine.
- Soft tissue contours that can highlight swelling, muscle atrophy, or hypertrophy.
- The position of the thoracic and cervical curves as well as the craniocervical posture.
- Scapular position in association with muscle bulk/tone of the axioscapular-girdle muscles both anteriorly and posteriorly.[79] Ideally, the resting scapulae should sit such that the superior angle lies level with the T2 or T3 spinous process, the root of the spine of the scapula level with the T3 or T4 spinous process, and the inferior angle level with the T7–9 spinous process.[128] Common "abnormal" postural positions of the scapula include a downwardly rotated and protracted scapula, which is often associated with a dominant action of the levator scapular and an increase resting length of the trapezius.[79,92,127] Conversely, the scapula may appear slightly elevated, indicating an adaptively shortened upper trapezius, protective positioning, or neural tissue mechanosensitivity.[79]
- Bone deformities (i.e., endocrine disorders). Conditions include abnormal bony enlargement of the face, jaw, hands, and feet (acromegaly); a "moon-faced," buffalo hump (fatty deposits) at the neck, axial obesity, generalized atrophy of muscles, and kyphotic posture due to excess cortisol production (Cushing's syndrome) or bulging eyes due to excess thyroid hormone (Graves disease).[129]
- Autonomic skin changes (increased sweating, trophic changes, and texture changes).
- Birthmarks.
- Changes in the patient's facial expression suggesting pain with transitional movements.

SIDE VIEW

- The forehead should be vertical.
- The tip of the chin should be in line with the manubrium. If the chin is anterior to the manubrium, a forward head

is present (see later discussion). The amount of forward head can be measured in two ways. The simplest method is to measure the distance between the tip of the chin and the manubrium. The more complex and expensive methods involve the use of computer-assisted digitizing systems.

- The clinician should observe the cervical lordosis. A flattened lordosis may be associated with stretched posterior cervical ligaments and extensor muscles, and adaptively shortened cervical flexors. An excessive lordosis is associated with a forward head and an adaptive shortening of the posterior ligaments and neck extensor muscles.
- The ears are inspected for signs of asymmetry, inflammation, rashes, lumps, scars, or other lesions. Discharge from within the external ear canal may indicate infection (i.e., otitis externa).[129]

POSTERIOR VIEW

- The clinician should assess muscular asymmetry, especially in the upper trapezius and SCM (see also Chapter 16).
- The spinous process of the axis should be in the midline.
- Usually, the shoulder on the dominant side is slightly lower than that on the nondominant side.
- Is there any atrophy of the deltoid suggesting axillary nerve palsy?
- As the patient rotates the head to each side, the tips of the transverse processes of the atlas should be felt to rotate anteriorly and then posteriorly. Both sides are compared. The procedure is repeated for side bending. The transverse process should become less prominent and should approximate the mastoid process, on the side of the side bending.

ANTERIOR VIEW

- The clinician should assess whether the patient's head is shifted to one side. A cervical disk protrusion (C3–4 or C4–5) can produce a horizontal side shift of the head.[83] This is side shift allows the patient to maintain eye level.
- A slight tilt of the head is normal but may indicate an upper cervical joint dysfunction.
- The eyes should be inspected for ptosis (droopy eyelid). The patient should be instructed to look up, while the clinician gently pulls down both lower eyelids to inspect the conjunctiva (for signs of anemia—bluish appearanc; and conjunctivitis—redness) and sclera (for jaundice—yellowish appearance).[129] The eyes should also be observed for other signs of discoloration, discharge, and any deformity of the iris. The clinician should also note any evidence of nystagmus (see Chapter 3), which may be positional and fatigable and which may be caused by a lesion anywhere from the eyes to the midbrain.[130] A Dix–Hallpike test (see Chapter 3) should be carried out in patients suspected of having a vestibular disorder.[130]
- Facial symmetry. The clinician visually splits the mass of the head into two vertical halves. Cerebral asymmetries in form and volume, associated with cranial asymmetries, are a common feature of the human race and are often associated with facial asymmetries.[131,132] This is asymmetry is, in many cases, related to asymmetric cerebral growth, which is mostly accomplished in utero,[133,134] although it may also have a local origin, for instance, in the case of mandibular asymmetry. Facial asymmetry can also be due to facial nerve (CN VII) paralysis or partial weakness. The trigeminal nerve (CN V) may be involved if asymmetry (deviation) is observed in the mouth due to muscle weakness or atrophy on one side of the jaw.[129]

Forward Head

The cervical and upper thoracic regions are highly prone to postural and degenerative dysfunctions. Poor posture and dysfunctional movement patterns may alter the normal segmental motion of the neighboring regions (Table 25-7). A forwardly inclined head increases the stresses at the cervicothoracic junction and increases the craniovertebral lordosis, producing a compensatory occipitoatlantal extension.

In the forward head posture, the upper trapezius can be maintained in a constant state of contraction[36] (Table 25-7). This is constant state of contraction can also occur as a result of a protective mechanism for the cervical joints, ligaments, or IVD.[135]

This is hypertonicity of the upper trapezius produces a paravertebral area that is broader and more prominent than normal. Tightness or adaptive shortening of the levator scapulae results in the contour of the neckline appearing as a double line (wave) where the muscle inserts into the scapula.[84] This is is described as Gothic shoulders because it is reminiscent of the form of a Gothic church tower.

Movement patterns performed on a poor postural base contribute to repetitive microtrauma of cervical structures. These structures include the zygapophyseal facets, IVD, ligaments, joint capsules, and muscles, all of which are capable of propagating the cycle of pain and dysfunction.[136,137]

Active Range of Motion

The clinical examination of the mobility of the cervical spine should consist of a comparison between active and passive ranges and coupled movements of the cervical spine. Knowledge of cervical anatomy and kinematics should assist the clinician in determining the structure responsible, based on the pattern of movement restriction noted in the physical examination (Table 25-8). The range-of-motion assessment of the craniovertebral region is described in Chapter 23.

The range of motion available at the cervical spine is the result of such factors as the motion available at each segment, the shape and orientation of the zygapophyseal joint surfaces, the inherent flexibility of the restraining ligaments and joint capsules, the height and pliability of the IVD, and the range available in the craniovertebral and upper thoracic joints. A movement restriction is a loss of movement in a specific direction, and one in which a movement toward or away from the

TABLE 25-7 Potential Consequences of the Forward Head

Deficit	Impairment	Effect
Cervical hyperlordosis	Overclosing of TMJ	Trigeminal facilitation
	Posterior compression	Suboccipital hypertonicity
	Capsular ligament injury	Scalene hypertonicity with first rib impairment
	Meniscal derangement	Trigeminal facilitation
	Craniovertebral Hyperextension	
	O-A flexion hypomobility	Masticator hypertonicity
	A-A rotation hypomobility	TMJ impairment
	O-A extension hypermobility	
	Craniovertebral instability	
	Midcervical hyperextension	C4 facilitation
	Flexion hypomobility	Levator scapulae hypertonicity with adduction of scapula and overuse of supraspinatus
	Extension hypermobility	
	Anterior instabilities	C5 facilitation
		Rotator cuff hypertonicity
		Tennis elbow
Shoulder protraction	Glenohumeral instability	Supraspinatus tendonitis
	Acromioclavicular instability	Infraspinatus tendonitis
		Acromioclavicular sprain
Cervicothoracic hyperkyphosis	Extension hypomobilities	Shoulder girdle hypomobility
		Glenohumeral instability
		Acromioclavicular instability
		Supraspinatus tendonitis

A-A, atlantoaxial; O-A, occipitoatlantal; TMJ, temporomandibular joint.

Data from Troyanovich SJ, Harrison DE, Harrison DD. Structural rehabilitation of the spine and posture: rationale for treatment beyond the resolution of symptoms. J Manipulative Phys Ther. 1998;21:37–50; Mannheimer JS. Prevention and restoration of abnormal upper quarter posture. In: Gelb H, Gelb M, eds. Postural Considerations in the Diagnosis and Treatment of Cranio-Cervical-Mandibular and Related Chronic Pain Disorders. St. Louis, MO: Ishiyaku EuroAmerica, 1991:93–161; Meadows JTS. Manual Therapy: Biomechanical Assessment and Treatment, Advanced Technique. Calgary: Swodeam Consulting, Inc., 1995.

restriction may alter the degree and location of those symptoms. When the cervical range of motion (CROM) is painful or restricted, muscle pathology is suggested if the restricted motion exists in the direction opposite to the action of the involved muscles. The clinician can apply resistance to the indicated muscle group(s) to verify this hypothesis.

CLINICAL PEARL

A motion that is restricted but painless, or normal but painful, could indicate a hypomobility. Pain that is produced by the motion that is restricted indicates an acute or subacute injury, whereas pain that is produced by the motion that is not restricted, or excessive, could indicate a hypermobility.

Because of the close relationship of the shoulder to the cervical spine, active elevation of each upper extremity should be assessed to rule out symptom reproduction from the shoulder movements. If there is a loss of one of the cervical motions, the restricted motion should be examined more closely by separating the motion into its various components. For example, a full cervical rotation requires motion at the craniovertebral joints, particularly the atlantoaxial joint, as well as segmental rotation at each of the cervical segments.

TABLE 25-8 Movement Restriction and Possible Causes

Movement Restriction	Possible Causes
Extension and right side bending	Right extension hypomobility
	Left flexor muscle tightness
	Anterior capsular adhesions
	Right subluxation
	Right small disk protrusion
Flexion and right side bending	Left flexion hypomobility
	Left extensor muscle tightness
	Left posterior capsular adhesions
	Left subluxation
Extension and right side bending restriction greater than extension and left side bending	Left capsular pattern (arthritis and arthrosis)
Flexion and right side bending restriction equal to extension and left side flexion	Left arthrofibrosis (very hard capsular end-feel)
Side bending in neutral, flexion, and extension	Uncovertebral hypomobility or anomaly

CLINICAL PEARL

Radiographic evaluation has long been considered the "gold standard" for studying CROM.[138–142] However, this method is invasive and is generally not feasible or practical. However, in situations in which accurate and reliable cervical ROM evaluation is needed, radiographic evaluation is the method of choice because of its greater sensitivity.[142]

The major movements that are assessed clinically are rotations out of neutral position VIDEO flexion–extension, and side bending (Fig. 25-12A-D). The most painful movements are performed last so that no residual pain is carried over from the previous movement. The dual inclinometer method recommended in the American Medical Association's Guides to the Evaluation *of* Permanent Impairment[143] and is often considered the clinical standard for assessing cervical ROM in the clinic.[144,145] This method requires accurate identification of anatomic landmarks (Table 25-9). Both inter- and intrarater reliability studies have shown the inclinometry method to be reliable.[146–149] Others dispute this conclusion and contend that the inclinometer method is flawed and should not be used in clinical settings.[150,151] Using the inclinometer technique, the normal active ranges of motion for the cervical spine are as follows:

- Forward flexion: 45–50 degrees;
- Extension: 85 degrees;
- Side bending: 40 degrees; and
- Rotation: 70–90 degrees.

The CROM instrument, introduced on the market by Performance Attainment Associates (Roseville, MN), measures the CROM for flexion, extension, side bending, and rotation using separate inclinometers. These inclinometers are attached to a frame similar to that for eyeglasses: one in the sagittal plane for flexion–extension, a second in the frontal plane for side bending, and a third in the horizontal plane of rotation.[140] Two of these inclinometers have a gravity-dependent needle (in the sagittal and frontal planes), and the other has a magnetic needle (in the horizontal plane).[140] A magnetic neck brace is worn by the patient. Several researchers have studied the instrument to investigate its intrarater and interrater reliability. Youdas et al.[150] reported an intraclass correlation coefficient (ICC) varying from 0.73 to 0.95 and an interrater reliability from 0.73 to 0.92 for six cervical movements assessed in 20 patients with orthopaedic disorders.[140] Capuano-Pucci et al.[146] obtained similar results with 20 healthy subjects.[140] A study by Tousignant et al.,[140] which attempted to estimate the criterion validity of the CROM goniometer using a healthy population, found the device to be valid for measurements of cervical flexion and extension. In a more recent study, which compared range-of-motion measurements using a CROM goniometer and an optoelectronic system (OPTOTRAK), Tousignant et al[141] reported that the CROM device showed excellent criterion validity for measurements of cervical rotation. Wainner et al.[152] used an inclinometer and a

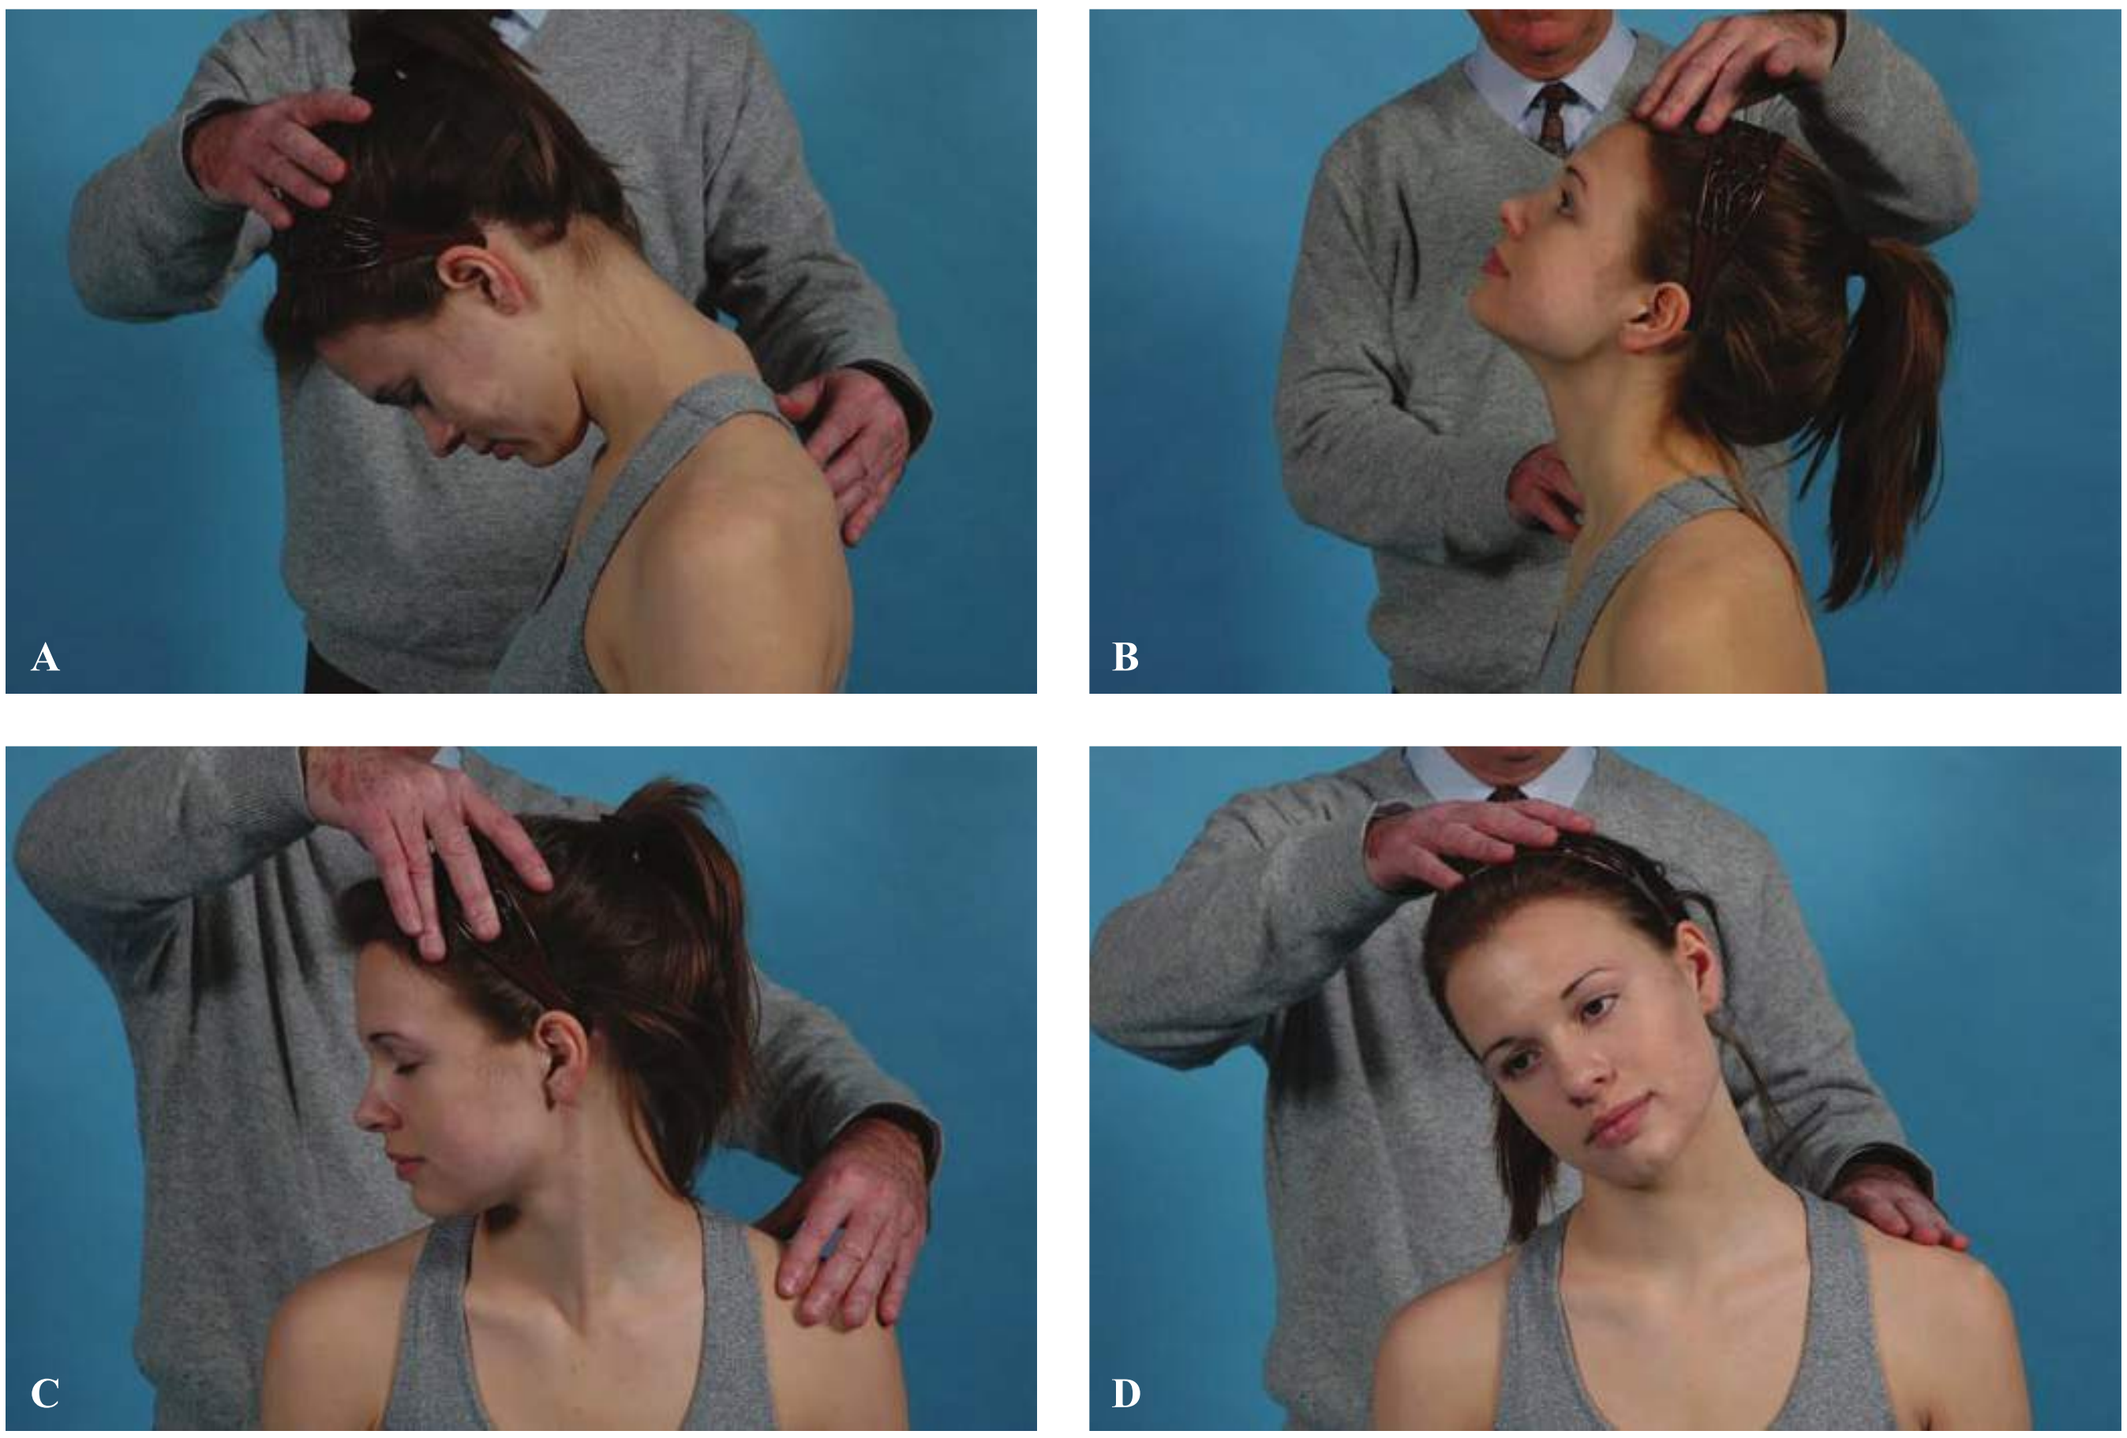

FIGURE 25-12 Cervical active range of motion with passive overpressure and resistance. A: Flexion. B: Extension. C: Rotation. D: Side bending.

TABLE 25-9 The American Medical Association Inclinometer Technique for Measuring Cervical ROM

Range	Method
Flexion	Two inclinometers are used, which are aligned in the sagittal plane. The center of the first inclinometer is placed over the T1 spinous process. The center of the second one is placed on top of the head, parallel to a line drawn from the corner of the eye to the ear, where the temple of eyeglasses would sit. The patient is asked to flex the neck, and both inclinometer angles are recorded. The cervical flexion angle is calculated by subtracting the T1 from the calvarium inclinometer angle.
Extension	Two inclinometers can be used, which are aligned as for measuring cervical flexion. The patient is asked to extend the neck, and both inclinometer angles are recorded. The cervical extension angle is calculated by subtracting the T1 from the calvarium inclinometer angle.
Rotation	The patient is positioned supine. One inclinometer is used, and it is aligned in the transverse plane. The base of the inclinometer is placed over the forehead. The patient is asked to rotate the neck, and the inclinometer angle is recorded. The test is repeated on the other side.
Side bending	Two inclinometers are used, which are aligned in the coronal plane. The center of the first inclinometer is placed over the T1 spinous process. The center of the second one is placed on top of the head, over the calvarium. The patient is asked to side bend the neck, and both inclinometer angles are recorded. The cervical side-bending angle is calculated by subtracting the T1 from the calvarium inclinometer angle.

ROM, range of motion.

goniometer in 50 patients with suspected cervical radiculopathy or carpal tunnel syndrome. The results of this study are summarized in Table 25-10.

Whichever method is chosen, it is important to remember that, as with other joints in the body, the range of motion in the cervical spine may vary according to a number of factors including the structural ones already mentioned. The available range of motion may be reduced based on the individual's age, neck girth and length, body habitus, diurnal changes,[153] neurologic disease, or other factors unrelated to the disability for which the exam is being performed. Without taking body size into account, measurements may underestimate or overestimate range of motion.[154] The decrease due to age is probably because of the development of degenerative changes, the only exception being the rotation available at C1–2, which may increase.[155] Gender influences on cervical mobility are somewhat more controversial. Dvorak et al.[155] reported women having greater CROM compared with men,

TABLE 25-10 Reliability of Cervical ROM Testing Using a Goniometer and Inclinometer

Motion	Instrumentation	Interexaminer Reliability ICC (95% CI)
Flexion	Inclinometer	0.79 (0.65, 0.88)
Extension	Inclinometer	0.84 (0.70, 0.95)
Left rotation	Goniometer	0.75 (0.59, 0.85)
Right rotation	Goniometer	0.63 (0.22, 0.82)
Left side bending	Inclinometer	0.63 (0.40, 0.78)
Right side bending	Inclinometer	0.68 (0.62, 0.87)

ROM, range of motion.
Data from Wainner RS, Fritz JM, Irrgang JJ, et al. Reliability and diagnostic accuracy of the clinical examination and patient self-report measures for cervical radiculopathy. Spine. 2003;28:52–62; Cleland J: Cervical Spine, Orthopaedic Clinical Examination: An Evidence-Based Approach for Physical Therapists. Carlstadt, NJ: Icon Learning Systems, LLC; 2005:92–140.

whereas other studies have shown men have greater available flexion,[156,157] women have a greater range in cervical extension only,[145] or that that gender is not a variable in CROM.[158]

Biomechanical studies have shown that during flexion of the cervical spine, the segments below the second vertebra are blocked.[14] Therefore, rotation out of maximum flexion of the cervical spine occurs at the atlantoaxial joint. However, rotation out of maximum extension occurs predominantly in the middle and lower cervical spine but includes the atlantoaxial joint, as well.[159]

Each of the active motions is tested with a gentle overpressure applied at the end of the range if the active range appears to be full and pain free. With the exception of rotation, the weight of the head usually provides sufficient overpressure. It is necessary to apply overpressure even in the presence of pain, in order to achieve an end-feel. If the application of overpressure produces pain, the presence of an acute muscle spasm is possible. Caution must be taken when using overpressure in the direction of rotation, especially if the rotation is combined with ipsilateral side bending and extension because this can compromise the vertebral artery.[160] Given the variability in CROM in the literature even with "normal" patients, recording absolute ranges of motion is perhaps not as important in the presence of pain and dysfunction as the assessment of the following:

- Quality and quantity of the motion. Quantity and quality of movement refer to the patient's ability to achieve the end range of cervical motion with a normal curve reversal and without any deviation from the intended movement plane.[161]
- Symptoms provoked. According to McKenzie, the use of repeated movements to provoke symptoms helps to differentiate between the postural, dysfunction, and derangement syndromes (see Chapter 22). For example, the pain of postural origin does not occur with repeated movements and does not limit movement in any direction but is felt only when the patient is stationary or when static loading has been prolonged. In contrast, the pain

experienced in the dysfunction syndrome is immediately felt when movement reaches the end of the limited range but stops immediately when the end range position is released. In addition, the pain felt by the patient with a dysfunction syndrome is always intermittent and is the same each day, provided that their activity levels are consistent. In the derangement syndromes, the symptoms can be produced or abolished, increased or decreased, or centralized or peripheralized in response to repeated movements or sustained positions.

- The willingness of the patient to move.
- The presence of specific patterns of restriction. According to Cyriax,[162] the capsular pattern of the cervical spine is full flexion in the presence of limited extension, and symmetric limitation of rotation and side bending.

When interpreting the motion findings, the position of the joint at the beginning of the test should be correlated with the subsequent mobility noted, because alterations in joint mobility may merely reflect an altered starting position.

Flexion

An assessment of the gross range of motion of cervical flexion is performed (Fig. 25-12A), and the clinician makes note of any motion that reproduces or enhances the symptoms and the location of the symptoms. Considerable emphasis should be placed on the amount and quality of flexion available, and the symptoms it provokes because flexion is the only motion normally tolerated well by the cervical spine. If the patient has poor concentric control of the deep neck flexors, the SCM will initiate the flexion movement, which will result in the jaw leading the movement instead of the nose (the SCM initially protrudes the chin before flexion occurs). The extreme of cervical flexion is normally found when the chin is able to reach the chest with the mouth closed, although a gap of up to two finger widths is also considered normal.

If end-range flexion is immediately painful, meningitis or acute radicular pain should be ruled out. If the pain is felt after a 15–20-second delay, ligament pain should be suspected. The most common restrictions to cervical flexion are an upper thoracic or cervicothoracic restriction or an occipitoatlantal joint restriction. If, during flexion, the patient pivots the head and neck over a hypomobile and fixed cervicothoracic region, the excessive motion will be noted at the levels of C4–6.

Flexion may also be limited by acute or severe trauma (muscle spasms straighten the lordosis), fracture dislocations, or IVD dysfunction.

Extension

The patient is asked to extend the neck (Fig. 25-12B). Normal extension motion allows the face to be parallel with the ceiling. The deep cervical flexors with their extensive longitudinal intersegmental attachments from the upper thoracic spine to the skull are best suited to control extension.[79] If the patient has poor eccentric control of the deep neck flexors, two characteristic patterns of movement are evident[79]:

- There is minimal, if any, movement of the head posteriorly during extension.
- At some point during the extension, the head appears to drop or translate backward.

The return from a fully extended position to a neutral upright position requires a coordinated concentric contraction of the cranial cervical flexors.

Cervical flexion or cervical extension can provoke dizziness. This is finding is thought to result from an osteophytic compression on the posterolateral aspect of the transverse foramen by the inferior articulating surface of the zygapophyseal joint.[163] Cervical distraction can be applied at the point of symptom provocation. If this maneuver increases the symptoms, manual or mechanical traction should not be part of the intervention plan.

Rotation

With rotation, the chin should be in line with the acromioclavicular joint at the end of the rotation (see Fig. 25-12C).

Limitation of or pain on cervical rotation usually suggests pathology at the C1–C2 (atlantoaxial) segment, because most rotation occurs at this joint.[110] However, if a patient is able to achieve 40–50 degrees of cervical rotation while maintaining eye level, atlantoaxial involvement is unlikely. If, on the other hand, the neck has to side bend early in the active rotation range in order to achieve full motion, the atlantoaxial joint is likely to be involved. If the full rotation is limited and cannot be achieved even with the substitution of neck side bending, the problem is likely with the mid-to-low cervical spine segments.

Two screening tests can be used to highlight the level of a rotation restriction. Both the tests utilize rotation of the neck, with the neck in various amounts of flexion.

1. Rotation with the neck in full side bending is reported to test the C1–2 level.
2. Rotation with the neck in a chin tuck tests the C2–3 level.

Side Bending

Side bending is performed to the left and right, while the ipsilateral and contralateral shoulder are monitored for movement by the clinician as stabilization of the ipsilateral shoulder merely tests the length of the upper trapezius (Fig. 25-12D). The range of side bending is always greater in the supine than in the sitting position. Active side bending is typically the first motion to demonstrate problems of the cervical spine.[164] Restricted cervical side bending could be the result of joint restriction, muscle tightness, or lack of pain-free movement or extensibility of the neural tissues.[69]

Finally, if, in the history, the patient has reported that repetitive movements or sustained postures have caused problems, these should be reproduced to try and provoke the symptoms.

PASSIVE RANGE OF MOTION

In those situations where the patient does not have full active range of motion and even in those situations when overpressure has been applied at the end of active range of motion to determine the end-feel, passive range of motion must be assessed. This is is best performed with the patient in supine to relax the muscles. Due to this muscle relaxation, passive range of motion in supine is greater than in sitting, particularly with side bending (approximately 45 degrees in sitting but

FIGURE 25-13 Cervical extension, side bending, and rotation.

75–80 degrees in supine), so an assessment of the end-feel in sitting can ot en be misleading. With each of the cervical motions, the end-feel should be a solid tissue stretch. As with the active motions, the most painful movements are performed last. Further assessment of passive movements can include position testing, and passive physiological intervertebral motion testing (see section "Differing Philosophies").

Combined Motion Testing

Because normal cervical function involves complex and combined motions, and because symptoms may only occur with these combined motions, combined motion testing may need to be assessed. Combined motion testing typically occurs when the testing of single plane motions (flexion, extension, side bending, and rotation) and end-feels were found to be normal and pain-free.

Using the osteopathic model, a restriction of cervical extension, side bending, and rotation (Fig. 25-13) to the same side as the pain is termed a closing restriction. T is restriction is the most common pattern producing distal symptoms. However, a limitation in cervical flexion accompanied by the production of distal symptoms can also occur.[164] Side bending toward or away from the side of the pain can also reproduce upper extremity symptoms, depending on the cause. Pain caused by intervertebral foraminal narrowing may be increased with ipsilateral side bending. Pain caused by an IVD protrusion may be increased with contralateral side bending.

A restriction of the opposite motions (cervical flexion, side bending, and rotation to the opposite side of the pain) is termed an opening restriction. Opening restrictions are slightly more dif cult to identify in the cervical spine because, frequently, there is no actual restriction of cervical flexion, but rather a restriction of rotation and side bending, along with reproduction of pain on the contralateral side.[164]

McKenzie[116] advocates using neck retraction and protrusion, with other motions and positions being superimposed. Neck protrusion produces an extension of the upper cervical spine and flexion of the mid and lower cervical spine, whereas neck retraction produces a flexion of the upper cervical spine and an extension of the mid and lower cervical spine. Neck retraction is performed with extension (Fig. 25-14), side bending (Fig. 25-15), and rotation to both sides in sitting

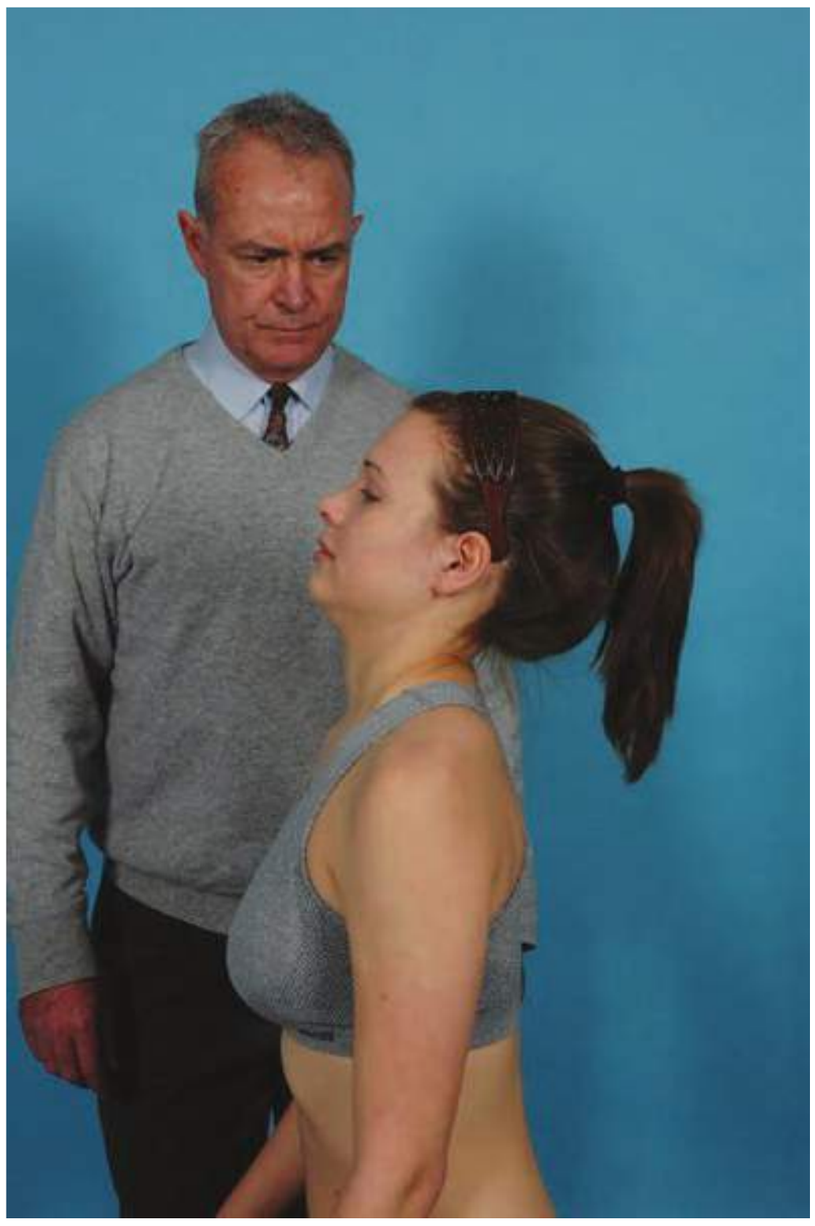

FIGURE 25-14 Neck retraction in extension.

position and then prone, with the head off the end of the table (Figs. 25-16 and 25-17). T e results from these motions are combined with the findings from the history and the single-plane motions to categorize the symptomatic responses into one of three syndromes: postural, dysfunction, or derangement. T is information can guide the clinician as to which motions to use in the intervention.

FIGURE 25-18 Resisted cervical rotation.

Key Muscle Testing

The purpose of resisted testing is outlined in Chapters 3 and 4. There are numerous smaller muscles throughout this area, so resistance needs to be applied gradually. The same movements that were done actively are tested isometrically. Some of these muscles are also tested as part of the Cyriax upper quarter scanning examination (see Chapter 4) and are used as a peripheral joint scanning examination to determine muscle power and possible neurological weakness. Ideally, the clinician should place the joint in its resting position before testing each muscle, and the contraction should be held for at least 5 seconds.

Resisted Cervical Flexion

Resisted cervical flexion tests the key muscle of C1–2, and cranial nerve XI (spinal accessory).

Resisted Cervical Rotation

Resisted cervical rotation (Fig. 25-18) tests the key muscle of C2.

Resisted Cervical Side Bending

Resisted side bending tests the key muscle of C3, and cranial nerve XI (Fig. 25-19).

Scapular Elevators (C4 and cranial nerve XI)

The clinician asks the patient to elevate the shoulders about one-half of full elevation. The clinician applies a downward force to both shoulders while the patient resists (Fig. 25-20).

Diaphragm (C4). Using a tape measure, the clinician measures the amount of rib expansion that occurs with a deep breath (Fig. 25-21). A comparison is made to a similar measurement at rest. Four measurement positions are used:

1. Fourth lateral intercostal space;
2. Axilla;
3. Nipple line; and
4. Tenth rib.

Shoulder Abduction (C5)

The clinician asks the patient to abduct the arms to approximately 80–90 degrees, with the forearms in neutral. The clinician applies a downward force on the humerus while the patient resists (Fig. 25-22).

Shoulder External Rotation (C5)

The clinician asks the patient to put the arms by the sides, with the elbows flexed to 90 degrees and the forearms in neutral. The clinician applies an inward force to the forearms (Fig. 25-23).

FIGURE 25-17 Neck retraction in prone—terminal position.

FIGURE 25-19 Resisted cervical side bending.

FIGURE 25-20 Resisted shoulder elevation.

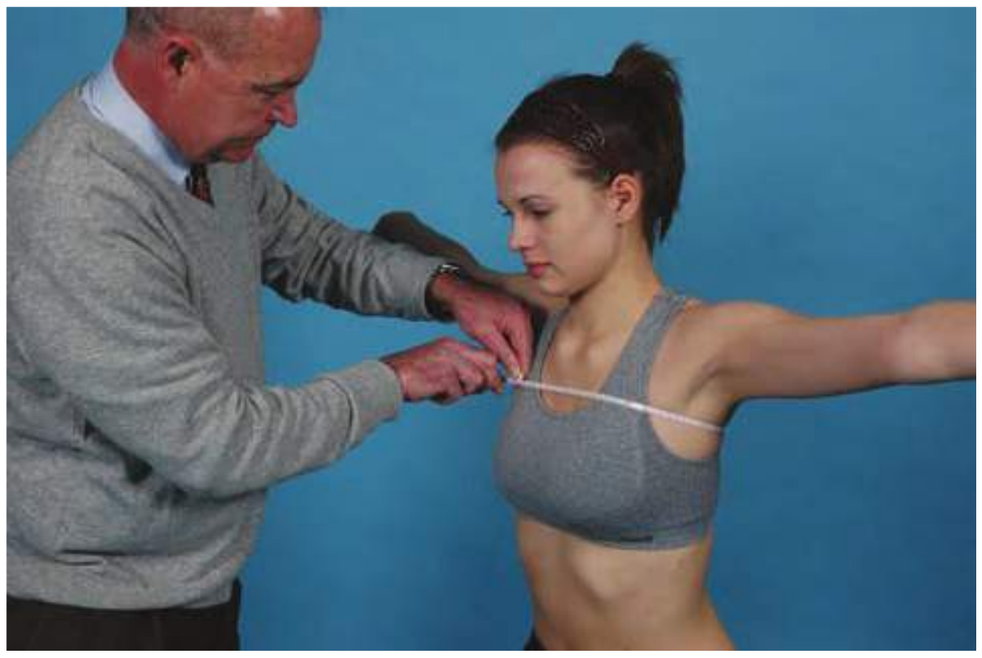

FIGURE 25-21 Chest expansion measurement.

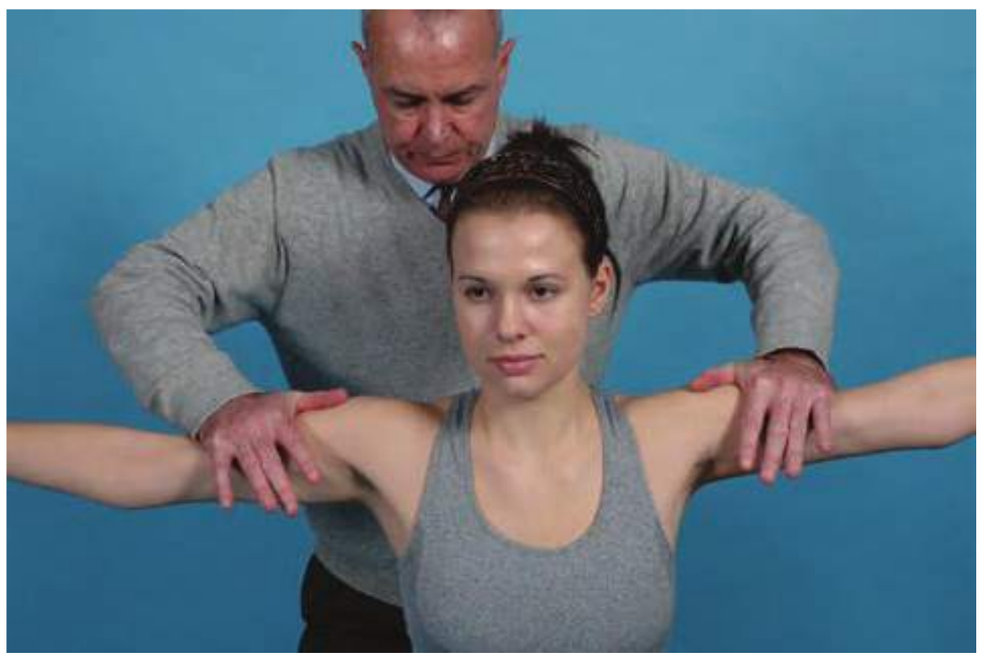

FIGURE 25-22 Resisted shoulder abduction.

FIGURE 25-23 Resisted shoulder external rotation.

FIGURE 25-24 Resisted elbow flexion.

Elbow Flexion (C6)

The clinician asks the patient to position the arms, with the elbows flexed to 90 degrees and the forearms supinated. The clinician applies a downward force to the forearms (Fig. 25-24).

Wrist Extension (C6)

The clinician asks the patient to place the arms by the sides, with the elbows flexed to 90 degrees and the forearms in neutral. The clinician applies a downward force to the back of the patient's extended wrist (Fig. 25-25).

Shoulder Internal Rotation (C6)

The clinician asks the patient to put the arms by the sides, with the elbows flexed to 90 degrees and the forearms in neutral. The clinician applies an outward force to the forearms (Fig. 25-26).

Elbow Extension (C7)

The patient is seated with the arm above the head, and the elbow flexed. The clinician stands beside the patient and tests the triceps by grasping the patient's forearm and attempting to flex the elbow (Fig. 25-27).

FIGURE 25-25 Resisted wrist extension.

FIGURE 25-26 Resisted shoulder internal rotation.

FIGURE 25-28 Resisted wrist flexion.

Wrist Flexion (C7)

The clinician asks the patient to place the arms out in front, with the elbows flexed slightly and the forearms in neutral. The clinician applies an upward force to the palm of the patient's flexed wrist (Fig. 25-28).

Thumb Extension (C8)

The patient extends the thumb just short of the full range of motion. The clinician stabilizes the patient's wrist with one hand and applies an isometric force into thumb flexion with the other (Fig. 25-29).

Hand Intrinsic (T1)

The patient is asked to squeeze the clinician's fingers between their fingers while the clinician tries to pull their fingers away (Fig. 25-30).

Based on the findings from the history, systems review, and key muscle testing, a sensory examination may be necessary (see Chapter 3).

Strength Testing of the Deep Segmental and Postural Support Muscles

Deep Neck Flexors

The patient is positioned in supine, with the knees bent and the feet flat on the bed. The patient's head and neck are positioned in the desired midrange neutral position of the craniocervical region—where the line of the forehead and chin is in a horizontal plane, and an imaginary line extending from the tragus and bisecting the neck longitudinally is parallel to the bed. If the patient does not adopt this position automatically, padding may be used. Once the correct position is obtained, an inflatable pressure sensor (Stabilizer,

FIGURE 25-29 Resisted thumb extension.

FIGURE 25-30 Strength test for finger adductors (hand intrinsics).

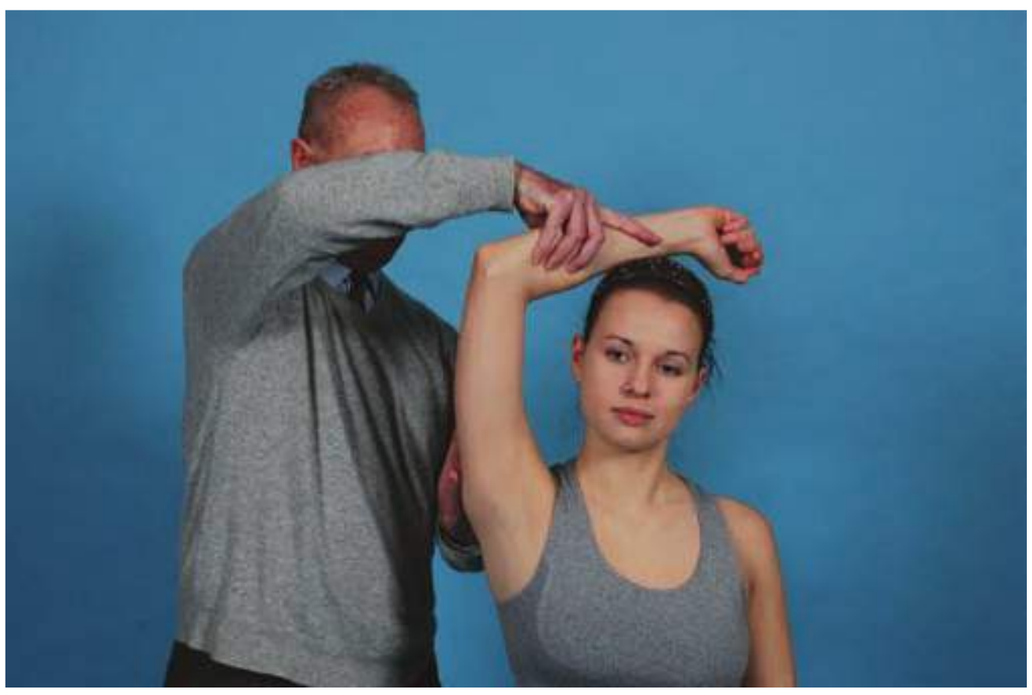

FIGURE 25-27 Resisted elbow extension.

FIGURE 25-31 Muscle function testing of deep neck flexors.

Chattanooga, South Pacific) is folded in three and positioned suboccipitally behind the neck (Fig. 25-31), such that it abuts the occiput. The bladder is inflated until the pressure is stabilized on the baseline of 20 mm Hg, a volume sufficient to just fill the space between the bed and the patient's neck, without exerting any pressure on the neck. The patient is instructed to gently nod the head slowly in an arc-like motion as if saying "yes," while the clinician notes both the quality and the quantity of motion. Ideally, there should be a pattern of progressively increasing craniocervical flexion (Table 25-11). With weak deep neck flexors in the presence of a strong SCM, the jaw juts forward at the beginning of the movement, producing hyperextension of the craniovertebral junction[85] (Fig. 25-32). Confirmation is made by applying a very slight amount of resistance (2–4 g) against the patient's forehead.

Holding Capacity of Deep Segmental and Postural Support Muscles

These tests are designed to assess the ability of a muscle group to sustain a low-load isometric contraction and to replicate the muscle group's function.

Deep Neck Flexors

The deep flexors of the craniovertebral and cervical regions are assessed by testing the patient's ability to sustain a precise inner range upper cervical flexion action.[69]

The patient is positioned in supine, with the head being supported on a folded towel, the knees flexed, and the feet flat on the bed. The inflatable pressure sensor is again positioned suboccipitally behind the neck (Fig. 25-31), and the bladder is inflated to 22 mm Hg to just fill the space between the bed and the patient's neck, without exerting any pressure on the neck.

The patient is asked to bring the chin toward the sternum in a gentle and slow manner. Ideally, the patient should attempt to target five incremental pressure targets (in increments of 2 mm Hg) from the baseline level of 22 mm Hg.[69]

TABLE 25-11 Common Faults in Performance of the Craniocervical Flexion Test and Suggestions for Correction

Common Faults	Correction
The patient performs a neck retraction movement rather than the rotation action of craniocervical flexion	Teach the patient to initiate the movement with their eyes. Look down with the eyes and follow with a slow and controlled chin nod. Look up to the ceiling with the eyes only and follow with the chin to resume the neutral position. Emphasize the sliding of the occiput on the bed to achieve the pure craniocervical flexion. The clinician may guide the movement with fingers placed on either side of the patient's head.
The pressure change is achieved using excessive superficial muscle activity	Palpate the sternocleidomastoid and scalene muscles during the test, to give the patient an awareness of the superficial muscle contraction. Limit the range of craniocervical flexion to the point just short of palpating the dominant superficial muscle activity. Teach the patient self-palpation and an awareness of the correct action. EMG biofeedback may also be beneficial, while the patient practices a slow and controlled craniocervical flexion.
The patient rests in a position of flexion, with associated tension in the scalene muscles	Re-educate the awareness of the neutral position by focusing the eyes on the ceiling above the head, lifting the chin, and palpating the relaxation in the scalenes. Relaxation training may be required in cases of anxiety. Diaphragmatic breathing training can help to relax the respiratory accessory muscles.
There is evident jaw clenching and use of the jaw muscles	Instruct the patient in the relaxed position of the mandible—the anterior one-third of the tongue on the roof of the mouth, lips together, teeth apart.
The patient is holding their breath	Instruct in relaxed nasal breathing while performing the exercise
The patient performs the action quickly and often overshoots the target pressure	Reteach the craniocervical flexion action and emphasize that the movement should be slow and controlled.

Data from Jull GA, Falla D, Treleaven J, et al. A therapeutic exercise approach or cervical disorders. In: Boyling JD, Jull GA, eds. Grieve's Modern Manual Therapy: The Vertebral Column. Philadelphia, PA: Churchill Livingstone; 2004:451–470.

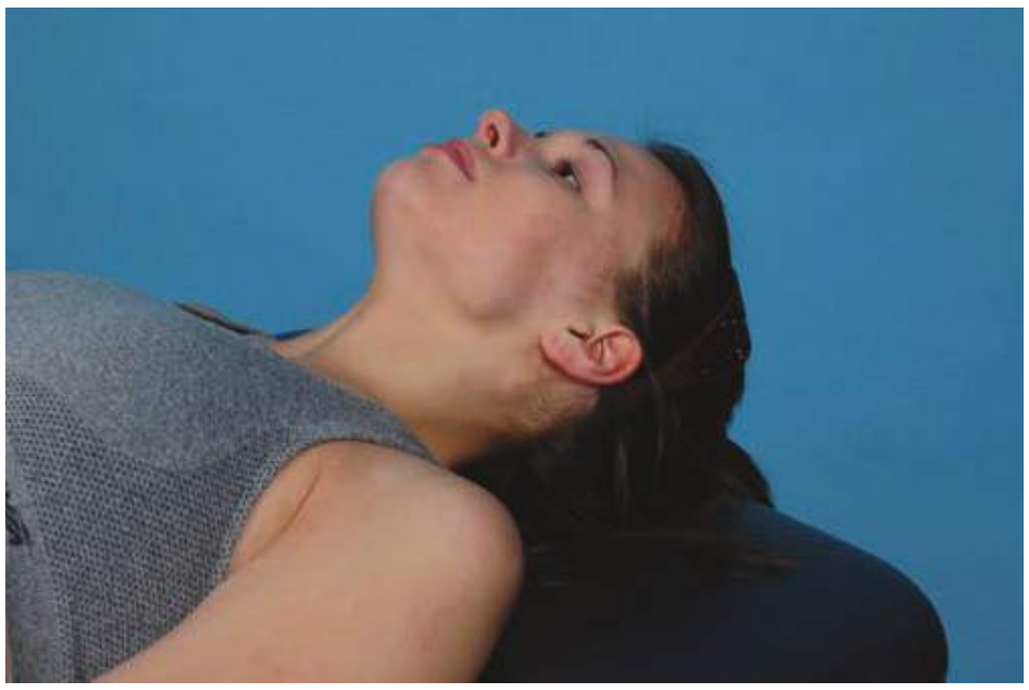

FIGURE 25-32 Patient demonstrating weak neck flexors in the presence of a strong SCM.

Lower Scapular Stabilizers

The mid and lower trapezius and serratus anterior muscles can be assessed with the patient positioned in prone or sitting. The patient is asked to sustain the scapula against the chest wall in a position of retraction and depression (Fig. 25-33) while the clinician palpates over the muscles.[69] The end-range position is sustained for 10 seconds, and the test is repeated 10 times.

Retraining the postural support muscles involves postural education initially, an emphasis on the relaxation of unwanted muscle activity, and repeated repetitions of 10-second holds of the corrected scapula position.

FIGURE 25-33 Testing the holding capacity of the lower scapular stabilizers (clinician not shown).

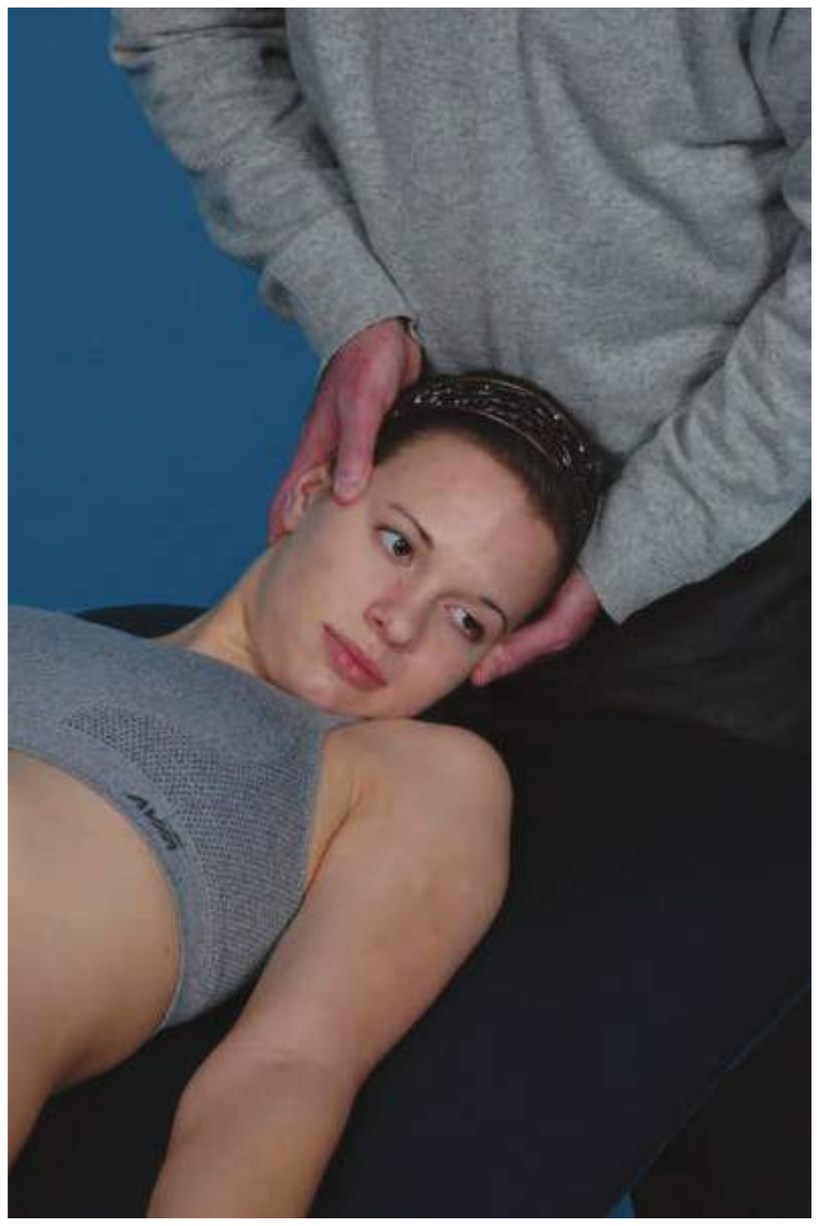

FIGURE 25-34 Cervical flexion, contralateral side flexion, and ipsilateral rotation. The amount of available rotation in this patient is minimal.

Muscle Length Testing

Upper Trapezius

The upper trapezius has a tendency to become adaptively shortened and overactive, which can have the effect of pulling the head laterally, as well as increasing the craniovertebral and cervical lordosis.[165]

The patient is positioned in supine. The patient's head is maximally flexed, inclined to the contralateral side (Fig. 25-34), and ipsilaterally rotated. A normal finding is free movement of about 45 degrees of rotation, with a soft motion barrier. Any tightness of this muscle can result in a restriction in the range of motion and a hard barrier.

Levator Scapulae

A quick test to determine the extensibility of the levator involves positioning the patient sitting. The patient is asked to place one hand on the head.[164] For example, the right hand if the length of the right levator is to be tested, the patient's neck and head are positioned in left side flexion, and the patient is asked to abduct the left arm as far as possible. Normal extensibility of the levator and the rhomboids, and the absence of shoulder girdle pathology should allow the patient to abduct the arm fully, while the head is side bent away (Fig. 25-35). The test is repeated on the other side for comparison.

The more specific test involves positioning the patient in supine. The clinician maximally flexes the patient's head (Fig. 25-36), induces contralateral rotation, and inclines the head toward the contralateral side. The clinician then depresses the patient's shoulder distally. If tightness is present,

FIGURE 25-35 Muscle length test of levator scapulae.

there will be tenderness at the levator insertion and a restriction of movement to less than 45 degrees.

Sternocleidomastoid

The SCM muscle has a tendency to become adaptively shortened and overactive, which can have the effect of altering the

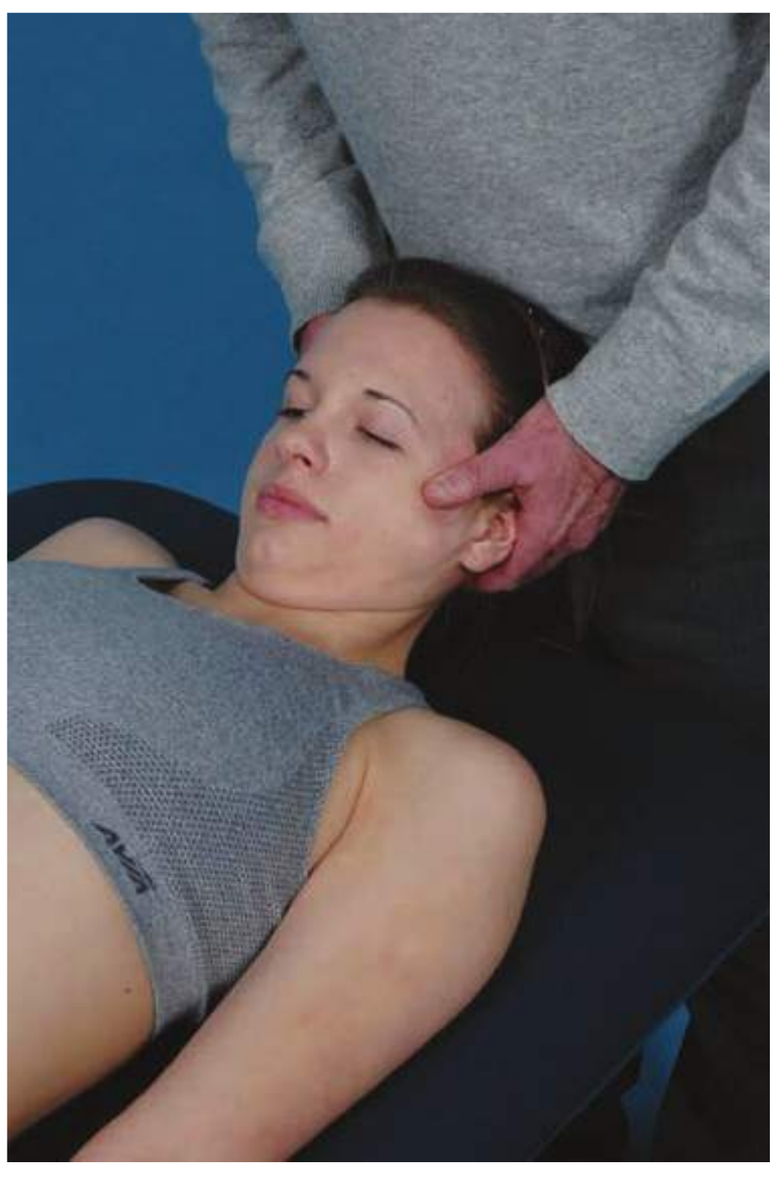

FIGURE 25-36 More specific test to assess the muscle length of the levator scapulae - initial cervical flexion.

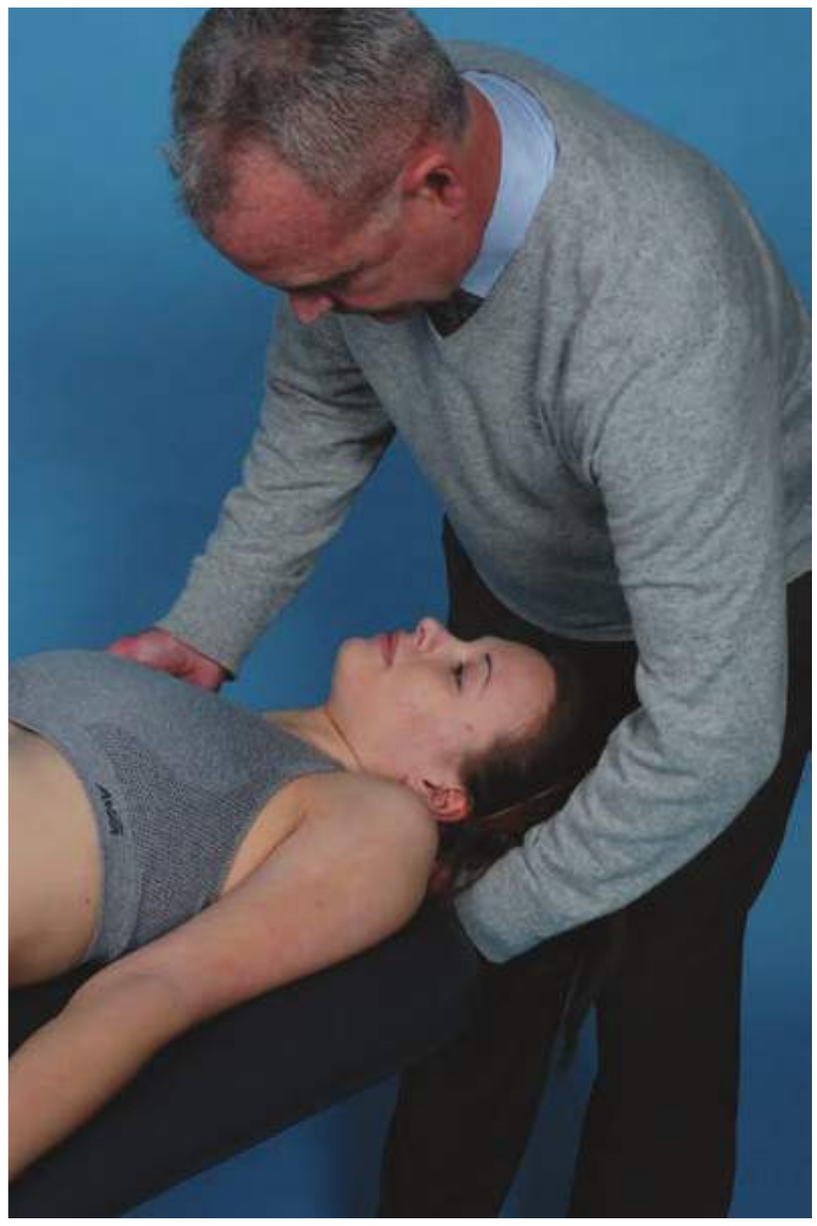

FIGURE 25-37 Muscle length test of the right sternocleidomastoid.

relationships between the head, neck, and shoulders and producing restrictions at the craniovertebral and cervicothoracic junctions.[165]

The patient is positioned in supine, with the head being supported. From this position, the clinician induces side bending of the neck to the contralateral side and extension of the neck (Fig. 25-37). The clinician stabilizes the scapula and rotates the patient's head and neck toward the ipsilateral side.

Scalenes

The patient is positioned in supine, with the clinician at the head of the bed. The clinician side flexes and extends the head to the contralateral side, while stabilizing the shoulder (Fig. 25-38). The normal range of motion should be 45 degrees.

Neurologic Examination

The neurologic examination is performed to assess the normal conduction of the central and peripheral nervous systems and to help rule out such conditions as brachial neuritis and TOS. The tests for the TOS are described under section "Special Tests" later. Depending on the results from the history, a cranial nerve examination may be warranted (see Chapter 3).

Sensory (Afferent System)

The clinician instructs the patient to say "yes" each time he or she feels something touching the skin. The clinician notes any hypoesthesia or hyperesthesia within the spinal and peripheral nerve distributions. A light touch on the hair follicles is used throughout the whole dermatome, followed by pinprick in the area of hypoesthesia. Remember that there is normally no C1 dermatome!

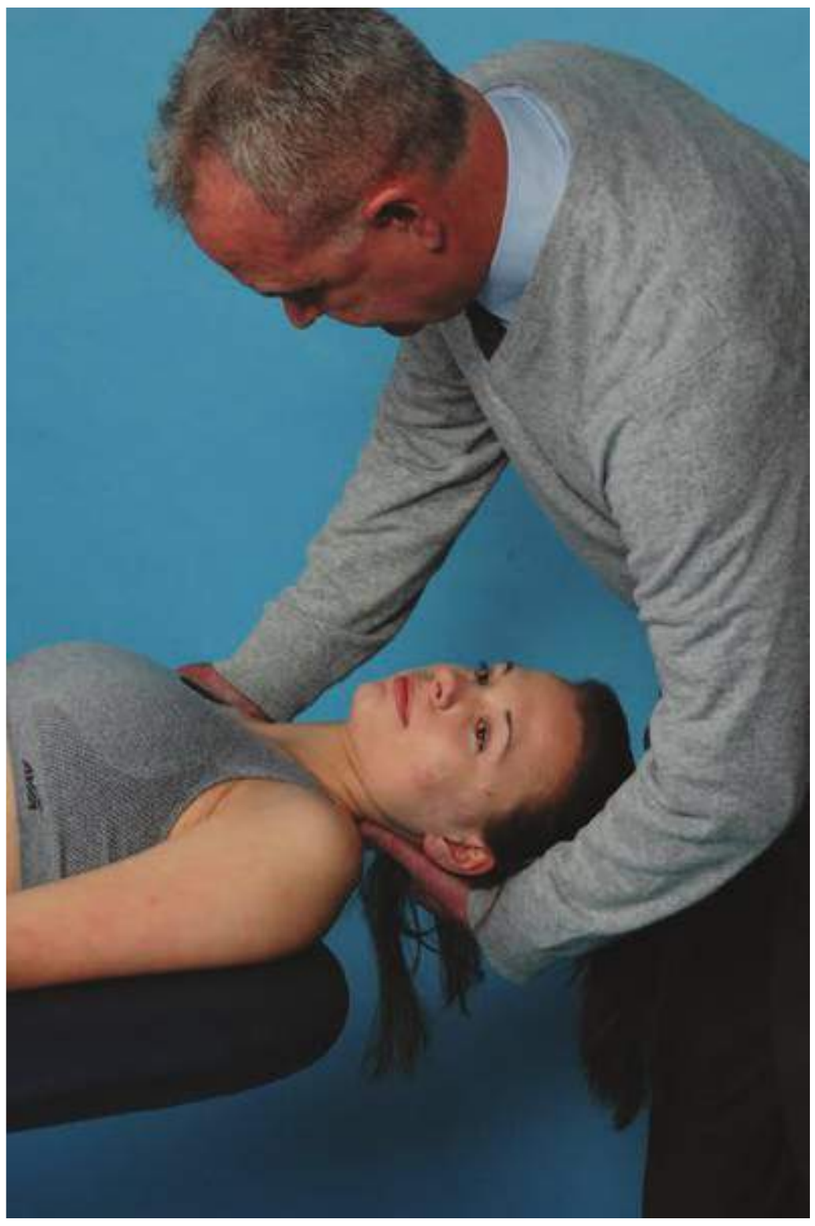

FIGURE 25-38 Muscle length test of scalenes.

Muscle Stretch Reflexes

The following muscle stretch reflexes should be checked for differences between the two sides:

- C5–6: brachioradialis (Fig. 25-39)
- C6: biceps (Fig. 25-40)
- C7: triceps (Fig. 25-41)

Pathological Reflexes

The following reflexes are tested:

- Hoffman sign (Fig. 3-35)
- Babinski (Fig. 3-29)
- Lower limb deep tendon reflexes (Achilles and patellar) for hyperreflexia

FIGURE 25-40 Biceps reflex.

Palpation

The results from palpation rely on the patient's subjective report; thus, changes in the patient's attention and pain tolerance affect reliability. It is important to place the patient in a position where the neck muscles can relax. Usually, this involves the patient lying supine with their head supported and the clinician positioned at the patient's head.

In the neck, the major lymph nodes are located along the anterior and posterior aspects of the neck, which is divided by the SCM muscle.[130] Usually, the closer the lymph node is to the spinal cord, the greater the size of the lymph node.[130] The neck is the exception to the rule. Other lymph nodes are also located on the underside of the jaw and suboccipital areas.[130] The number and size of lymph nodes usually decrease with aging.

The anterior neck can be palpated for the thyroid gland by gently displacing the trachea laterally and palpating each side in turn. Asking the patient to swallow during the palpation can help locate the thyroid gland, as it should be felt to slide under the fingers while it moves upward.

Using the index fingers, the clinician slides the fingers under the SCM and begins to palpate the anterior aspect of the cervical vertebral bodies (from C7 to C3) for tenderness. The posterior aspects, including the facet joints, can be palpated with the other hand. If palpation reveals some tenderness, the clinician can further stress the segment by gently

FIGURE 25-39 Brachioradialis reflex.

FIGURE 25-41 Triceps reflex.

applying a posteroanterior pressure.[166] T is is accomplished using the hand under the neck and applying an anterior shear at each segmental level. T is pressure should result in a slight increase in the cervical lordosis. If it results in an excessive anterior glide at the segment compared with the segment above or below, the test can be considered positive, and a stability test of that segment should be performed.

CLINICAL PEARL

Sandmark and Nisell[167] reported that palpation over the facet joints was the most appropriate screening to corroborate self-reported neck dysfunction.

According to Hoppenfeld,[168] all the spinous processes lower than C2 are usually palpable. T e interval between the external occipital protuberance and the spine of C2 contains the posterior arch of vertebra C1, which is very deeply located and usually not palpable. T e C2 spinous process can be palpated in the midline below the external occipital protuberance, the prominent midline elevation on the posteroinferior aspect of the occipital bone.[1] Occasionally, because of a bifid spine that is not symmetric, the spine may appear to be lateral to the midline, or two bony prominences may be felt at a single level between C3 and C6. C7 is usually the longest spinous process, being referred to as the vertebra prominens, although the spinous process of either C6 or T1 might be quite long, as well. T e spinous process of C7 is located by either counting down to the correct level or using a motion test. T e motion test involves the clinician feeling for the largest spinous process located at the base of the neck and then asking the patient to extend the neck. T e C6 spinous process will be felt to move anteriorly with neck extension, whereas the spinous process of C7 does not.

CLINICAL PEARL

Palpation is a key component of the evaluation for cervical myofascial pain.[169]

T e following muscles should be palpated for tenderness:

- Trapezius;
- Sternocleidomastoid;
- Splenius;
- Semispinalis;
- Multifidus; and
- Suboccipitals (see Chapter 23).

T e TMJ can be checked for clicking, limited range of motion, tenderness, or swelling by gently palpating the area immediately anterior of the tragus of each ear while the patient slowly opens and closes the mouth (see Chapter 26).[130]

Differing Philosophies

T e next stage in the examination process depends on the clinician's background. Many manual techniques are used to examine the cervical spine, but the reproducibility of these techniques is questionable.[170–174] Clinicians who are heavily influenced by the muscle energy techniques of the osteopaths[175] use position testing to determine the segment on which to focus. Other clinicians omit the position tests and proceed to the combined motion and passive physiologic tests.

FIGURE 25-42 Palpating the articular pillar just lateral to the spinous process.

Position Testing

T e position tests are screening tests that, like all screening tests, are valuable in focusing the attention of the clinician on one segment, but not appropriate for making a definitive statement concerning the movement status of the segment. However, when combined with the results of the active and passive movement testing, they help to form a working hypothesis.

T e patient is positioned sitting, and the clinician stands behind the patient. T e clinician palpates the articular pillars of the cranial vertebra of the segment to be tested using both thumbs (Fig. 25-42). T e patient is asked to flex the neck, and the clinician assesses the position of the cranial vertebra relative to its caudal neighbor and notes which articular pillar of the cranial vertebra is the most posterior (dorsal). A posterior (dorsal) let articular pillar of the cranial vertebra relative to the caudal vertebra is indicative of a let -rotated position of the segment in flexion.[175]

In the following example, the C4 and C5 segments are used. T e patient is asked to extend the joint complex while the clinician assesses the position of the C4 vertebra relative to C5 by noting which articular pillar is the most posterior (dorsal). A posterior (dorsal) let articular pillar of C4 relative to C5 is indicative of a let -rotated position of the C4–5 joint complex in extension.[175]

T is test may also be performed with the patient supine. However, in the sitting position, one can better observe the effect of the weight of the head on the joint mechanics.

Passive Physiologic Intervertebral Mobility Testing

T ese screening tests examine intersegmental mobility. As with any other screening test, these tests quickly obviate the need for more exhaustive testing and focus the clinician's attention on a specific level or levels and specific movement(s).

TABLE 25-12	Usefulness of Passive Physiological Testing in the Cervical Spine

[a]Humphreys BK, Delahaye M, Peterson CK. An investigation into the validity of cervical spine motion palpation using subjects with congenital block vertebrae as a 'gold standard'. BMC Musculoskeletal Disorders. 2004;5:19.

Manual examination of the cervical spine by experienced clinicians has shown good sensitivity and specificity to detect cervical zygapophyseal syndromes compared with other medical diagnostic tools, including radiographs, and are sensitive for identifying fused joint levels (Table 25-12).[97,176] However, the protocols used to assess general mobility and intersegmental mobility of the cervical spine have demonstrated difficulty achieving reasonable interexaminer agreement and reliability.[171,174]

To test the intersegmental mobility of the midcervical region, the patient is positioned in supine and the patient's neck is placed in the neutral position of the head on the neck, and the neck on the trunk. Once in this position, lateral glides are performed, beginning at C2 and progressing inferiorly VIDEO. The lateral glides are usually tested in one direction before repeating the process on the other side. The lateral glides result in a relative side bending of the cervical spine in the direction opposite to the glide. Light pressure from the clinician's body can be applied to the top of the patient's head to hold the head in position. This reinforces the stabilization caused by the weight of the patient's thorax against the table. Each spinal level is glided laterally to the left and right while the clinician palpates for muscle guarding, range of motion, end-feel, and the provocation of symptoms VIDEO. Lateral glides are performed as far inferiorly as possible.

Following these procedures, the areas in which a restricted glide was found are targeted, and repetition of the lateral glides is performed in the flexed and then extended positions.

Flexion

The same considerations are pertinent for flexion hypomobilities. To test in flexion, the patient's head and neck are flexed without allowing a chin tuck, which would tighten the nuchal ligament (Fig. 25-43). For example, if left side bending is restricted in flexion, the right side of the segment is not flexing sufficiently (see Table 25-8). The opposite occurs if the restriction occurs with right side bending (the left side is not flexing sufficiently).

Extension
